AN ANALYSIS OF MULTIPLE-SKEW ARCHES ON ELASTIC PIERS

BY J. CHARLES RATHBUN,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. B. L. WEINER, G. D. HOUTMAN, CHARLES L. NORD, F. W. KEYSER, A. A. EREMIN, RICHARD M. HODGES, AND J. CHARLES RATHBUN.

SYNOPSIS

The purpose of this paper is to extend the analysis of the ring of a skew arch that was given in a previous paper[2] to include skew arches of more than one span and, by placing the skew equal to zero, to show how this method may be applied to the multiple right arch on elastic piers. In this latter case, the effect of eccentric loads is brought out by the formulas.

With the idea of being consistent with the method of analysis used in the first paper, the simple method of deflections was retained instead of using one of the more elegant methods, such as virtual work, or a procedure of a similar nature. In order that this paper may be more complete in itself an outline of the method of analysis of the single-span skew arch will be reviewed briefly. For the derivation of the formula for the deflection of a skewed cantilever under the various loads used, reference should be made to the previous paper.

As the use of the integral signs has had a tendency to confuse some of the designing engineers who might otherwise use this theory, the deflection formula is also given as a summation of a series of elastic blocks, the designer dividing the ring in somewhat the same manner as is customary in designing right arches. In this latter case, the terms due to ring-shortening, deformations due to shear, both radial and horizontal, and the terms containing the moment of inertia about the normal to the neutral surface may be omitted. Except possibly in rings of very unusual shapes, these terms are small, and

---

NOTE.—Published in April, 1931, *Proceedings*.

[1] Associate Prof. of Civ. Eng., Coll. of the City of New York, New York, N. Y.

[2] "Analysis of the Stresses in the Ring of a Concrete Skew Arch," by J. Charles Rathbun, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 611.

the effect of omitting them will not be as great as the approximation of dividing the ring into blocks of finite lengths. In the case of ribbed arches the latter term, however, may reach an appreciable value.

The paper is divided into four parts:

Part I.—Outline of the Theory of the Skew Arch and a description of the method of extending it to two or more spans. By placing the angle of skew equal to zero the effect of eccentrically placed loads on a multiple right arch is found, and the results are summarized briefly.

Part II.—Method of Computing the Unit Stresses that occur in the concrete, and the reinforcing steel required.

Part III.—Application of the Theory to the Analysis of a Skew Arch with approach spans for concentrated loads.

Part IV.—An Experiment to Verify the Computations of Part III.

The notation used in the paper is given in Appendix I; the formulas for the skew cantilever are given in Appendix II, and those for the two-hinged single-span skew arch ring, in Appendix III.

It is believed that the examples of Part III should make clear the method of dividing the multiple-skew arch on elastic piers into a series of skew cantilevers that are determinate structures and can be designed by the ordinary methods. The unusual features of these computations are given in Part III, while the method of reducing them to the forces, and of reducing moments to unit stresses, is given in Part II.

INTRODUCTION

The multiple-span skew arch bridge will be found to be a solution for the case shown in Figs. 1 and 2, in which the roadways are parallel on both sides of the crossing. By using three skew spans with the piers between consisting of posts, the curves at the crossing can be made comparatively easy and the line of sight correspondingly long.

In adopting this type of structure the wing-walls that are generally used to retain the fill are replaced by approach spans (see Fig. 2). These spans not only present a better appearance, but they also increase the line of sight in many cases. The extra cost of the approach span will be offset approximately by the saving in the cost of the wing-walls.

The ring of a skew arch is a statically indeterminate structure containing forces and moments in such positions that, in general, all cannot be made parallel to a single plane. It must be analyzed, therefore, in three dimensions instead of the two that are used in the right arch. However, for the preliminary analysis for dead load, or any other loading in which the funicular polygon may be made to follow the arch ring approximately (as viewed in the direction parallel to the barrel of the arch), and in which the loads are placed symmetrically with respect to a plane midway between spandrel walls, a section parallel to the spandrels can be used. The dead load and total uniform load usually approximate these requirements. This same situation prevails with respect to the multiple skew with elastic piers. The skew introduces certain forces and moments not present in right arches for loads on the

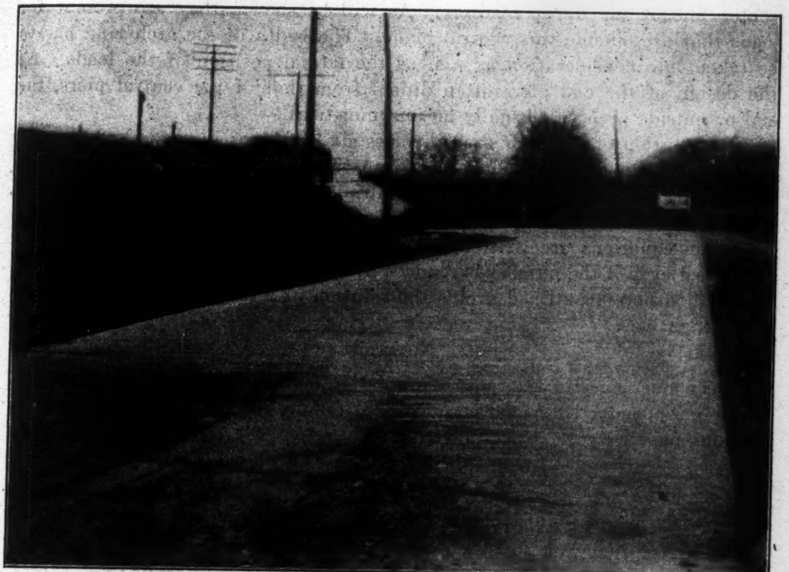

FIG. 1.—AN IDEAL SITE FOR A SKEW UNDER-CROSSING

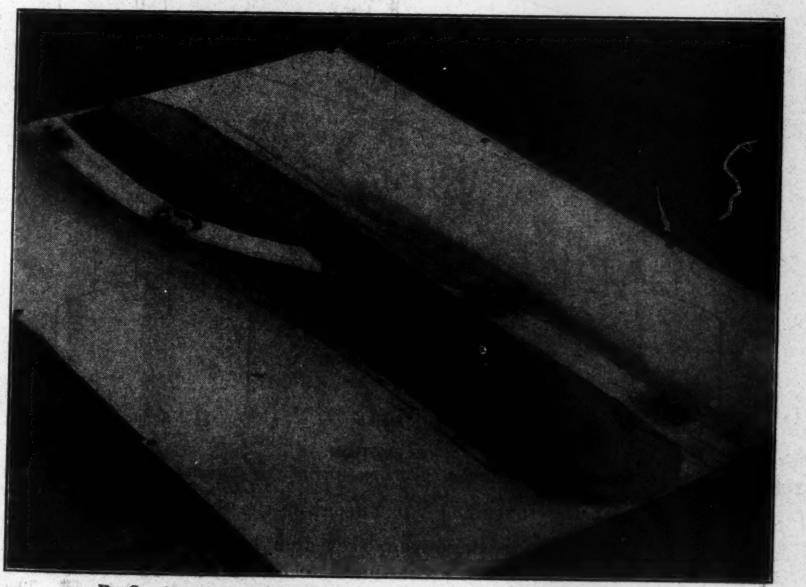

FIG 2.—MODEL OF MULTIPLE-SPAN SKEW UNDER-CROSSING, SHOWING INCREASED LINE OF VISION

center line of the upper roadway. As will be shown, they are present for loads that are outside this central plane. The width of the arch ring has to be taken into consideration as well as the lateral position of the loads. As the design of the end piers often differs from that of the central piers, the end or outside arch will usually be unsymmetrical.

The solution of the skew arch involves six equations in six unknowns. In the symmetrical arch these break up into two groups, one of four equations and one of two. In the case of the multiple-skew arch the addition of each pier will involve the addition of six more unknowns. If the corresponding deflection equations are written, and are solved simultaneously, the labor is very great even if the number is reduced by symmetry. Although it is lengthy, the method herein outlined avoids the solution of a large number of simultaneous equations.

NOTATION

For convenience of reference the notation adopted for use in this paper, is given in Appendix I. As far as possible it follows the notation of the writer's previous paper.

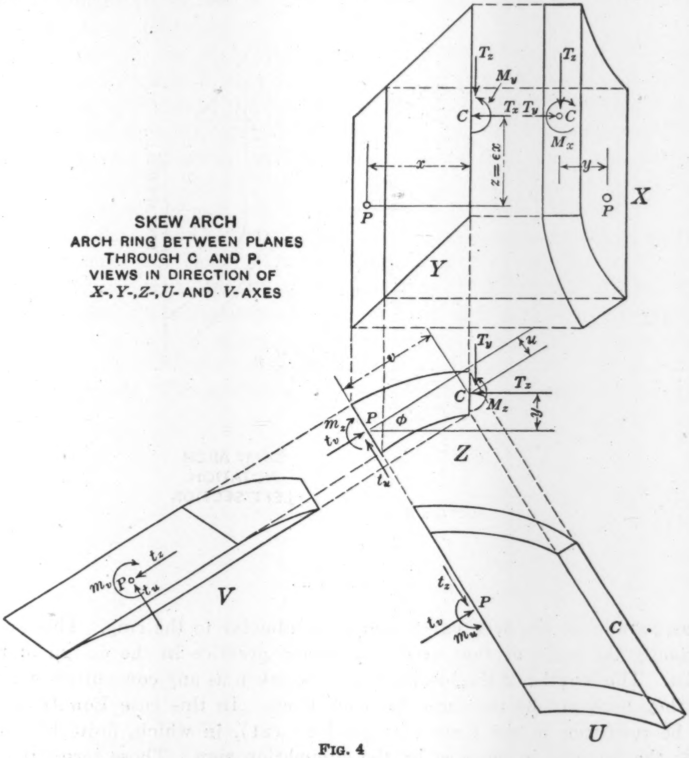
FIG. 3.—MULTIPLE-SKEW ARCH BRIDGE DIVIDED BY CUTTING PLANES

PART I.—OUTLINE OF THE THEORY OF THE SKEW ARCH

Let Fig. 3 represent a three-span, skew-arch bridge on vertical elastic piers (*A*, *B*, *C*, and *D*) which are assumed to be rigidly supported at their bases. The arch can be considered as loaded with concentrated loads. The ring can be divided into sections, as shown, by cutting planes, making a series of skewed cantilevers. If the arch ring has symmetry about any plane, as is usually the case, some labor can be saved by choosing that plane as the cutting plane.

First, consider the cantilever at the left, the one containing Pier *A*. This part is acted upon by the external loads and by three unknown forces and three unknown moments at the cutting plane. After the values of these six unknown quantities are obtained the stresses at any plane section of the cantilever can be determined by the usual processes of static mechanics from a diagram similar to Fig. 4.



SKEW ARCH
ARCH RING BETWEEN PLANES THROUGH C AND P.
VIEWS IN DIRECTION OF *X*-, *Y*-, *Z*-, *U*- AND *V*- AXES

FIG. 4

The deflection at the cutting plane of this cantilever can be computed from Equations (20) (see Appendix II), the unknown reactions being carried as algebraic quantities, which are to be solved subsequently. The derivation of this formula is not given because it was developed in full in the paper on the single-span skew arch.[3] The origin of co-ordinates has been taken at the center of the cut section and the usual rectangular co-ordinate system used. The method of choosing the co-ordinate system and the meaning of a part of the notation are given in Fig. 5. In order to shorten the formulas the terms, v and u, are introduced to replace the expressions:

---

[3] *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 640.

$$v = x \cos\phi + y \sin\phi \text{......................} (1)$$

and,

$$u = x \sin\phi - y \cos\phi \text{......................} (2)$$

If the arch is of a mathematical shape, Equations (20) may be used as written if the integrations present no difficulties. However, in most designs, the arch ring is of a shape that does not lend itself to this form of treatment, and the analyst must divide the ring into a finite number of blocks by means of planes parallel to the arch barrel and perpendicular to the ring. This process is exactly the same as that used in common practice in the design of right arches. The lengths of the blocks, s, may be taken as any convenient quantity, but they need not be the same for each block. In this case Equations (20) can be rewritten in the form of Equations (21), in which, finite blocks are used; the integral is replaced by the summation sign. Those terms that are normally small may be neglected, giving Equations (22). It is suggested that the designer check the writer's judgment in the matter of neglecting terms for any arch that he may be called upon to design. These neglected terms represent deformations due to shear, rib-shortening, and rotation about the radial axis. In rib arches the rotation, particularly, may be quite large. For the various types of loading terms it is suggested that the previous paper be consulted. The terms for vertical, dead load, uniform load, temperature,

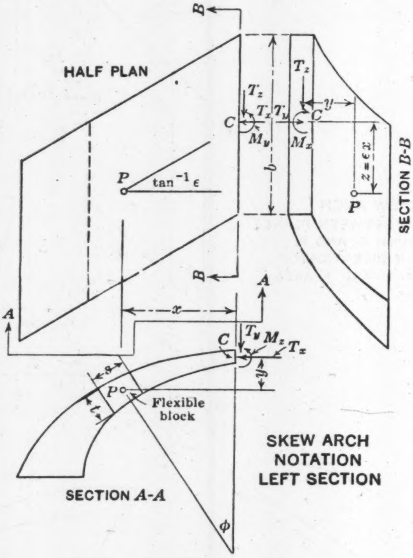


FIG. 5

and concentrated load at a point, $x' z'$, are given. The terms due to grade and horizontal earth pressure are not repeated.

If Equations (21) are used the length, thickness, co-ordinate of the center, as well as the slope of the arch ring, can be obtained by scaling. The values of u and v can also be obtained from the layout, or they may be computed.

The deflection of this cantilever is expressed in terms of its components along each of the three axes and its rotation about each of these axes. Thus, six quantities, or six equations of deflection, are set up, which involve the six unknown quantities at the cutting plane; namely, the three components of the force and the three components of the moment. These quantities of force and moment are independent of each other. This is also true of the six quantities of deflection.

Next, consider the cantilever containing Pier *B* in Fig. 3. Except for the effect of the arch, *b*, this cantilever can be treated in exactly the same way, and the deflection of the cut section can be obtained. The forces at this section are the same as those of the cantilever, *A*, but opposite in direction, being action and reaction. As the abutments of each cantilever are fixed, the movement of the crown of one is necessarily equal to the movement of the crown of the other in each of the directions or rotations, because they must coincide both before and after deflecting. These six conditions can be expressed as six equations, care being taken as to the selection of the sign of the movement. Thus, six equations are set up in terms of the known external loads, certain physical characteristics of the arch ring, and the six unknown literal reactions at the cutting plane. These are taken so that they are mutually independent. As all these equations are linear, they can be solved by simple algebraic methods. The mathematical treatment may be lengthy, but it is not involved.

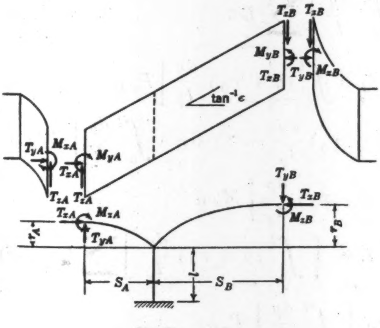

FIG. 6.—DIRECTIONS OF POSITIVE FORCES AND MOMENTS

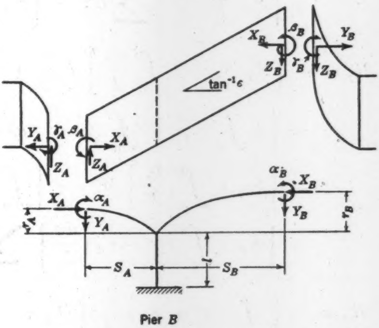

FIG. 7.—DIRECTIONS OF POSITIVE MOVEMENTS

If the skew structure consists of one span only, the indeterminate feature of the problem is complete. If another arch, such as Arch *b* in Fig. 3, is present, in computing the deflection of the right cantilever of Arch *a*, recognition must be taken of the deflection caused by the loads from this second arch. These loads consist of the six unknown components of the reaction at the cutting plane and the external loads between the cutting plane of Arch *b*, and the pier, *B*. By examining the forces acting on this cantilever in Fig. 6 and the direction of the movement of the crown in Fig. 7, one can write the following equations of deflection:

For the right side:

$$\begin{aligned} R_x = &-\left[\int_0^l \frac{\lambda}{A}\,dy + \int_0^l (y + r_A)(y + r_B)\frac{dy}{I_z} - S_A S_B \varepsilon^2 \lambda \int_0^l \frac{dy}{F}\right] T_{xB} \\ &+ \left[S_B \int_0^l (y + r_A)\frac{dy}{I_z}\right] T_{yB} - \left[S_A S_B \varepsilon \lambda \int_0^l \frac{dy}{F}\right] T_{zB} \\ &- \left[\int_0^l (y + r_A)\frac{dy}{I_z}\right] M_{zB} + \left[S_A \varepsilon \lambda \int_0^l \frac{dy}{F}\right] M_{yB} \\ &+ \left[S_B \int_0^l (y + r_A)\frac{dy}{I_z}\right] \sum L - \left[\int_0^l (y + r_A)\frac{dy}{I_z}\right] \sum L x' \;..(3a) \end{aligned}$$

$$\begin{aligned} R_y = &\left[S_A \int_0^l (y + r_B)\frac{dy}{I_z}\right] T_{xB} \\ &+ \left[\int_0^l \frac{dy}{A} - S_A S_B \int_0^l \frac{dy}{I_z} - S_A S_B \varepsilon^2 \int_0^l \frac{dy}{I_y}\right] T_{yB} \\ &+ \left[S_A \varepsilon \int_0^l (y + r_B)\frac{dy}{I_y}\right] T_{zB} + \left[S_A \int_0^l \frac{dy}{I_z}\right] M_{zB} \\ &- \left[S_A \varepsilon \int_0^l \frac{dy}{I_y}\right] M_{xB} \\ &+ \left[\int_0^l \frac{dy}{A} - S_A S_B \int_0^l \frac{dy}{I_z} - S_A S_B \varepsilon^2 \int_0^l \frac{dy}{I_y}\right] \sum L \\ &+ \left[S_A \int_0^l \frac{dy}{I_y}\right] \sum L z' + \left[S_A \int_0^l \frac{dy}{I_z}\right] \sum L x' \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3b) \end{aligned}$$

$$\begin{aligned} R_z = &-\left[S_A S_B \varepsilon \lambda \int_0^l \frac{dy}{F}\right] T_{xB} + \left[S_B \varepsilon \int_0^l (y + r_A)\frac{dy}{I_y}\right] T_{yB} \\ &- \left[\lambda \int_0^l \frac{dy}{A} + \int_0^l (y + r_B)(y + r_A)\frac{dy}{I_y} - S_A S_B \lambda \int_0^l \frac{dy}{F}\right] T_{zB} \\ &- \left[S_A \lambda \int_0^l \frac{dy}{F}\right] M_{yB} + \left[\int_0^l (y + r_A)\frac{dy}{I_y}\right] M_{xB} \\ &+ \left[S_B \varepsilon \int_0^l (y + r_A)\frac{dy}{I_y}\right] \sum L - \left[\int_0^l (y + r_A)\frac{dy}{I_y}\right] \sum L z' . (3c) \end{aligned}$$

$$\begin{aligned} R_\alpha = &-\left[\int_0^l (y + r_B)\frac{dy}{I_z}\right] T_{xB} + S_B \left[\int_0^l \frac{dy}{I_z}\right] T_{yB} \\ &- \left[\int_0^l \frac{dy}{I_z}\right] M_{zB} + S_B \left[\int_0^l \frac{dy}{I_z}\right] \sum L - \left[\int_0^l \frac{dy}{I_z}\right] \sum L x' \;\ldots (3d) \end{aligned}$$

$$R_\beta = \left[S_B \varepsilon \lambda \int_0^l \frac{dy}{F}\right] T_{xB} - \left[S_B \lambda \int_0^l \frac{dy}{F}\right] T_{zB} + \left[\lambda \int_0^l \frac{dy}{F}\right] M_{yB} \;\ldots (3e)$$

and,

$$\begin{aligned} R_\gamma = {} & \left[-S_B\,\varepsilon\int_0^l\frac{dy}{I_y}\right]T_{yB} + \left[\int_0^l(y+r_B)\frac{dy}{I_y}\right]T_z - \left[\int_0^l\frac{dy}{I_y}\right]M_x \\ & - \left[S_B\,\varepsilon\int_0^l\frac{dy}{I_y}\right]\sum L + \left[\int_0^l\frac{dy}{I_y}\right]\sum L z' \ldots\ldots\ldots\ldots (3f) \end{aligned}$$

For the left side :

$$\begin{aligned} L_x = {} & -\left[\int_0^l\frac{\lambda}{A}\,dy + \int_0^l(y+r_A)(y+r_B)\frac{dy}{I_z} - S_A S_B\,\varepsilon^2\lambda\int_0^l\frac{dy}{F}\right]T_{xA} \\ & - \left[S_A\int_0^l(y+r_B)\frac{dy}{I_z}\right]T_{yA} - \left[S_A S_B\,\varepsilon\lambda\int_0^l\frac{dy}{F}\right]T_{zA} \\ & - \left[\int_0^l(y+r_B)\frac{dy}{I_z}\right]M_{zA} - \left[S_B\,\varepsilon\lambda\int_0^l\frac{dy}{F}\right]M_{yA} \\ & + \left[S_A\int_0^l(y+r_B)\frac{dy}{I_z}\right]\sum L - \left[\int_0^l(y+r_B)\frac{dy}{I_z}\right]\sum L x' \,.\,.\, (4a) \end{aligned}$$

$$\begin{aligned} L_y = {} & \left[S_B\int_0^l(y+r_A)\frac{dy}{I_z}\right]T_{xA} \\ & + \left[S_A S_B\int_0^l\frac{dy}{I_z} - \int_0^l\frac{dy}{A} + S_A S_B\,\varepsilon^2\int_0^l\frac{dy}{I_y}\right]T_{yA} \\ & + \left[S_B\,\varepsilon\int_0^l(y+r_A)\frac{dy}{I_y}\right]T_{zA} + \left[S_B\int_0^l\frac{dy}{I_z}\right]M_{zA} \\ & - \left[S_B\,\varepsilon\int_0^l\frac{dy}{I_y}\right]M_{xA} \\ & - \left[S_A S_B\int_0^l\frac{dy}{I_z} - \int_0^l\frac{dy}{A} + S_A S_B\int_0^l\frac{dy}{I_y}\right]\sum L \\ & + \left[S_B\int_0^l\frac{dy}{I_z}\right]\sum L x' + \left[S_B\,\varepsilon\int_0^l\frac{dy}{I_y}\right]\sum L z' \ldots\ldots\ldots\ldots (4b) \end{aligned}$$

$$\begin{aligned} L_z = {} & -\left[S_A S_B\,\varepsilon\lambda\int_0^l\frac{dy}{F}\right]T_{xA} - \left[S_A\,\varepsilon\int_0^l(y+r_B)\frac{dy}{I_y}\right]T_{yA} \\ & + \left[S_A S_B\lambda\int_0^l\frac{dy}{F} - \lambda\int_0^l\frac{dy}{A} - \int_0^l(y+r_A)(y+r_B)\frac{dy}{I_y}\right]T_{zA} \\ & + \left[S_B\lambda\int_0^l\frac{dy}{F}\right]M_{yA} + \left[\int_0^l(y+r_B)\frac{dy}{I_y}\right]M_{xA} \\ & + \left[S_A\,\varepsilon\int_0^l(y+r_B)\frac{dy}{I_y}\right]\sum L - \left[\int_0^l(y+r_B)\frac{dy}{I_y}\right]\sum L z' \,.\, (4c) \end{aligned}$$

$$\begin{aligned} L_\alpha = {} & -\left[\int_0^l(y+r_A)\frac{dy}{I_z}\right]T_{xA} - \left[S_A\int_0^l\frac{dy}{I_z}\right]T_{yA} - \left[\int_0^l\frac{dy}{I_z}\right]M_{zA} \\ & + \left[S_A\int_0^l\frac{dy}{I_z}\right]\sum L - \left[\int_0^l\frac{dy}{I_z}\right]\sum L x' \ldots\ldots\ldots\ldots\ldots\ldots (4d) \end{aligned}$$

$$L_\beta = \left[S_A\,\varepsilon\lambda\int_0^l\frac{dy}{F}\right]T_{xA} - \left[S_A\lambda\int_0^l\frac{dy}{F}\right]T_{zA} - \left[\lambda\int_0^l\frac{dy}{F}\right]M_{yA} \,.\,.\, (4e)$$

and,

$$L_\gamma = \left[S_A\,\varepsilon \int_0^l \frac{dy}{I_y}\right] T_{y\,A} + \left[\int_0^l (y + r_A)\,\frac{dy}{I_y}\right] T_{z\,A} - \left[\int_0^l \frac{dy}{I_y}\right] M_{x\,A}$$
$$- \left[S_A\,\varepsilon \int_0^l \frac{dy}{I_y}\right] \sum L - \left[\int_0^l \frac{dy}{I_y}\right] \sum L\,z' \quad\ldots\ldots\ldots\ldots\ldots(4f)$$

It is to be noted in this cantilever that, except for forces and moments at the cut sections, the section from the crown of Arch *a* to the top of the pier has no force from Arch *b* acting on it, and also that the deformation of the section from the crown of Arch *b* to the top of the pier does not influence the deflection of the crown of Arch *a*. Therefore, the summation of the terms of deflection need be taken over the pier only. As this pier is usually vertical and straight, the formulas are written with this condition in mind. The deflections thus obtained must be added to those already computed for the right half of Arch *a*, before combining it with those of the left half to obtain the six equations. Incidentally, the deflection of the cut section of Arch *b*, due to the forces at the cut section of Arch *a*, can be written at once from Equations (3) producing Equations (4).

Solving the six equations obtained for Arch *a*, the values of the reactions at the crown of this arch are obtained in terms of all loads between the section of Arch *b* and the abutment of Pier *A*, and of the six reactions at the section of Arch *b*.

The cantilever consisting of Pier *B* and the left portion of Arch *b* can now be taken up in the same way as the cantilever of Arch *a*. The deflection of this cantilever is caused by the loads acting directly upon it and the reactions from the section of Arch *a*, as well as the six unknowns from the section of Arch *b*. For the deflection due to the loads on the ring of Arch *b*, Equations (20) or Equations (21) in Appendix II should be used, while for the deflection due to the reactions from Arch *a*, Equations (4) are to be taken. This deflection can thus be written in terms of the external loads and their reactions from the cut sections of Arch *a* and Arch *b*. The reactions from Arch *a* involve the unknown reactions from Arch *b*. Writing the deflections, equations similar to those for the left cantilever of Arch *a* are obtained after collecting the terms. No operations of a higher degree than the first are involved (six first-degree equations in six unknowns), in obtaining the reactions at the crown of Arch *b*. These represent the deflections of the system consisting of all of Arch *a* and the portion of Arch *b* to the left of the section.

If the system is symmetrical about the crown of the center span, as is true in the example given, the deflections of the arch on the right and the right side of Arch *b* will involve the same equations, except possibly for loading terms. Equating these six deflections against their corresponding six on the left half of the system gives four equations in four unknowns and two equations in two unknowns, which when solved fully determine the reactions in the ring of Arch *b*. If, however, the ring is not symmetrical, Arch *a*, together with the left portion of Arch *b*, can be treated in the same manner that was used on the left part of Arch *a*. The right part of Arch *b* is treated in the same way that was used on the right part of Arch *a*. In this case the reactions of the section of Arch *b* will be found in terms of the loads and the reactions from Arch *c*. This process must be continued until the arch on the extreme right is reached, when the right cantilever will have no unknown loads acting on it.

Having obtained the reaction of the right-hand arch, or the center arch in the case of symmetry, the reaction of the arch to the left can be found by substituting these values in the reaction at the cut section of this second arch. The process is continued until the left arch, or Arch *a*, is reached.

The entire system is now broken up into a system of cantilevers acted upon by known loads. By means of Fig. 4 and Equations (5), which are presented under "Method of Computing Unit Stresses", the stresses on any other section can be obtained.

It is interesting to note that if the skew is made equal to zero (a right multiple arch), the crown forces and moments, T_x, T_y, and M_z, are independent of the three remaining forces and moments. The six equations break up into two groups of three equations each. This independence remains throughout the entire set of computations. (Note Equations (30), (31), (32), and (33) which develop from Equations (20), (24), (3), and (4), by placing ϵ equal to zero.) As a result the equations and method herein given can be used to study the effect of loads that are not in the center of the upper roadway on a multiple arch with elastic piers, or, in fact, the effect on a single span right arch.

This procedure also gives a method of analysis for a right multiple arch on elastic piers which at no time involves the solution of more than three equations in three unknowns in one group. A discussion on the relative merits of this solution of the multiple arch and the others known to the profession would be valuable.

PART II.—METHOD OF COMPUTING THE UNIT STRESSES

As the writer showed[4] in the previous paper, the polygon of forces follows the central line of the skew arch as closely as possible. In an arch of the ideal shape, therefore, it follows this line exactly, and the distribution of forces and moments along the cutting plane, such as shown in Fig. 8, or the crown section, is uniform; that is, the thrust is uniformly distributed along this section while the shear is non-existent. If the adjustment is not so perfect the thrust can still be taken as uniformly distributed. Consider, therefore, any section at a point, *P*, Fig. 4. The computed components of the force on this section are t_v, t_u, and t_z, and the moments are m_z, m_u, and m_v. The force can also be resolved into three components: One parallel to the spandrel wall and perpendicular to the radius, t; another parallel to the radius, t_u; and the third, perpendicular to these two forces, s. The moment can be resolved into components around these axes. The main reinforcement steel is parallel to the force, t. This force can be considered as uniformly distributed over a section the area of which is the projected area of the section in the direction of this force, t, proper allowance being made for steel area. The shear, s, can be distributed over this same projected section using the parabolic distribution. This gives zero shear at the edges. At this place the force, of necessity, must be parallel to the spandrel walls. Three halves of the average shear value is the maximum at the center. These values will usually not be great enough to require reinforcement.

---

[4] *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 611.

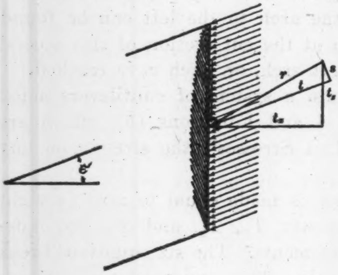

FIG. 8

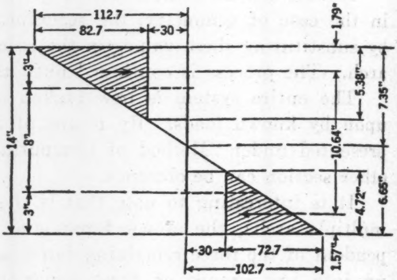

FIG. 9

The moment, *m*, about the axis parallel to *s* is treated in the same way as the force, *t*; it acts directly on the steel, and the projected area of the concrete is used in computing width. The torque, *f*, about the axis parallel to *t* will usually be small in value, but it can be computed on the projected section. The distribution of this stress is parabolic along each side of the section, with a maximum value in the center of the long side, and a zero value at the corners.

As the main reinforcing steel is parallel to the spandrel walls, the thrust and moment acting on this steel are next computed, as are the shear and thrust at the maximum point of the section; that is, the center of the top and bottom sides.

In making these computations after having obtained the crown reactions, the following formulas are used. Equations (5) are set up directly from Fig. 4, by taking forces and moments in the direction of and about the various axes.

$$t_v = T_x \cos \phi + T_y \sin \phi + V \sin \phi - H \cos \phi \quad \text{(5a)}$$

$$t_u = - T_x \sin \phi + T_y \cos \phi + V \cos \phi + H \sin \phi \quad \text{(5b)}$$

$$t_z = T_z \quad \text{(5c)}$$

$$m_z = T_x y - T_y x + M_z - M_{L\,z} \quad \text{(5d)}$$

$$m_u = T_x z \cos \phi + T_y z \sin \phi - T_z v + M_y \cos \phi + M_x \sin \phi + \varepsilon M_{L\,z} \sin \phi \quad \text{(5e)}$$

and,

$$m_v = - T_x z \sin \phi + T_y z \cos \phi + T_z u - M_y \sin \phi + M_x \cos \phi + \varepsilon M_{L\,z} \cos \phi \quad \text{(5f)}$$

For brevity substitute ϵ' for $\tan^{-1} \epsilon'$; then, by resolving forces about a set of axes making an angle of ϕ with the original set of *u*, *v*, *z*:

$$\varepsilon' = \varepsilon \cos \phi \quad \text{(6)}$$

$$t = t_v \cos \varepsilon' + t_z \sin \varepsilon' \qquad (7a)$$

$$s = t_v \sin \varepsilon' - t_z \cos \varepsilon' \qquad (7b)$$

$$m = m_z \cos \varepsilon' - m_v \sin \varepsilon' \qquad (7c)$$

and,

$$f = m_z \sin \varepsilon' + m_v \cos \varepsilon' \qquad (7d)$$

Example 1.—To illustrate the method here outlined a numerical example will be given. For this purpose an arch is chosen other than the one used to illustrate the method of computing the crown reactions in the multiple-skew arch, which is tested with the model. The following quantities have been measured or computed: $\epsilon = \tan 47° 11' = 1.079$; $b = 45.6$ ft.; crown thickness = 14 in.; and $b \cos 47° 11' = 31$ ft. = 372 in.

By methods described in Appendix II of this paper, the crown stresses are as listed in Table 1.

TABLE 1.—THRUST AND MOMENTS AT THE CROWN; EXAMPLE 1

Load	T_x	T_z	M_z	M_x
Dead	259.33	273.43	262.94	—234.37
Temperature	—37.92	—55.71	145.93	— 10.28
Uniform	6.16	6.04	20.50	— 16.21
Concentrated	13.80	13.44	104.20	—101.08

At the crown, $\phi = 0$; $\cos \phi = 1$; $\sin \phi = 0$; $\varepsilon = \varepsilon' = 1.079$; $\cos \varepsilon' = 0.6796$; and $\sin \epsilon' = 0.7335$. Substituting these values in Equations (7),

$$t = 259.33 \times 0.6796 + 273.43 \times 0.7335 = 176.35 + 200.57 = 376.92$$

$$s = 259.33 \times 0.7335 - 273.43 \times 0.6796 = 190.22 - 185.33 = 4.89$$

$$m = 262.94 \times 0.6796 + 234.37 \times 0.7335 = 178.71 + 171.92 = 350.63$$

$$f = 262.94 \times 0.7335 - 234.37 \times 0.6796 = 192.87 - 159.29 = 35.58$$

In a similar manner the stresses for the other loads may be computed. The values are as shown in Table 2.

TABLE 2.—STRESSES DETERMINED BY EQUATIONS (7); EXAMPLE 1

Load	t	s	m	f
Dead	376.92	4.89	350.63	33.58
Temperature, 50°	68.64	— 10.04	106.73	100.06
Uniform	8.62	0.42	25.80	4.00
Concentrated	19.28	1.04	140.04	7.76
Total with 50° drop	336.18	16.39	628.19	145.40
Total with 30° rise	446.00	0.32	457.47	— 14.66

It is now necessary to design a section, 14 in. thick and 372 in. wide, to carry the thrusts and moments in Table 2. The design for t and m presents no unusual problem, being the simple case of an eccentric load on a column.

The horizontal shear at the center equals $\frac{16.39 \times 1.5}{14 \times 372} = 5.0$ lb. per sq. in.

Shear due to torque, or f, using the formula for torque,

$$v = \frac{9\,f}{2\,b\,d^2} \qquad \text{(8)}$$

is equal to $\frac{9 \times 145.40 \times 12}{2 \times 372 \times 14^2} = 107.7$ lb. per sq. in., and the shearing stress on the section equals $\pm\, 107.7 + 5.0 = -\,102.7$, or $+\,112.7$ lb. per sq. in.

Thus, at the upper surface of the crown there is a shear stress of 112.7 lb. per sq. in., while on the lower surface the shear is 102.7 lb. per sq. in. Assuming a straight-line variation of shear between surfaces, Fig. 9 represents this distribution. If 30 lb. per sq. in. is allowed for concrete, a force represented by the volume of a wedge (base, 82.7 lb. per sq. in., height, 5.38 in., and depth, 12 in.) must be taken up by reinforcement on the upper surface. On the lower surface the force is likewise represented by the volume of a wedge, $\frac{72.7 \times 4.72 \times 12}{2}$. This reinforcement must be adequate to take the torque of these two forces when acting through a lever arm equal to the distance apart of the two rows of steel, in this case, 8 in.

Noting that the center of gravity of the triangle is one-third the distance from the base to the altitude and using a steel stress of 22 000 lb. per sq. in.,

$$\frac{82.7 \times 5.38 \times 12 \times 10.64}{2 \times 8 \times 22\,000} = 0.1614 \text{ sq. in.}$$

and,

$$\frac{72.7 \times 4.72 \times 12 \times 10.64}{2 \times 8 \times 22\,000} = 0.1245 \text{ sq. in.}$$

This steel is laid at right angles to the main reinforcement and if considered advisable, may be reduced toward the spandrel walls, since the shear is distributed according to the ordinates of a parabola.

The stresses in any other section than the crown present no unusual difficulties that have not been clarified in the foregoing computations.

PART III.—APPLICATION OF THE THEORY TO THE ANALYSIS OF A SKEW ARCH

In order to illustrate the application of this theory to the analysis of a structure, Fig. 10 will be taken as an example. The entire set of computations will not be given, but it is hoped that the outline will prove sufficiently complete to be followed readily by those familiar with the method as applied to the single-span skew arch.

Example 2.—The arch rings, including the outside piers (Fig. 10), have been divided into blocks of finite length and, by scaling, the values listed in Table 3 have been obtained. Furthermore, from Fig. 10, $b = 42$ ft.; $\varepsilon = \tan 34° 55' = 0.698$; and $\lambda = 2.5$.

In computing temperature the loading terms for Arch *a* are taken as:

$$L_x + R_x = 42 \times 23.5 \times 0.0000065 \times 2\,000 \times 144 = 1\,848$$

and,

$$L_z + R_z = \varepsilon \times 1\,848 = 1\,290$$

and for Arch *b* these terms are:

$$L_x = 42 \times 26.5 \times 0.0000065 \times 2\,000 \times 144 = 2\,083.5$$

and,

$$L_z = \varepsilon \times 2\,083.5 = 1\,454.31$$

	RIGHT HALF OF ARCH *a* (POINTS 1 TO 7 ARE THE SAME AS THE LEFT SIDE)													
8	10.95	1.50	1.35	4.10	10.95	2.10	0.265	......	......	....	....	....	......	......

In both cases this is *b E*, or 42 *E* times the expansion in the direction of *X* or *Z*. The multiple, 42, is used because each term has the common factor, 42, cancelled from the denominator (as is also *E*), or 2 000 × 144 kips per sq. ft. The coefficient of expansion was taken as 0.0000065.

By computation from the scaled quantities in Table 3 the summations or approximations of the integrals used in the formulas are found to be as shown in Table 4. The summations are taken from the crown to the abutment, or from the load to the abutment in the case of partial summations for the left side of Arch *a*. In the case of the right side of Arch *a* and the left side of Arch *b*, the posts of the intermediate pier presented a problem somewhat different from the blocks. This section of the arch was omitted, therefore, and the effect of the posts was treated separately.

In this example the writer carried the computations to a larger number of significant figures than a practical designer would have done. This was done in order to study the results better. Furthermore, it required little more effort, because a multiplying machine was used. The values are published as computed, because it is felt that an experienced designer can balance time against accuracy as he sees fit, and would not take these computations as an example in this particular. Others may be interested in the numbers as computed.

The piers consist of five 3 by 3-ft. posts, 9 ft. 6 in. long and 9 ft. 8 in. on centers. They were assumed to be held rigidly, top and bottom. The

evaluations of the deflections are given in a few cases in the following computations. As the other computations for deflection of the post are of a similar nature, they are here omitted.

The deflection of five posts due to the moment about the Y-axis equals:

Shaft action:

$$T = \frac{E_s\,F}{l}\,\theta = \frac{180 \times 3^4 \times 5 \times \theta}{2.5 \times 9.5 \times 2.05 \times \pi \times (3^2 + 3^2)} = 2.383\,\theta$$

Cantilever action:

$$T = 2\,(19\tfrac{1}{3}^{\,2} + 9\tfrac{2}{3}^{\,2})\,\frac{3 \times 8 \times 3^4}{12 \times 9.5^3 \times 2}\,\theta = 88.281\,\theta$$

Total:

$$T = (2.383 + 88.281)\,\theta = 90.664\,\theta$$

$$b\,\frac{\lambda\ s}{F} = \frac{42}{90.664} = 0.4632$$

$$\int y\,\frac{ds}{I_z} = \frac{12}{5 \times 3^4}\int_4^{13.5} y\,dy = \frac{12}{2 \times 5 \times 3^5}\,(13.5^2 - 4^2) = 2.463$$

$$\int y^2\,\frac{ds}{I_z} = \frac{12}{5 \times 3^4 \times 3}\,(13.5^3 - 4^3) = 23.668$$

FIG. 10.—DIMENSIONAL DRAWING OF ARCH ANALYZED IN EXAMPLE 2

The following values are obtained for the various terms for the pier of five posts, in which allowance is made for the elasticity of the base:

$$\frac{b\,\lambda\,s}{F} = 0.3330 + 0.4632 = 0.7962$$

$$\frac{b\,s}{I_y} = 0.00227 + 42 \times 0.001125 = 0.00227 + 0.04725 = 0.04952$$

$$\frac{b\,s}{I_z} = 0.4444 + \frac{12 \times 42 \times 9.5}{3^4 \times 5} = 0.4444 + 11.8222 = 12.2666$$

$$\int (y + 4)\,\frac{b\,dy}{I_y} = 14 \times 0.00227 + \frac{b}{I_y}\int y\,dy + \frac{4\,b}{I_y}\int dy = 0.03175 + 0.41347 = 0.44522$$

and,

$$\int (y + 5.75)\,\frac{b\,dy}{I_y} = 15.75 \times 0.00227 + 0.49616 = 0.53188$$

Terms containing I_z are similarly computed.

For simplicity of arrangement, the equations for deflection of the skewed cantilevers may be written in the following form:

$$A\,T_x + B\,T_y + C\,T_z + D\,M_z + E\,M_y + F\,M_x + L_x \;\ldots\ldots (9a)$$
$$B\,T_x + G\,T_y + H\,T_z + I\,M_z + F\,M_y + K\,M_x + L_y \;\ldots\ldots (9b)$$
$$C\,T_x + H\,T_y + L\,T_z + N\,M_y + O\,M_x + L_z \;\ldots\ldots (9c)$$
$$D\,T_x + I\,T_y + P\,M_z + L_\alpha \;\ldots\ldots (9d)$$
$$E\,T_x + F\,T_y + N\,T_z + Q\,M_y + R\,M_x + L_\beta \;\ldots\ldots (9e)$$

and,

$$F\,T_x + K\,T_y + O\,T_z + R\,M_y + S\,M_x + L_\gamma \;\ldots\ldots (9f)$$

The coefficients are evaluated from the summations as given in Equations (20) and are made up of the following terms:

$A = 6.703 + 13.230 + 1\,098.224 + 0.652 + 1.765 + 537.922 = +\ 1\,658.496$
$B = -\ 1.399 - 1\,229.946 + 0.189 - 0.141 - 31.277 = -\ 1\,262.574$
$C = -\ 0.896 - 2.543 - 781.677 = -\ 785.118$
$D = \qquad = 108.900$
$E = +\ 0.140 + 0.217 + 66.411 = 66.768$
$F = +\ 0.031 - 0.023 - 7.278 = -\ 7.270$
$G = +\ 5.292 + 16.759 + 1\,995.259 + 2.367 + 0.486 + 186.717 = 2\,206.880$
$H = -\ 2.742 + 0.079 + 19.669 = 17.006$
$I = \qquad = -\ 241.024$
$K = 0.291 + 0.104 + 58.993 = 59.388$
$L = 30.000 + 4.325 + 3.684 + 1\,140.855 = 1\,178.864$
$N = -\ 0.197 - 0.312 - 96.181 = -\ 96.690$
$O = -\ 0.350 + 0.019 + 4.586 = 4.255$
$P = \qquad = 54.052$
$Q = +\ 0.032 + 0.067 + 20.721 = -\ 20.820$
$R = +\ 0.006 - 0.005 - 2.484 = -\ 2.483$
$S = 0.036 + 0.034 + 32.137 = 32.207$

The values of these coefficients for the right side of Arch *a* are computed as follows:

$A = 6.703 + 1.141 + 90.444 + 0.650 + 0.139 + 27.597 + (22.116) + (994.056) + (32.500) = 1\,175.396$
$B = -\ 1.158 - 111.959 + 0.128 - 0.096 - 25.196 - (1\,241.333) = -\ 1\,379.614$
$C = -\ 0.952 - 0.184 - 36.287 - (46.562) = -\ 83.985$
$D = 12.673 + (103.444) = 116.117$

Q &= 0.032 + 0.006 + 1.442 + (.463) &&= 1.943\\
R &= 0.005 - 0.004 - 2.365 &&= -2.364\\
S &= 0.003 + 0.034 + 31.759 + 0.047 &&= 31.843
\end{aligned}$$

Deflections due to the post are enclosed in parentheses. To compute the deflections due to the loads, the partial summations are substituted in Equations (24), in which formula, the load is not at the crown.

For load at Point *a* (Fig. 3):

$$\begin{aligned}
L_x &= -0.893 - 1\,216.792 + 0.176 - 0.131 - 22.270\\
&\quad + 632.376 - 0.385 + 0.287 + 54.142 &&= -553.490\\
L_y &= 5.262 + 5.321 + 1\,744.501 + 2.366 + 0.384\\
&\quad + 96.572 - 956.002 - 4.271 - 0.926 - 247.271 &&= 645.936\\
L_z &= -2.726 + 0.072 + 14.210 + 5.017\\
&\quad - 0.245 - 36.274 &&= -19.946\\
L_\alpha &= -159.334 + 90.259 &&= -69.075\\
L_\beta &= 0.026 - 0.020 - 3.405 - 0.059 + 0.044 + 9.367 &&= 5.935\\
L_\gamma &= 0.291 + 0.063 + 16.835 - 0.526\\
&\quad - 0.158 - 46.864 &&= -30.349
\end{aligned}$$

For load at Point (*b*):

$$\begin{aligned}
R_x &= -0.652 - 98.804 + 0.114 - 0.085 - 16.339\\
&\quad + 55.008 + 0.114 - 0.085 - 18.307\\
&\quad - 1\,241.331 + 620.666 &&= -699.431\\
R_y &= 0.427 + 5.322 + 299.200 - 0.185 + 0.383\\
&\quad + 82.004 - 211.133 + 0.144 + 0.398\\
&\quad + 94.439 + 8.866 + 1\,702.399 + 3.315\\
&\quad - 851.200 + 7.498 &&= 1\,137.247\\
R_z &= -0.432 + 0.060 + 11.540 - 0.368 + 0.105\\
&\quad + 12.681 - 3.463 - 2.609 &&= 17.514\\
R_\alpha &= -35.189 + 26.244 - 141.867 + 70.933 &&= -79.879\\
R_\beta &= 0.018 - 0.013 - 2.858 + 0.019 - 0.014 - 3.275 &&= -6.123\\
R_\gamma &= 0.023 + 0.063 + 14.962 + 0.018 + 0.068\\
&\quad + 17.869 + 0.396 + 0.314 &&= 33.713
\end{aligned}$$

In the case of the crown loads, the value of the load for T_y and the load times z' for M_x may be substituted in Equations (9). With the co-ordinates, x', of Point (a) equal to 6.00, $z' = 14.688$, and with the co-ordinates, x', of Point (b) equal to 6.00, $z' = -6.312$.

From Equations (3) the deflections of the right cantilever of Arch a, due to the crown reactions and loads on Arch b are computed, as follows:

$$\begin{aligned} R_x = & -(23.0 + 1\,274.184 - 123.356)\,T_{x\,B} + 2\,906.152\,T_{y\,B} \\ & - 176.728\,T_{z\,B} + 109.666\,M_{z\,B} - 6.669\,M_{y\,B} + 1\,590.167\,c \\ & + 2\,906.152\,d \ldots\ldots\ldots\ldots \end{aligned} \tag{10a}$$

$$\begin{aligned} R_y = & \ 1\,573.600\,T_{x\,B} + (9.2 - 3\,900.800 - 7.672)\,T_{y\,B} + 4.455\,T_{z\,B} \\ & + 147.200\,M_{z\,B} + 0.4148\,M_{x\,B} - 2\,125.030\,c - 3\,894.910\,d \ldots \end{aligned} \tag{10b}$$

$$\begin{aligned} R_z = & -176.728\,T_{x\,B} + 8.235\,T_{y\,B} - (23.0 + 5.340 - 253.192)\,T_{z\,B} \\ & - 9.554\,M_{y\,B} + 0.4452\,M_{x\,B} + 0.169\,c + 3.561\,d \ldots\ldots\ldots \end{aligned} \tag{10c}$$

$$\begin{aligned} R_\alpha = & -131.133\,T_{x\,B} + 325.068\,T_{y\,B} - 12.267\,M_{z\,B} + 177.267\,c \\ & + 325.068\,d \ldots\ldots\ldots\ldots \end{aligned} \tag{10d}$$

$$R_\beta = 14.727\,T_{x\,B} - 21.099\,T_{z\,B} + 0.7962\,M_{y\,B} \ldots\ldots\ldots\ldots \tag{10e}$$

and,

$$\begin{aligned} R_\gamma = & -0.916\,T_{y\,B} + 0.532\,T_{z\,B} - 0.0495\,M_{x\,B} + 365.088\,c \\ & + 669.490\,d \ldots\ldots\ldots\ldots \end{aligned} \tag{10f}$$

Equations (10) may be summed up, as follows:

$$\begin{aligned} R_x = & -1\,171.927\,T_{x\,B} + 2\,906.152\,T_{y\,B} - 176.728\,T_{z\,B} \\ & + 109.666\,M_{z\,B} - 6.669\,M_{y\,B} + 1\,590.167\,c + 2\,906.152\,d \ldots \end{aligned} \tag{11a}$$

$$\begin{aligned} R_y = & \ 1\,573.600\,T_{x\,B} - 3\,899.265\,T_{y\,B} + 4.455\,T_{z\,B} + 147.200\,M_{z\,B} \\ & - 0.4148\,M_{x\,B} - 2\,125.030\,c - 3\,894.910\,d \ldots\ldots\ldots\ldots \end{aligned} \tag{11b}$$

$$\begin{aligned} R_z = & -176.728\,T_{x\,B} + 8.235\,T_{y\,B} - 224.995\,T_{z\,B} + 9.5544\,M_{y\,B} \\ & - 0.4452\,M_{x\,B} + 0.169\,c + 3.561\,d \ldots\ldots\ldots\ldots \end{aligned} \tag{11c}$$

$$\begin{aligned} R_\alpha = & -131.133\,T_{x\,B} + 325.068\,T_{y\,B} - 12.267\,M_{z\,B} + 177.267\,c \\ & + 325.068\,d \ldots\ldots\ldots\ldots \end{aligned} \tag{11d}$$

$$R_\beta = 14.727\,T_{x\,B} - 21.099\,T_{y\,B} + 0.7962\,M_{y\,B} \ldots\ldots\ldots\ldots \tag{11e}$$

and,

$$\begin{aligned} R_\gamma = & -0.916\,T_{y\,B} + 0.532\,T_{z\,B} - 0.0495\,M_{x\,B} + 365.088\,c \\ & + 669.490\,d \ldots\ldots\ldots\ldots \end{aligned} \tag{11f}$$

The deflections of the left cantilever of Arch b, due to the crown reactions of Arch a, can be written at once without further computation; thus:

$$\begin{aligned} L_x = & -1\,171.927\,T_{x\,A} - 1\,573.600\,T_{y\,A} - 176.728\,T_{z\,A} \\ & - 131.133\,M_{z\,A} - 14.727\,M_{y\,A} + 786.800\,b \ldots\ldots\ldots\ldots \end{aligned} \tag{12a}$$

$$\begin{aligned} L_y = & \ 2\,906.152\,T_{x\,A} + 3\,899.265\,T_{y\,A} + 8.235\,T_{z\,A} + 325.068\,M_{z\,A} \\ & - 0.916\,M_{x\,A} - 1\,931.582\,b \ldots\ldots\ldots\ldots \end{aligned} \tag{12b}$$

$$\begin{aligned} L_z = & \ 176.728\,T_{x\,A} + 4.455\,T_{y\,A} - 224.995\,T_{z\,A} - 21.099\,M_{y\,A} \\ & - 0.532\,M_{x\,A} - 5.585\,b \ldots\ldots\ldots\ldots \end{aligned} \tag{12c}$$

$$L_\alpha = -109.666\,T_{x\,A} - 147.200\,T_{y\,A} - 12.267\,M_{z\,A} + 73.600\,b \ldots \tag{12d}$$

$$L_\beta = 6.669\, T_{x\,A} - 9.554\, T_{z\,A} - 0.7962\, M_{y\,A} \ldots\ldots\ldots\ldots (12e)$$

$$L_\gamma = 0.4148\, T_{x\,A} + 0.4452\, T_{z\,A} - 0.0495\, M_{x\,A} + 0.5292\, b \ldots\ldots (12f)$$

The equations for obtaining the crown reactions of Arch *a* may now be set up by placing the deflections of the left side equal to those of the right side, thus producing the following six equations:

$$\begin{gathered} 2\,833.892\, T_{x\,A} + 117.162\, T_{y\,A} - 869.103\, T_{z\,A} + 225.017\, M_{z\,A} \\ + 59.040\, M_{y\,A} - 13.714\, M_{x\,A} = 1\,171.927\, T_{x\,B} - 2\,906.152\, T_{y\,B} \\ + 176.728\, T_{z\,B} + 109.666\, M_{z\,B} - 6.669\, M_{y\,B} + 1\,848.00\, t^\circ \\ + 553.490\, a + 699.431\, b - 1\,590.167\, c - 2\,906.152\, d \ldots\ldots (13a) \end{gathered}$$

$$\begin{gathered} 117.162\, T_{x\,A} + 4\,679.454\, T_{y\,A} + 3.856\, T_{z\,A} + 17.722\, M_{z\,A} \\ - 13.644\, M_{y\,A} + 1.743\, M_{x\,A} = 1\,573.600\, T_{x\,B} - 3\,899.265\, T_{y\,B} \\ + 4.455\, T_{z\,B} + 147.200\, M_{z\,B} - 0.4148\, M_{x\,B} - 645.939\, a \\ + 1\,137.247\, b - 2\,125.030\, c - 3\,894.910\, d \ldots\ldots (13b) \end{gathered}$$

$$\begin{gathered} - 869.103\, T_{x\,A} + 3.856\, T_{y\,A} + 1\,341.497\, T_{z\,A} - 86.314\, M_{y\,A} \\ + 0.7913\, M_{x\,A} = 176.728\, T_{x\,B} - 8.235\, T_{y\,B} - 224.995\, T_{z\,B} \\ + 9.5544\, M_{y\,B} - 0.4492\, M_{x\,B} + 1\,290.000\, t^\circ - 19.946\, a \\ - 17.514\, b + 0.169\, c - 3.561\, d \ldots\ldots (13c) \end{gathered}$$

$$\begin{gathered} 225.017\, T_{x\,A} + 17.722\, T_{y\,A} + 109.256\, M_{z\,A} = 131.133\, T_{x\,B} \\ - 325.068\, T_{y\,B} + 12.267\, M_{z\,B} + 69.075\, a + 79.879\, b - 177.267\, c \\ - 325.068\, d \ldots\ldots (13d) \end{gathered}$$

$$\begin{gathered} 59.040\, T_{x\,A} - 13.644\, T_{y\,A} - 86.314\, T_{z\,A} + 22.763\, M_{y\,A} - 0.119\, M_{x\,A} \\ = 14.727\, T_{x\,B} - 21.099\, T_{z\,B} + 0.7962\, M_{y\,B} - 5.953\, a - 6.123\, b \ldots (13e) \end{gathered}$$

$$\begin{gathered} - 13.714\, T_{x\,A} + 1.743\, T_{y\,A} + 7.913\, T_{z\,A} - 0.119\, M_{y\,A} \\ + 64.050\, M_{x\,A} = 0.916\, T_{y\,B} - 0.532\, T_{z\,B} + 0.0495\, M_{x\,B} + 30.349\, a \\ - 33.713\, b - 0.019\, c + 0.396\, d \ldots\ldots (13f) \end{gathered}$$

The solution of these six equations is as follows:

$$\begin{gathered} 1\,804.086\, T_{x\,A} = 982.464\, T_{x\,B} - 2\,170.911\, T_{y\,B} + 38.049\, T_{z\,B} \\ + 81.730\, M_{z\,B} - 0.7666\, M_{y\,B} - 0.2681\, M_{x\,B} + 2\,666\,278\, t^\circ + 415.954\, a \\ + 499.621\, b - 1\,186.400\, c - 2\,168.103\, d \ldots\ldots (14a) \end{gathered}$$

$$\begin{gathered} 4\,661.994\, T_{y\,A} = 1\,524.094\, T_{x\,B} - 3\,743.919\, T_{y\,B} - 24.430\, T_{z\,B} \\ + 141.197\, M_{z\,B} + 1.1091\, M_{y\,B} - 0.4243\, M_{x\,B} - 65.639\, t^\circ \\ - 682.886\, a + 1\,102.424\, b - 2\,038.019\, c - 3\,735.900\, d \ldots\ldots (14b) \end{gathered}$$

$$\begin{gathered} 1\,013.343\, T_{z\,A} = 598.806\, T_{x\,B} - 821.460\, T_{y\,B} - 291.600\, T_{z\,B} \\ + 30.616\, M_{z\,B} + 12.311\, M_{y\,B} - 0.5510\, M_{x\,B} + 2\,240.613\, t^\circ + 95.312\, a \\ + 152.825\, b - 444.135\, c - 815.579\, d \ldots\ldots (14c) \end{gathered}$$

$$\begin{gathered} 109.256\, M_{z\,A} = 2.800\, T_{x\,B} - 40.066\, T_{y\,B} - 4.653\, T_{z\,B} + 1.536\, M_{z\,B} \\ + 0.0914\, M_{y\,B} + 0.0350\, M_{x\,B} - 332.306\, t^\circ + 19.791\, a \\ + 13.372\, b - 21.545\, c - 40.447\, d \ldots\ldots (14d) \end{gathered}$$

$$\begin{gathered} 22.763\, M_{y\,A} = 38.045\, T_{x\,B} - 9.897\, T_{y\,B} - 47.249\, T_{z\,B} + 0.346\, M_{z\,B} \\ + 1.873\, M_{y\,B} - 0.0392\, M_{x\,B} + 103.406\, t^\circ - 13.385\, a - 6.289\, b \\ - 4.978\, c - 9.464\, d \ldots\ldots (14e) \end{gathered}$$

$$\begin{gathered} 64.050\, M_{x\,A} = 2.422\, T_{x\,B} - 7.823\, T_{y\,B} + 1.796\, T_{z\,B} + 0.331\, M_{z\,B} \\ - 0.0925\, M_{y\,B} + 0.0518\, M_{x\,B} + 3.337\, t^\circ + 32.952\, a - 31.553\, b \\ - 4.834\, c - 8.369\, d \ldots\ldots (14f) \end{gathered}$$

The labor of dividing by the coefficients of the six unknowns need not be performed if the computations are made with the aid of a machine. Substituting the values from Equations (14) in Equations (12), the loading terms on Arch *b* are found in terms of the crown reaction of this arch and the external loads. The substitutions are, as follows:

$$\begin{aligned} L_x = &- 1\,285.052\, T_{x\,B} + 2\,871.685\, T_{y\,B} + 70.539\, T_{z\,B} - 108.157\, M_{z\,B} \\ &- 3.345\, M_{y\,B} + 0.3968\, M_{x\,B} - 1\,738.666\, t^\circ - 71.419\, a \\ &- 735.296\, b + 1\,565.128\, c + 2\,866.306\, d \ldots\ldots\ldots\ldots\ldots\ldots (15a) \end{aligned}$$

$$\begin{aligned} L_y = &\ 2\,871.685\, T_{x\,B} - 6\,754.194\, T_{y\,B} + 24.577\, T_{z\,B} + 254.566\, M_{z\,B} \\ &+ 0.0659\, M_{y\,B} - 0.6878\, M_{x\,B} + 3\,269.587\, t^\circ + 158.075\, a \\ &+ 1\,768.366\, b - 3\,683.369\, c - 6\,744.073\, d \ldots\ldots\ldots\ldots\ldots\ldots (15b) \end{aligned}$$

$$\begin{aligned} L_z = &\ 70.540\, T_{x\,B} + 24.577\, T_{y\,B} - 112.229\, T_{z\,B} - 1.019\, M_{z\,B} \\ &+ 4.542\, M_{y\,B} - 1.315\, M_{x\,B} + 332.239\, t^\circ - 31.064\, a - 22.155\, b \\ &+ 14.902\, c + 26.030\, d \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (15c) \end{aligned}$$

$$\begin{aligned} L_a = &- 108.157\, T_{x\,B} + 254.675\, T_{y\,B} - 1.020\, T_{z\,B} - 9.598\, M_{z\,B} \\ &+ 0.0013\, M_{y\,B} + 0.0258\, M_{x\,B} - 122.694\, t^\circ - 5.902\, a \\ &- 66.680\, b + 138.886\, c + 254.294\, d \ldots\ldots\ldots\ldots\ldots\ldots\ldots (15d) \end{aligned}$$

$$\begin{aligned} L_\beta = &- 3.345\, T_{z\,B} + 0.066\, T_{y\,B} + 4.543\, T_{z\,B} + 0.001\, M_{z\,B} \\ &- 0.1844\, M_{y\,B} + 0.0056\, M_{x\,B} - 14.887\, t^\circ + 1.107\, a + 0.626\, b \\ &- 0.024\, c + 0.006\, d \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (15e) \end{aligned}$$

$$\begin{aligned} L_\gamma = &\ 0.397\, T_{x\,B} - 0.687\, T_{y\,B} - 0.131\, T_{z\,B} + 0.026\, M_{z\,B} \\ &+ 0.0056\, M_{y\,B} - 0.0002\, M_{x\,B} + 0.975\, t^\circ + 0.044\, a + 0.189\, b \\ &- 0.372\, c - 0.683\, d \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (15f) \end{aligned}$$

The coefficients in Equations (9) for Point (*b*) are determined in the same way as for Point (*a*). The computed values are as follows:

$$\begin{aligned}
A &= 12.500 + 1.370 + 141.887 + 7.150 + 0.753 \\
&\quad + 153.289 + (22.167) + (1\,392.313) \\
&\quad + (158.494) &&= 1\,889.923 \\
B &= -2.065 - 529.654 + 1.253 - 0.934 - 229.953 \\
&\quad - (3\,289.533) &&= -4\,050.886 \\
C &= -10.437 - 0.940 - 189.669 - (227.070) &&= -428.116 \\
D &= 29.201 + (124.133) &&= 153.334 \\
F &= 0.100 - 0.075 - 21.996 &&= -21.971 \\
G &= 0.548 + 31.250 + 4\,499.351 + 1.010 + 5.330 \\
&\quad + 1\,481.291 + (8.867) + (8\,302.157) \\
&\quad + (16.185) &&= 14\,345.989 \\
H &= -2.490 + 0.591 + 157.823 - (9.178) &&= 146.746 \\
I &= -351.760 - (313.289) &&= -665.049 \\
K &= 0.060 + 0.486 + 173.571 + (0.874) &&= 174.991 \\
L &= 32.620 + 15.797 + 1.263 + 251.842 + (22.167) \\
&\quad + (5.553) + (325.316) &&= 654.558 \\
O &= -0.182 + 0.050 + 15.529 - (0.496) &&= 14.901 \\
P &= 43.598 + (11.822) &&= 55.420
\end{aligned}$$

$$\begin{aligned}
Q &= 0.059 + 0.007 + 1.655 + (0.463) &&= 2.184\\
R &= 0.009 - 0.007 - (2.547) &&= -\,2.545\\
S &= 0.004 + 0.063 + 31.838 + (0.047) &&= 31.952
\end{aligned}$$

As before, deflections due to the post are enclosed in parentheses.

For load at Point (c), Fig. 31 ($x' = 12.00$ and $z' = 18.876$):

$$\begin{aligned}
L_x = (&-1.338 - 461.340 + 1.125 - 0.839\\
&- 180.674 + 260.078 - 1.535 + 1.144\\
&+ 265.355 - 3\,289.533 + 1\,489.600) &&= -\,1\,917.960\\
L_y = (&0.504 + 11.959 + 3\,044.843 + 0.997 + 4.376\\
&+ 957.615 - 1\,944.633 - 1.089 - 6.031\\
&- 1\,425.817 + 8.866 + 8\,302.157 + 16.167\\
&- 3\,759.467 - 16.496) &&= +\,5\,193.951\\
L_z = (&-2.306 + 0.521 + 121.384 + 2.917 - 0.736\\

\end{array}$$

In each of Equations (16), the first line of values represents the loads on Arch *b* itself; the second line represents the reaction from the crown of Arch *a*; and the final result is given in the third line. The result of solving Equations (16) is, as follows:

$$T_{x\,B} = +0.134\,a - 0.055\,b + 0.469\,c + 0.941\,d + 13.780\,t^\circ \ldots (17a)$$
$$T_{y\,B} = -0.012\,a + 0.012\,b - 0.108\,c - 0.396\,d \qquad \ldots (17b)$$
$$T_{z\,B} = +0.117\,a - 0.023\,b + 0.312\,c + 0.533\,d + 11.020\,t^\circ \ldots (17c)$$
$$M_{z\,B} = -0.065\,a - 0.022\,b + 0.488\,c + 3.565\,d + 10.665\,t^\circ \ldots (17d)$$
$$M_{y\,B} = -0.404\,a - 0.023\,b - 2.958\,c - 5.522\,d \qquad \ldots (17e)$$
$$M_{x\,B} = +0.036\,a - 0.018\,b + 0.823\,c + 2.908\,d + 4.188\,t^\circ \ldots (17f)$$

Substituting these values back into Equations (14) and collecting terms, the values of the crown reactions of Arch *a*, in terms of loads only, are:

$$T_{x\,A} = +0.317\,a + 0.231\,b - 0.242\,c - 0.039\,d + 9.697\,t^\circ \ldots (18a)$$
$$T_{y\,A} = -0.096\,a + 0.208\,b - 0.185\,c - 0.072\,d + 4.768\,t^\circ \ldots (18b)$$
$$T_{z\,A} = +0.142\,a + 0.114\,b - 0.185\,c - 0.042\,d + 4.974\,t^\circ \ldots (18c)$$
$$M_{z\,A} = +0.183\,a + 0.117\,b - 0.154\,c - 0.177\,d - 3.006\,t^\circ \ldots (18d)$$
$$M_{y\,A} = -0.635\,a - 0.329\,b - 0.272\,c - 0.178\,d + 4.860\,t^\circ \ldots (18e)$$
$$M_{x\,A} = +0.525\,a - 0.497\,b - 0.028\,c - 0.003\,d + 0.941\,t^\circ \ldots (18f)$$

The entire system is now broken up into a system of cantilevers which are determinate in every way, and from Equations (5) the stresses at any section can be obtained and the arch properly reinforced.

The reactions in the Y and X directions at the base of the second pier (Pier B), have been computed and found to be, respectively:

$$T_x = 0.183\,a + 0.286\,b - 0.711\,c - 0.980\,d - 0.515\,e + 0.136\,f - 0.007\,g \qquad (19a)$$

and,

$$T_y = 0.085\,a + 0.816\,b + 1.077\,c + 0.677\,d + 0.139\,e + 0.012\,f - 0.018\,g \qquad (19b)$$

PART IV.—An Experiment to Verify the Computations of Part III

In order to obtain an experimental verification of the theory and to check the computations given in Part III, a celluloid model was made of the structure to a scale of $\frac{3}{16}$ in. to the foot (Figs. 10 to 13), which was tested by the deflection method devised by George E. Beggs, M. Am. Soc. C. E.,[5] and contours of deflection were obtained for the several movements of the piers. In tests applied to solid figures, Professor Beggs used very rigid apparatus.[6] The writer was not able to secure this rigidity and, therefore, used the method herein described to annul the influence of the deflections of the apparatus.

The celluloid sheet used was $1\frac{1}{8}$ in. thick, and was built up by cementing three thinner sheets together. The arch rings were cut from this sheet and the four piers were fastened to the rings with cement furnished for the purpose. The ring was cut on a milling machine. During this operation a stream of water was kept flowing on the tool to prevent fire and to keep the surface of the material cool and hard.

Although the work on the model was carefully and accurately done, it did not prove as satisfactory for the purpose as was anticipated. During the milling of the ring the sheet showed some tendency to split into the three original sheets. After several trials a ring was obtained in which this tendency did not appear to be very serious, but doubtless it had some influence on the results. The joints at which the legs were cemented to the horizontal part could not be relied upon to be 100% perfect for deflection, although they appeared to be rigid as far as could be observed. The model showed a strong tendency to warp out of shape when left out of the clamps, and doubtless there were stresses induced in it by the testing frame when the legs were in a neutral position. A line across the crown that should have been level and was made true in the milling machine, showed a crown in the center of more than $\frac{1}{20}$ in. However, even with these imperfections the writer questions whether a better model could have been made of this material.

Steel collars were secured on the model at the positions that represented the plane that was considered immovable in the bridge; that is, the contact of the ground and the foundation. As shown in Figs. 11, 12, and 13, each collar consisted of two sheets of $\frac{1}{8}$-in. steel, one on each side of a leg. These sheets were drawn toward each other by screws, thus clamping them securely together with the leg between them. One collar was placed on each leg, so that it responded accurately to any movement of the leg at the place where it was fastened.

---

[5] This method is described in *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 1208, by Professor Beggs as applied to plane figures.

[6] *Engineering News-Record*, July 21, 1927, as applied to solid figures.

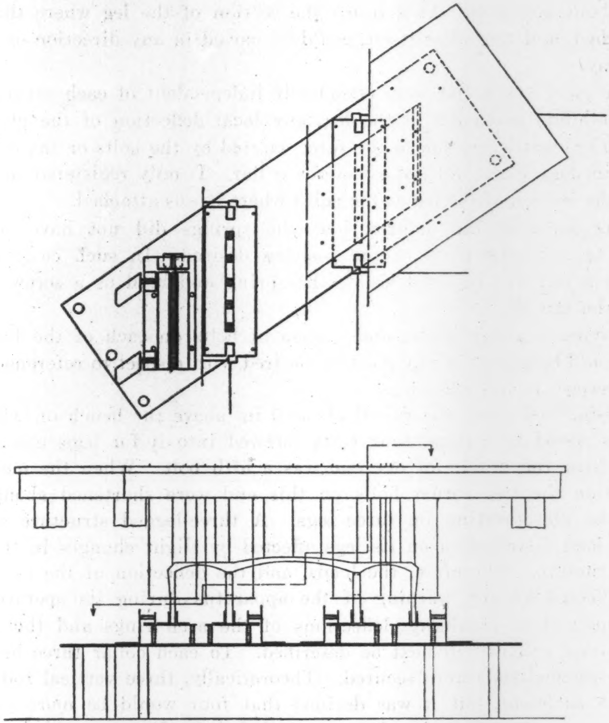

FIG. 11.—SCHEMATIC DRAWING OF TESTING APPARATUS

A horizontal plate was clamped to the bottom of each leg. Two angles, one on either side of the leg, were fastened together with bolts running through holes in the leg, thus clamping them securely to it and to each other. These angles, in turn, were bolted to the plate. This plate was approximately 2 in. below the collar. Figs. 11, 12, and 13 should serve to make clear the position and method of fastening both the collar and plate.

Each horizontal plate was fastened to a $\frac{3}{8}$-in. steel base plate by seven bolts set in slotted holes. Four of these bolts were vertical and three, horizontal. Each horizontal bolt was passed through holes in angles that, in turn, were bolted one to the base-plate and one to the horizontal plate. Around each bolt was a strong spring, so that the horizontal plate could be moved one way by tightening the nut on a bolt, and in the opposite direction by the spring when the nut was loosened. A vertical motion could be induced by tightening or loosening all vertical bolts; a horizontal motion could be produced by means of the horizontal bolts. Rotation about the vertical axis could be obtained by loosening one of the bolts and tightening another. By this system the base of the leg could be moved in any direction, or could be rotated about any axis. As a result the section of the leg where the collar was attached, and the collar itself, could be moved in any direction or rotated in any way.

As the plate and collar were completely independent of each other, except for the celluloid extension of the leg, any local deflection of the plate as a beam slab or cantilever, due to the force exerted by the bolts or the deflection of the $\frac{3}{8}$-in. base-plate, did not affect the collar. It only registered the movement of the section of the leg at the point where it was attached.

During some of the deformations the springs did not have sufficient strength to force the plate to the position desired. In such cases a short bolt with a nut was inserted beside the spring and used as a screw-jack by backing the nut off.

By having a collar, plate, and system of bolts on each of the four legs, any leg could be placed in any position desired with respect to reference planes or with respect to the other legs.

The $\frac{3}{8}$-in. base-plate was raised about 6 in. above the bench on which the apparatus rested by having four bolts screwed into it for legs, one in each corner. Near the middle of one end was a fifth bolt. When the model was in operation the two corner bolts on this end were shortened about $\frac{1}{4}$ in., leaving the plate resting on three legs. A three-legged structure will not have the load distribution on its legs affected by slight changes in the shape of the structure. Therefore, the loads, and the deflection of the bench, will not be affected by any warping of the apparatus during its operation.

The method of obtaining deflections of the arch rings and the motions of the several collars will next be described. To each collar three horizontal and four vertical rods were secured. Theoretically, three vertical rods would have been sufficient, but it was decided that four would be more practical. The same was true of the four vertical bolts. Three could have been used. The ends of the horizontal rods were passed through holes in heavy steel stands. The vertical rods were passed through holes in the top of a small table which was especially made for the purpose. At the position on the arch where the reading of the vertical movement was desired, a vertical rod was passed through this table top.

The amount that these rods projected above the table or through the stands was read by means of an Ames dial (reading to 0.001 in.) mounted on a tripod. This was carried from point to point by the operator and was read before and after moving one of the legs of the model. It was found that the readings were consistent by this method and no error within the limits of accuracy of the dial was found when the legs of the tripod were shifted about while the dial was on one definite rod.

With this arrangement it is to be noted that the movement of any or all of the four collars can be obtained with reference to (1) the bench on which the apparatus rests; (2) the table under which it is placed; and (3) the steel

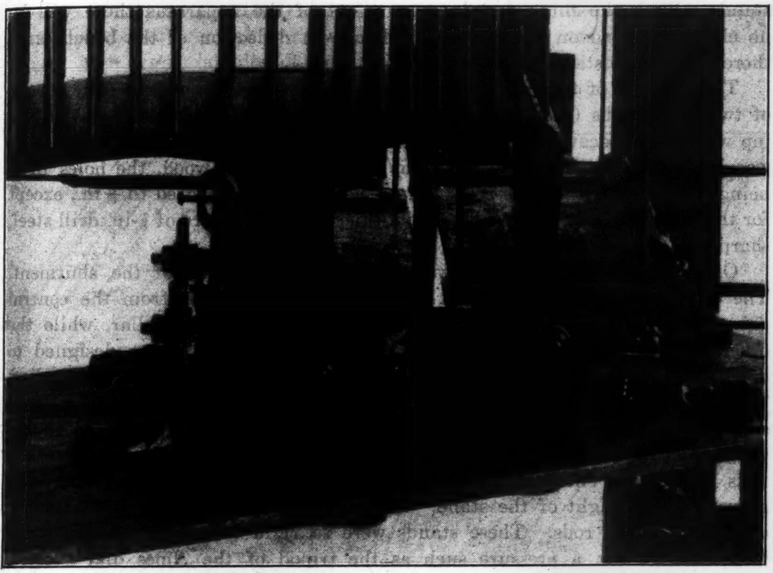

FIG. 12.—CELLULOID MODEL BEING TESTED, SHOWING COMPLETE SET-UP

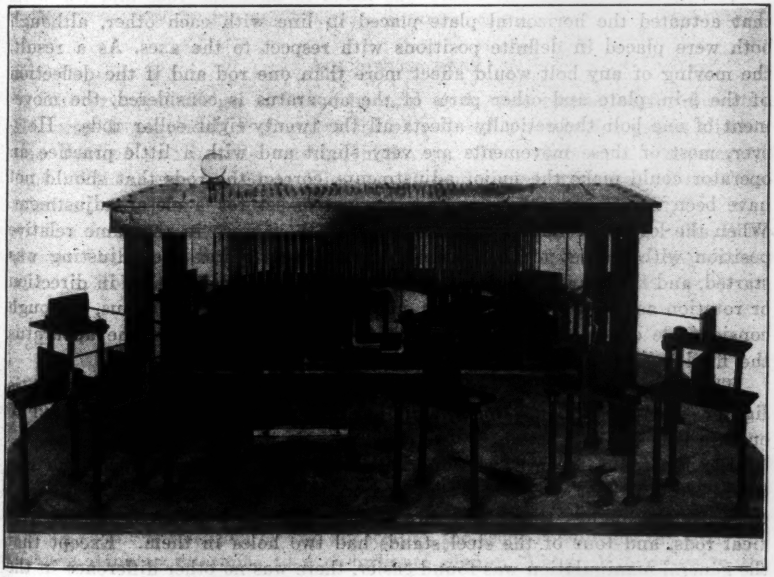

FIG. 13.—DISTANT VIEW OF END PIER OF MODEL BEING TESTED

stands. With the three-legged arrangement of the apparatus there will be no change in load on the bench, no change in deflection of the bench, and, therefore, of the stands or small table.

The position of the table with the holes in the top was adjusted by means of two plumb-bobs (see Fig. 12), the string passing through two holes in the top which were located over two punch-marks in the base-plate when the table was in proper position. The table top was of three-ply wood, the holes in it being 1/32 in. larger than the rods. These holes were back-bored to 1/4 in., except for the upper ply, which was about 1/8 in. thick. All rods were of 1/8-in. drill steel, sharpened at both ends.

One of the horizontal rods was located on the **Z**-axis of the abutment. The other two were at right angles to it and equi-distant from the central point. One end of the rod rested in a punch-mark on the collar, while the other extended about 1/8 in. through the steel stand which was designed to hold it. A rubber band was used to hold the rod firmly against the collar. The stands were made by sawing a 4-in. length from an 8-in. **H**-beam, and sawing this section in two through the web. Three holes were bored in the web, and bolts were inserted in them to form legs. On these bolts were two nuts so that the entire stand was heavy and rigid. This design allowed for adjusting the height of the stand. Holes through the web were bored 1/32 in. over-size for the rods. These stands were so rigid that no deflection could be observed from a pressure such as the tripod of the Ames dial exerted. The vertical rods rested in punch-marks on the collar or on the model.

It will be noted that no effort was made to have the rods and the bolts that actuated the horizontal plate placed in line with each other, although both were placed in definite positions with respect to the axes. As a result, the moving of any bolt would affect more than one rod and if the deflection of the 3/8-in. plate and other parts of the apparatus is considered, the movement of one bolt theoretically affects all the twenty-eight collar rods. However, most of these movements are very slight and with a little practice an operator could make the major adjustments, correct the rods that should not have been moved, and then go over the entire set for a closer adjustment. When the legs were finally adjusted three of them were in the same relative position with respect to the bench that they were before the adjusting was started, and the fourth had been given a definite movement either in direction or rotation as indicated by the rods on the collar of that leg. Thus, although considerable deflection had been given to the several parts of the apparatus the final position was obtained independent of these deflections.

The advantage of this apparatus over the more rigid type is that it is lighter, and takes up less room, and that only one Ames dial is required to operate it.

For the square arch or the one with zero skew, the same apparatus was used. Another set of holes was bored in the base-plate for the bolts and to secure the angles; the table had a second top with holes in it for the vertical rods, and four of the steel stands had two holes in them. Except that the general manipulation was found easier, there was no other difference in the operation between the two arches.

Fig. 14(*a*) and Fig. 14(*b*) show the contour surfaces obtained for the movement of the left central pier along the *X* and the *Y*-axes (Pier *B*, Fig. 3). These give a general idea of the work and a comparison with the computed quantities.

FIG. 14.—CONTOURS OF INFLUENCE SURFACE

ACKNOWLEDGMENT

The practical design and experimental work were conducted for the State Highway Department of Connecticut as part of a study for grade elimination between two heavily traveled highways. It is through the courtesy of E. C. Weldon, Deputy State Highway Commissioner, and that of the Commission itself, that this analysis and description are being published.

The formulas in Appendix III were derived by the writer for the Westchester County Park Commission and are reproduced through the courtesy of L. G. Holleran and Arthur G. Hayden, Members, Am. Soc. C. E.

APPENDIX I

NOTATION

As far as possible, the notation used follows the precedent established by the first paper on the single-span skew arch.[7] However, the interaction of adjacent arch spans requires the introduction of some new symbols. For example, when a factor is modified by two subscripts, the second identifies the span and the first denotes reference to a co-ordinate plane: Thus, $M_{x\,A}$ refers to the moment in Span A, taken about the X-axis, etc. Dimensional notation may be identified most readily by reference to the various diagrams. The capital letter coefficients introduced in Equations (9) duplicate some of the symbols used elsewhere in the paper, with other meanings. It is felt, however, that no confusion will result.

---

[7] *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), pp. 615–616.

Attention is called particularly to the following symbols, as used in this paper:

A = the area of the arch cut by a plane through P radial to the arch ring and parallel to the axis of the arch panel.
F = the factor of torsion (see Equations (16)).
I_y = the moment of inertia of the area, A, about the line through P normal to the neutral surface.
I_z = the moment of inertia of the area, A, about a horizontal line through P parallel to the Z-axis.
M = the total crown moment.
M_x, M_y, M_z = the components of M about the X-axis, Y-axis, and Z-axis, respectively.
P = any point on the neutral axis of the arch ring lying in that vertical plane which is half way between the spandrel walls.
R_x and L_x denote the deflection of the crown at the right (or left) cantilever in the direction of the X-axis due to external loads.
T = the total crown thrust.
T_x, T_y, T_z = the components of T parallel, respectively, to the X-axis, Y-axis, and Z-axis.
W = the vertical load at the point x', z', or vertical dead load between the crown and P.
b = the width of the arch ring measured parallel to the Z-axis.
f = the torsional force on a block corresponding to the moment about the V-axis.
h = rise from hinge to crown on a hinged skew arch.
l = the half span of hinged skew arch.
r_A, r_B = rise of Arch a or Arch b above vertical pier.
S_A, S_B = the half span of Arch a, or Arch b, measured in X-direction.
t = the thickness of the arch measured radially at the point, P.
u, v = the co-ordinates of the crown center referred to the tangent and radial lines through P and parallel to the plane, $Z = 0$ (see Equations (1) and (2)).
x, y = the co-ordinates of P referred to vertical and horizontal axes through the crown.
x', z' = co-ordinates with respect to the crown of a concentrated load.
α, β, and γ = subscripts denoting angular rotation or moment about the Z, Y, or X-axes, respectively.
θ = angular deflection at the top of a pier due to a torsion, T, about the vertical or Y-axis.
λ = the ratio, $\dfrac{\text{modulus of elasticity in compression}}{\text{modulus of elasticity in shear}}$.
ϵ = the tangent of the angle of skew of the arch.
ϵ' = the complement of the angle between the cut section at P and the plane of the spandrels.
ϕ = the angle of slope of a plane tangent to the neutral surface of the arch at P.
w = the uniform live load per square unit of surface.

APPENDIX II

FORMULAS FOR THE SKEW CANTILEVER

The deflections of a skewed cantilever in the directions of the several axes and the rotations of the end of this cantilever about these axes when acted upon by loads, are given by the following equations:

$$\begin{aligned}
E\,\Delta x = &\Big\{ \int \cos^2\phi \frac{ds}{A} + \lambda \int \sin^2\phi \frac{ds}{A} + \int y^2 \frac{ds}{I_z} + \varepsilon^2 \int x^2 \cos^2\phi \frac{ds}{I_y} \\
&+ \varepsilon^2 \lambda \int x^2 \sin^2\phi \frac{ds}{F} \Big\} T_x + \Big\{ (1-\lambda) \int \sin\phi \cos\phi \frac{ds}{A} - \int x\,y \frac{ds}{I_z} \\
&+ \varepsilon^2 \int \left(\frac{1}{I_y} - \frac{\lambda}{F}\right) x^2 \sin\phi \cos\phi \, ds \Big\} T_y - \Big\{ \varepsilon \int v\,x \cos\phi \frac{ds}{I_y} \\
&+ \varepsilon \lambda \int u\,x \sin\phi \frac{ds}{F} \Big\} T_z + \Big\{ \int y \frac{ds}{I_z} \Big\} M_z + \Big\{ \varepsilon \int x \cos^2\phi \frac{ds}{I_y} \\
&+ \varepsilon \lambda \int x \sin^2\phi \frac{ds}{F} \Big\} M_y + \Big\{ \varepsilon \int \left(\frac{1}{I_y} - \frac{\lambda}{F}\right) x \sin\phi \cos\phi \, ds \Big\} M_x + L_x \text{..(20}a\text{)}
\end{aligned}$$

$$\begin{aligned}
E\,\Delta y = &\Big\{ (1-\lambda) \int \sin\phi \cos\phi \frac{ds}{A} - \int x\,y \frac{ds}{I_z} \\

and,

$$\begin{aligned} E\,\Delta\,\gamma = {} & \Big\{ \varepsilon \sum x \sin \phi \cos \phi \frac{S}{I_y} - \varepsilon\,\lambda \sum x \sin \phi \cos \phi \frac{S}{F} \Big\} T_x \\ & + \Big\{ \varepsilon \sum x \sin^2 \phi \frac{S}{I_y} + \varepsilon\,\lambda \sum x \cos^2 \phi \frac{S}{F} \Big\} T_y - \Big\{ \sum v \sin \phi \frac{S}{I_y} \\ & - \lambda \sum u \cos \phi \frac{S}{F} \Big\} T_z + \Big\{ \sum \sin \phi \cos \phi \frac{S}{I_y} - \lambda \sum \sin \phi \cos \phi \frac{S}{F} \Big\} M_y \\ & + \Big\{ \sum \sin^2 \phi \frac{S}{I_y} + \lambda \sum \cos^2 \phi \frac{S}{F} \Big\} M_z + L_\gamma \;\ldots\ldots\ldots\; (21f) \end{aligned}$$

In the usual type of arch the terms due to shear and direct thrust may be omitted; this is also true for those due to rotation about the radial axis if the arch is of the barrel type:

$$\begin{aligned} E\,\Delta\,x = {} & \Big\{ \sum y^2 \frac{S}{I_z} + \varepsilon^2 \lambda \sum x^2 \sin^2 \phi \frac{S}{F} \Big\} T_x + \Big\{ -\sum x\,y \frac{S}{I_z} \\ & - \varepsilon^2 \lambda \sum x^2 \sin \phi \cos \phi \frac{S}{F} \Big\} T_y - \Big\{ \varepsilon\,\lambda \sum u\,x \sin \phi \frac{S}{F} \Big\} T_z \\ & + \Big\{ \sum y \frac{S}{I_z} \Big\} M_z + \Big\{ \varepsilon\,\lambda \sum x \sin^2 \phi \frac{S}{F} \Big\} M_y \\ & - \Big\{ \varepsilon\,\lambda \sum x \sin \phi \cos \phi\, S \Big\} M_x + L_x \;\ldots\ldots\ldots\ldots\; (22a) \end{aligned}$$

$$\begin{aligned} E\,\Delta\,y = {} & \Big\{ -\sum x\,y \frac{S}{I_z} - \varepsilon^2 \lambda \sum x^2 \sin \phi \cos \phi \frac{S}{F} \Big\} T_x + \Big\{ \sum x^2 \frac{S}{I_z} \\ & + \varepsilon^2 \lambda \sum x^2 \cos^2 \phi \frac{S}{F} \Big\} T_y + \Big\{ \varepsilon\,\lambda \sum u\,x \cos \phi \frac{S}{F} \Big\} T_z - \Big\{ \sum x \frac{S}{I_z} \Big\} M_z \\ & - \Big\{ \varepsilon\,\lambda \sum x \sin \phi \cos \phi \frac{S}{F} \Big\} M_y + \Big\{ \varepsilon\,\lambda \sum x \cos^2 \phi \frac{S}{F} \Big\} M_x + L_y \ldots (22b) \end{aligned}$$

$$\begin{aligned} E\,\Delta\,z = {} & -\Big\{ \varepsilon\,\lambda \sum u\,x \sin \phi \frac{S}{F} \Big\} T_x + \Big\{ \varepsilon\,\lambda \sum u\,x \cos \phi \frac{S}{F} \Big\} T_y \\ & + \Big\{ \lambda \sum u^2 \frac{S}{F} \Big\} T_z - \Big\{ \lambda \sum u \sin \phi \frac{S}{F} \Big\} M_y \\ & + \Big\{ \lambda \sum u \cos \phi \frac{S}{F} \Big\} M_x + L_z \;\ldots\ldots\ldots\ldots\ldots\; (22c) \end{aligned}$$

$$E\,\Delta\,\alpha = \Big\{ \sum y \frac{S}{I_z} \Big\} T_x - \Big\{ \sum x \frac{S}{I_z} \Big\} T_y + \Big\{ \sum \frac{S}{I_z} \Big\} + L_\alpha \ldots\ldots (22d)$$

$$\begin{aligned} E\,\Delta\,\beta = & \left\{ \varepsilon\,\lambda \sum x \sin^2 \phi \frac{S}{F} \right\} T_x - \left\{ \varepsilon\,\lambda \sum x \sin \phi \cos \phi \frac{S}{F} \right\} T_y \\ & + \left\{ \lambda \sum u \sin \phi \frac{S}{F} \right\} T_z + \left\{ \lambda \sum \sin^2 \phi \frac{S}{F} \right\} M_y \\ & - \left\{ \lambda \sum \sin \phi \cos \phi \frac{S}{F} \right\} M_x + L_\beta \ldots\ldots\ldots\ldots\ldots \quad (22e) \end{aligned}$$

and,

$$\begin{aligned} E\,\Delta\,\gamma = & - \left\{ \varepsilon\,\lambda \sum x \sin \phi \cos \phi \frac{S}{F} \right\} T_x + \left\{ \varepsilon\,\lambda \sum x \cos^2 \phi \frac{S}{F} \right\} T_y \\ & + \left\{ \lambda \sum u \cos \phi \frac{S}{F} \right\} T_z - \left\{ \lambda \sum \sin \phi \cos \phi \frac{S}{F} \right\} M_y \\ & + \left\{ \lambda \sum \cos^2 \phi \frac{S}{F} \right\} M_x + L_\gamma \ldots\ldots\ldots\ldots\ldots \quad (22f) \end{aligned}$$

Terms for various types of load have been developed, as follows:

Temperature Loading Terms:

$$L_x = S_A\, t^\circ\, e\, E \ldots\ldots\ldots\ldots\ldots \quad (23a)$$

$$L_z = \varepsilon\, S_A\, t^\circ\, e\, E \ldots\ldots\ldots\ldots\ldots \quad (23b)$$

Concentrated Loading Terms (the integrations or summations of Equations (24) and (25) are taken from the load to the abutment only):

$$\begin{aligned} L_x = & \left\{ (1 - \lambda) \int \sin \phi \cos \phi \frac{ds}{A} - \int x\, y \frac{ds}{I_z} \right. \\ & \left. + \varepsilon^2 \int x^2 \sin \phi \cos \phi \left(\frac{1}{I_y} - \frac{\lambda}{F} \right) ds \right\} W + \left\{ \int y \frac{ds}{I_z} \right\} W\, x' \\ & - \left\{ \varepsilon \int x \sin \phi \cos \phi \left(\frac{1}{I_y} - \frac{\lambda}{F} \right) ds \right\} W\, z' \ldots\ldots\ldots \quad (24a) \end{aligned}$$

$$\begin{aligned} L_y = & \left\{ \int \sin^2 \phi \frac{ds}{A} + \lambda \int \cos^2 \phi \frac{ds}{A} + \int x^2 \frac{ds}{I_z} + \varepsilon^2 \int x^2 \sin^2 \phi \frac{ds}{I_y} \right. \\ & \left. + \varepsilon^2 \lambda \int x^2 \cos^2 \phi \frac{ds}{F} \right\} W - \left\{ \int x \frac{ds}{I_z} \right\} W\, x' - \left\{ \varepsilon \int x \sin^2 \phi \frac{ds}{I_y} \right. \\ & \left. + \varepsilon\, \lambda \int x \cos^2 \phi \frac{ds}{F} \right\} W\, z' \ldots\ldots\ldots\ldots\ldots \quad (24b) \end{aligned}$$

$$\begin{aligned} L_z = & - \left\{ \varepsilon \int v\, x \sin \phi \frac{ds}{I_y} - \varepsilon\, \lambda \int u\, x \cos \phi \frac{ds}{F} \right\} W + \left\{ \int v \sin \phi \frac{ds}{I_y} \right. \\ & \left. - \lambda \int u \cos \phi \frac{ds}{F} \right\} W\, z' \ldots\ldots\ldots\ldots\ldots \quad (24c) \end{aligned}$$

$$L_\alpha = - \left\{ \int x \frac{ds}{I_z} \right\} W + \left\{ \int \frac{ds}{I_z} \right\} W\, x' \ldots\ldots\ldots\ldots\ldots \quad (24d)$$

$$\begin{aligned} L_\beta = & \left\{ \varepsilon \int \left(\frac{1}{I_y} - \frac{\lambda}{F} \right) x \sin \phi \cos \phi \, ds \right\} W \\ & - \left\{ \int \left(\frac{1}{I_y} - \frac{\lambda}{F} \right) \sin \phi \cos \phi \, ds \right\} W\, z' \ldots\ldots\ldots \quad (24e) \end{aligned}$$

and,

$$L_\gamma = \left\{ \varepsilon \int x \sin^2 \phi \frac{ds}{I_y} + \varepsilon \lambda \int x \cos^2 \phi \frac{ds}{F} \right\} W$$
$$- \left\{ \int \sin^2 \phi \frac{ds}{I_y} + \lambda \int \cos^2 \phi \frac{ds}{F} \right\} W z' \dots\dots\dots\dots (24f)$$

As in the case of Equations (21) the terms of Equations (24) may be written for finite blocks, as follows:

Concentrated Loading Terms:

$$L_x = - \left\{ \sum x y \frac{S}{I_z} + \varepsilon^2 \sum x^2 \sin \phi \cos \phi \frac{\lambda}{F} S \right\} W + \sum y \frac{S}{I_z} W x'$$
$$+ \varepsilon \sum x \sin \phi \cos \phi \frac{\lambda s}{F} W z' \dots\dots\dots\dots (25a)$$

$$L_y = \left\{ \sum x^2 \frac{S}{I_z} + \varepsilon^2 \lambda \sum x^2 \cos^2 \phi \frac{S}{F} \right\} W - \left\{ \sum x \frac{S}{I_z} W x' \right.$$
$$\left. - \varepsilon \lambda \sum x \cos^2 \phi \frac{S}{F} \right\} W z' \dots\dots\dots\dots (25b)$$

$$L_z = \left\{ \varepsilon \lambda \sum u x \cos \phi \frac{S}{F} \right\} W - \left\{ \lambda \sum u \cos \phi \frac{S}{F} \right\} W z' \dots\dots\dots (25c)$$

$$L_\alpha = - \left\{ \sum x \frac{S}{I_z} \right\} W + \left\{ \sum \frac{S}{I_z} \right\} W x' \dots\dots\dots\dots (25d)$$

$$L_\beta = - \left\{ \varepsilon \sum x \sin \phi \cos \phi \frac{\lambda}{F} S \right\} W + \left\{ \sum \sin \phi \cos \phi \frac{\lambda}{F} S \right\} W z' . (25e)$$

and,

$$L_\gamma = \left\{ \varepsilon \lambda \sum x \cos^2 \phi \frac{S}{F} \right\} W - \left\{ \lambda \sum \cos^2 \phi \frac{S}{F} \right\} W z' \dots\dots\dots\dots (25f)$$

In the case of dead load and uniform load the terms due to horizontal earth thrust have been omitted for the sake of brevity. The remaining terms, have been reproduced for the finite blocks only:

Dead Vertical Loading Terms:

$$L_x = \sum (1 - \lambda) \sum W \sin \phi \cos \phi \frac{S}{A} - \sum W \bar{x} y \frac{S}{I_z}$$
$$+ \varepsilon^2 \sum W \bar{x} x \sin \phi \cos \phi S - \varepsilon^2 \lambda \sum W \bar{x} x \sin \phi \cos \phi \frac{S}{F} .. (26a)$$

$$L_y = \sum W \sin^2 \phi \frac{S}{A} + \lambda \sum W \cos^2 \phi \frac{S}{A} + \sum W \bar{x} x \frac{S}{I_z}$$
$$+ \varepsilon^2 \sum W \bar{x} x \sin^2 \phi \frac{S}{I_y} + \varepsilon^2 \lambda \sum W \bar{x} x \cos^2 \phi \frac{S}{F} \dots\dots (26b)$$

$$L_z = - \varepsilon \sum W \bar{x} v \sin \phi \frac{S}{I_y} + \varepsilon \lambda \sum W \bar{x} u \cos \phi \frac{S}{F} \dots\dots\dots\dots (26c)$$

$$L_\alpha = - \sum W \bar{x} \frac{S}{I_z} \dots\dots\dots\dots\dots\dots\dots\dots (26d)$$

$$L_\beta = \varepsilon \sum W \overline{x} \sin\phi \cos\phi \frac{S}{I_y} - \varepsilon \lambda \sum W \overline{x} \sin\phi \cos\phi \frac{S}{F} \ldots\ldots (26e)$$

and,

$$L_\gamma = \varepsilon \sum W \overline{x} \sin^2\phi \frac{S}{I_y} + \lambda \varepsilon \sum W \overline{x} \cos^2\phi \frac{S}{F} \ldots\ldots (26f)$$

Uniform Vertical Loading Terms:

$$L_x = b\, w \left\{ (1-\lambda) \sum x \sin\phi \cos\phi \frac{S}{A} - \frac{1}{2} \sum x^2 y \frac{S}{I_z} \right.$$
$$\left. + \frac{1}{2} \varepsilon^2 \sum x^3 \sin\phi \cos\phi \frac{S}{I_y} - \frac{1}{2} \varepsilon^2 \lambda \sum x^3 \sin\phi \cos\phi \frac{S}{F} \right\} \ldots (27a)$$

$$L_y = b\, w \left\{ \sum x \sin^2\phi \frac{S}{A} + \lambda \sum x \cos^2\phi \frac{S}{A} + \frac{1}{2} \sum x^3 \frac{S}{I_z} \right.$$
$$\left. + \frac{1}{2} \varepsilon^2 \sum x^3 \sin^2\phi \frac{S}{I_y} + \frac{1}{2} \lambda \varepsilon^2 \sum x^3 \cos^2\phi \frac{S}{F} \right\} \ldots\ldots (27b)$$

$$L_z = b\, w \left\{ -\frac{1}{2} \varepsilon \sum x^2 v \sin\phi \frac{S}{I_y} + \frac{1}{2} \lambda \varepsilon \sum x^2 u \cos\phi \frac{S}{F} \right\} \ldots (27c)$$

$$L_\alpha = b\, w \left\{ -\frac{1}{2} \sum x^2 \frac{S}{I_z} \right\} \ldots\ldots\ldots\ldots (27d)$$

$$L_\beta = b\, w \left\{ \frac{1}{2} \varepsilon \sum x^2 \sin\phi \cos\phi \frac{S}{I_y} - \frac{1}{2} \varepsilon \lambda \sum x^2 \sin\phi \cos\phi \frac{S}{F} \right\} \ldots (27e)$$

and,

$$L_\gamma = b\, w \left\{ \frac{1}{2} \varepsilon \sum x^2 \sin^2\phi \frac{S}{I_y} + \frac{1}{2} \lambda \varepsilon \sum x^2 \cos^2\phi \frac{S}{F} \right\} \ldots\ldots (27f)$$

The value of F is given by the expression:

$$\frac{I}{F} = \frac{205\, \pi\, (t^2 + b^2)}{180\, b^3\, t^3} \ldots\ldots\ldots\ldots (28)$$

When λ is 2.5 this becomes $\frac{\lambda}{F} = 8.95 \frac{1}{b} \left(\frac{1}{b^2 t} + \frac{1}{t^3} \right)$, which may be written:

$$\frac{\lambda}{F} = 9 \times \frac{1}{b} \left(\frac{1}{b^2 t} + \frac{1}{t^3} \right) \ldots\ldots\ldots\ldots (29)$$

If the angle of skew is made equal to zero, these equations reduce as follows:

Equations (20) become,

$$E\, \varDelta x = \left\{ \int \cos^2\phi \frac{ds}{A} + \lambda \int \sin^2\phi \frac{ds}{A} + \int y^2 \frac{ds}{I_z} \right\} T_x$$
$$+ \left\{ (1-\lambda) \int \sin\phi \cos\phi \frac{ds}{A} - \int x\, y \frac{ds}{I_z} \right\} T_y + \left\{ \int y \frac{ds}{I_z} \right\} M_z + L_x \ldots (30a)$$

$$E\,\Delta y = \left\{(1-\lambda)\int \sin\phi\cos\phi\,\frac{ds}{A} - \int x\,y\,\frac{ds}{I_z}\right\} T_x + \left\{\int \sin^2\phi\,\frac{ds}{A} + \lambda\int \cos^2\phi\,\frac{ds}{A} + \int x^2\,\frac{ds}{I_z}\right\} T_y + \left\{\int x\,\frac{ds}{I_z}\right\} M_z + L_y \ldots\ldots (30b)$$

$$E\,\Delta\alpha = \left\{\int \gamma\,\frac{ds}{I_z}\right\} T_x - \left\{\int x\,\frac{ds}{I_z}\right\} T_y + \left\{\int \frac{ds}{I_z}\right\} M_z + L_\alpha \ldots\ldots (30d)$$

$$E\,\Delta z = \left\{\lambda\int \frac{ds}{A} + \int v^2\,\frac{ds}{I_y} + \lambda\int u^2\,\frac{ds}{F}\right\} T_z - \left\{\int v\cos\phi\,\frac{ds}{I_y} + \lambda\int u\sin\phi\,\frac{ds}{F}\right\} M_y - \left\{\int v\sin\phi\,\frac{ds}{I_y} - \lambda\int u\cos\phi\,\frac{ds}{F}\right\} M_x + L_z \ldots\ldots (30c)$$

$$E\,\Delta\beta = -\left\{\int v\cos\phi\,\frac{d\,s}{I_y} + \lambda\int u\sin\phi\,\frac{ds}{F}\right\} T_z + \left\{\int \cos^2\phi\,\frac{ds}{I_y} + \lambda\int \sin^2\phi\,\frac{ds}{F}\right\} M_y + \left\{\int\left(\frac{1}{I_y} - \frac{\lambda}{F}\right)\sin\phi\cos\phi\,ds\right\} M_x + L_\beta \ldots\ldots (30e)$$

and,

$$E\,\Delta\gamma = -\left\{\int v\sin\phi\,\frac{ds}{I_y} - \lambda\int u\cos\phi\,\frac{ds}{F}\right\} T_z + \left\{\int\left(\frac{1}{I_y} - \frac{\lambda}{F}\right)\sin\phi\cos\phi\,ds\right\} M_y + \left\{\int \sin^2\phi\,\frac{ds}{I_y} + \lambda\int \cos^2\phi\,\frac{ds}{F}\right\} M_x + L_\gamma \ldots\ldots (30f)$$

Equations (24) become

$$L_x = \left\{(1-\lambda)\int \sin\phi\cos\phi\,\frac{ds}{A} - \int x\,y\,\frac{ds}{I_z}\right\} W + \left\{\int y\,\frac{ds}{I_z}\right\} W x' \,.\, (31a)$$

$$L_y = \left\{\int \sin^2\phi\,\frac{ds}{A} + \lambda\int \cos^2\phi\,\frac{ds}{A} + \int x^2\,\frac{ds}{I_z}\right\} W - \left\{\int x\,\frac{ds}{I_z}\right\} W x' \ldots\ldots (31b)$$

$$+ \left\{ s_B \; \lambda \int \frac{dy}{F} \right\} M_{y\,A} + \left\{ \int (y + r_B) \frac{dy}{I_y} \right\} M_{x\,A}$$

$$- \left\{ \int (y + r_B) \frac{dy}{I_y} \right\} \sum L\,z' \ldots\ldots\ldots\ldots\ldots \text{(33}c\text{)}$$

$$L_\beta = - \left\{ s_A \; \lambda \int \frac{dy}{F} \right\} T_{z\,A} - \left\{ \lambda \int \frac{dy}{F} \right\} M_{y\,A} \ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(33}e\text{)}$$

and,

$$L_\gamma = \left\{ \int (y + r_B) \frac{dy}{I_y} \right\} T_{z\,A} - \left\{ \int \frac{dy}{I_y} \right\} M_{x\,A} - \left\{ \int \frac{dy}{I_y} \right\} \sum L\,z' . \text{(33}f\text{)}$$

All groups of equations for zero skew are arranged in two parts of three equations each, so that two sets of computations can be carried through entirely independent of each other.

APPENDIX III

Equations for Skew Arch, When Abutments Are Free to Rotate

As the formulas for the skew arch, when the abutments are considered free to rotate, have been requested on numerous occasions they are given in Appendix III with a brief outline of their derivation.

From Fig. 3 and Equations (5),

$$dv = t_v \frac{ds}{A\;E} = (T_x \cos \phi \pm T_y \sin \phi + V \sin \phi - H \cos \phi) \frac{ds}{A\;E} \ldots\ldots \text{(34}a\text{)}$$

$$du = t_u \frac{\lambda\;ds}{A\;E} = (- T_x \sin \phi \pm T_y \cos \phi + V \cos \phi + H \sin \phi) \frac{\lambda\;ds}{A\;E} \ldots \text{(34}b\text{)}$$

$$dz = t_z \frac{\lambda\;ds}{A\;E} = T_z \frac{\lambda\;ds}{A\;E} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{(34}c\text{)}$$

$$d\alpha = m_z \frac{ds}{E\,I_z} = [T_x\,y \mp T_y\,x + M_z - V\,(x - x') - H\,(y - y')]\frac{ds}{E\,I_z} \,\ldots (34d)$$

$$d\beta = m_u \frac{ds}{E\,I_y} = [T_x\,\varepsilon\,x \cos\phi \pm T_y\,x \sin\phi - T_z\,v \pm M_y \cos\phi$$
$$+ M_x \sin\phi + V\,(\varepsilon\,x - z') \sin\phi - H\,(\varepsilon\,x - z') \cos\phi]\,v \ldots\ldots (34e)$$

$$d\gamma = m_v \frac{\lambda\,ds}{E\,F} = [- T_x\,\varepsilon\,x \sin\phi \pm T_y\,x \cos\phi + T_z\,u \mp M_y \sin\phi$$
$$+ M_x \cos\phi + V\,(\varepsilon\,x - z') \cos\phi + H\,(\varepsilon\,x - z') \sin\phi]\,v \ldots\ldots (34f)$$

If a unit force, p_x, is placed at the right abutment, the thrust on any block length, *ds*, making an angle, ϕ, with the horizontal is,

$$T = p_x \cos\phi\,d\,v \ldots\ldots\ldots\ldots\ldots\ldots (35)$$

Table 5, which gives the forces and moments at each section due to forces and moments at the abutments, may be derived with the guidance of Fig. 15.

TABLE 5.—FORCES AND MOMENTS AT VARIOUS SECTIONS OF AN ARCH DUE TO ABUTMENT REACTIONS

(1)	x (2)	y (3)	z (4)	α (5)	β (6)	γ (7)

n_v	$- p_x (\epsilon\,l + \epsilon\,x) \sin\phi$	$\pm p_y (\epsilon\,l + \epsilon\,x) \cos\phi$	$+ p_z (u \pm l \sin\phi + h \cos\phi)$	……	$\pm n_y \sin\phi$	$n_x \cos\phi$

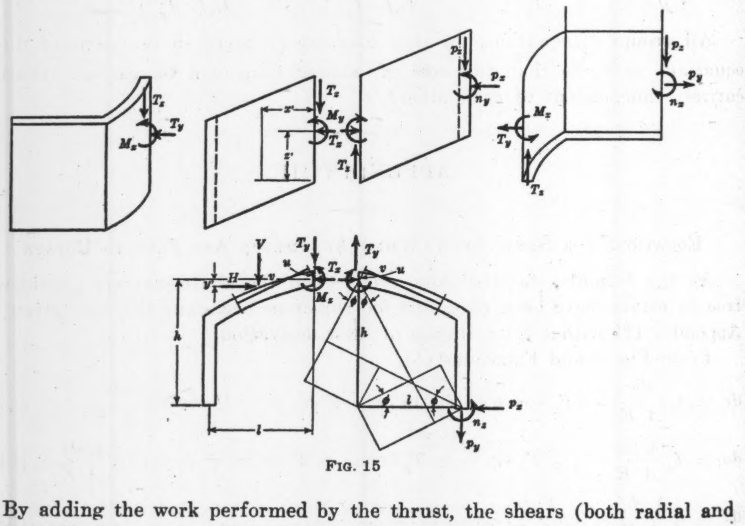

FIG. 15

By adding the work performed by the thrust, the shears (both radial and horizontal), the moments about the horizontal and radial axes, and the torque, the total work performed in deforming this block may be determined. This is equal to the work performed by the force, p_x, moving through the distance that the abutment is deflected in the direction in which the force is acting.

If p_x equals unity, the expression for the deflection of the abutment in the direction, X, due to the deformation of one block of length, ds, is:

$$d\,\Delta = p_v\,dv + p_u\,du + p_z\,dz + n_z\,d\alpha + n_u\,d\beta + n_v\,d\gamma \ldots\ldots (36)$$

The total deflection is the integral of the several terms producing Δ.

In obtaining $d\,\Delta$ to find the expressions for p_v, p_u, n_z, etc., for a deflection in the direction, X, only those terms in Column (2) Table 5 are used; for the y-deflection, Column (3) is used, etc.

Collecting terms and using the values of Δ_x, Δ_y, etc., as defined in Equations (20), the several deflections of the right abutment of the arch when considered as fixed at the left abutment, are:

$\Delta x - h\,\Delta\,\alpha + \varepsilon\,l\,\Delta\,\beta$ = deflection of right abutment in x-direction.....(37a)

$\Delta y + l\,\Delta\,\alpha - \varepsilon\,l\,\Delta\,\gamma$ = deflection of right abutment in y-direction.....(37b)

$\Delta z + h\,\Delta\,\gamma - l\,\Delta\,\beta$ = deflection of right abutment in z-direction.....(37c)

$\Delta\,\alpha$ = rotation of right abutment about z-axis........(37d)

$\Delta\,\beta$ = rotation of right abutment about y-axis........(37e)

$\Delta\,\gamma$ = rotation of right abutment about x-axis........(37f)

If the right sides of Equations (37) are all placed equal to zero, they represent the fixed-ended skew arch and the equations reduce at once to those already obtained for this condition, as they should. However, with the right abutment on a hinge, the axis of which is parallel to the z-axis, Equation (37d) cannot be placed equal to zero although Equations (37a), (37c), (37e), and (37f) may; and these four equations reduce to:

$$\Delta\,x - h\,\Delta\,\alpha = 0 \ldots\ldots (38a)$$

$$\Delta\,z = 0 \ldots\ldots (38c)$$

$$\Delta\,\beta = 0 \ldots\ldots (38e)$$

$$\Delta\,\gamma = 0 \ldots\ldots (38f)$$

With the left abutment hinged Equations (37b) and (37d) can be produced from purely static considerations, and a little algebraic transforming produces the following equations:

$$T_y = -\frac{1}{2\,l}(l - x')\,V - \frac{1}{2\,l}(h - y')\,H \ldots\ldots (39a)$$

$$Q\,M_y = -F\,T_y + e_v + e_h \ldots\ldots (39b)$$

$$A'\,T_x + C\,T_z + F\,M_x = a_v + a_h \ldots\ldots (39c)$$

$$C\,T_x + L\,T_z + O\,M_x = c_v + c_h \ldots\ldots (39d)$$

$$F\,T_x + O\,T_z + S\,M_x = f_v + f_h \ldots\ldots (39e)$$

$$M_z = \frac{1}{2}(l - x')\,V - h\,T_x + \frac{1}{2}(h - y')\,H \ldots\ldots (39f)$$

The formulas for the coefficients in Equations (39), are:

$$\begin{aligned} A' = A - 2\,h\,D + P\,h^2 = {} & \sum \cos^2\phi\,\frac{S}{A} + \lambda \sum \sin^2\phi\,\frac{S}{A} + \sum y^2\,\frac{S}{I_z} \\ & + \varepsilon^2 \sum x^2 \cos^2\phi\,\frac{S}{I_y} + \varepsilon^2\,\lambda \sum x^2 \sin^2 \frac{S}{F} - 2\,h \sum y\,\frac{S}{I_z} + h\,\varepsilon^2 \sum \frac{S}{I_z} \end{aligned} \quad \text{(40}a\text{)}$$

$$C = -\left\{ \varepsilon \sum v\,x \cos\phi\,\frac{S}{I_y} + \varepsilon\,\lambda \sum u\,x \sin\phi\,\frac{S}{F} \right\} \ldots\ldots\ldots\ldots \text{(40}b\text{)}$$

$$F = \varepsilon \sum x \sin\phi \cos\phi\,\frac{S}{I_y} - \varepsilon\,\lambda \sum x \sin\phi \cos\phi\,\frac{\lambda}{F} \ldots\ldots\ldots\ldots \text{(40}c\text{)}$$

$$L = \sum v^2\,\frac{S}{I_y} + \lambda \sum u^2\,\frac{S}{F} + \lambda \sum \frac{S}{A} \ldots\ldots\ldots\ldots \text{(40}d\text{)}$$

$$O = -\left\{ \sum v \sin\phi\,\frac{S}{I_y} - \lambda \sum u \cos\phi\,\frac{S}{F} \right\} \ldots\ldots\ldots\ldots \text{(40}e\text{)}$$

$$Q = \sum \cos^2\phi\,\frac{S}{I_y} + \lambda \sum \sin^2\phi\,\frac{S}{F} \ldots\ldots\ldots\ldots \text{(40}f\text{)}$$

and,

$$S = \sum \sin^2\phi\,\frac{S}{I_y} + \lambda \sum \cos^2\phi\,\frac{S}{F} \ldots\ldots\ldots\ldots \text{(40}g\text{)}$$

In Equations (39) the terms due to vertical loads are:

$$\begin{aligned} a_v = -\frac{1}{2} \Big\{ & (l - x') \left[\sum_A^B y\,\frac{S}{I_z} - h \sum_A^P \frac{S}{I_z} \right] \\ & + (1 - \lambda) \sum_A^P \sin\phi \cos\phi\,\frac{S}{A} - \sum_A^P x\,y\,\frac{S}{I_z} + h \sum_A^P x\,\frac{S}{I_z} \\ & - h\,x' \sum_A^P \frac{S}{I_z} + x' \sum_A^P y\,\frac{S}{I_z} + \varepsilon^2 \sum_A^P x^2 \sin\phi \cos\phi\,\frac{S}{I_y} \\ & - \varepsilon^2\,\lambda \sum_A^P x^2 \sin\phi \cos\phi\,\frac{S}{F} - \varepsilon^2\,x' \sum_A^P x \sin\phi \cos\phi\,\frac{S}{I_y} \\ & + \varepsilon^2\,x'\,\lambda \sum_A^P x \sin\phi \cos\phi\,\frac{S}{F} \Big\} V \ldots\ldots\ldots\ldots \text{(41}a\text{)} \end{aligned}$$

$$\begin{aligned} c_v = -\frac{1}{2} \Big\{ & -\varepsilon \sum_A^P v\,x \sin\phi\,\frac{S}{I_y} + \varepsilon\,\lambda \sum_A^P u\,x \cos\phi\,\frac{S}{F} \\ & + \varepsilon\,x' \sum_A^P v \sin\phi - \varepsilon\,x'\,\lambda \sum_A^P u \cos\phi\,\frac{S}{F} \Big\} V \ldots\ldots\ldots\ldots \text{(41}b\text{)} \end{aligned}$$

$$\begin{aligned} f_v = -\frac{1}{2} \Big\{ & \varepsilon \sum_A^P x \sin^2\phi\,\frac{S}{I_y} + \varepsilon\,\lambda \sum_A^P x \cos^2\phi\,\frac{S}{F} \\ & - \varepsilon\,x' \sum_A^P \sin^2\phi\,\frac{S}{I_y} - \varepsilon\,x'\,\lambda \sum_A^P \cos^2\phi\,\frac{S}{F} \Big\} V \ldots\ldots\ldots \text{(41}c\text{)} \end{aligned}$$

and,

$$\begin{aligned} e_v = -\frac{1}{2} \Big\{ & \varepsilon \sum_A^P x \sin\phi \cos\phi \left(\frac{S}{I_y} - \frac{\lambda\,S}{F} \right) \\ & - \varepsilon\,x' \sum_A^P \sin\phi \cos\phi \left(\frac{S}{I_y} - \frac{\lambda\,S}{F} \right) V \ldots\ldots\ldots\ldots \text{(41}d\text{)} \end{aligned}$$

In Equations (39) the terms due to horizontal loads are:

$$\begin{aligned} a_h = -\frac{1}{2}\Big\{ & (h-y')\left[\sum_A^P y\frac{S}{I_z} - h\sum_A^P \frac{S}{I_z}\right] - \sum_A^P \cos^2\phi\,\frac{S}{A} \\ & -\lambda\sum_A^P \sin^2\phi\,\frac{S}{A} - \sum_A^P y^2\frac{S}{I_z} + y'\sum_A^P y\frac{S}{I_z} + h\sum_A^P y\frac{S}{I_z} \\ & -h\,y'\sum_A^P \frac{S}{I_z} - \varepsilon^2\sum_A^P x^2\cos^2\phi\,\frac{S}{I_y} + \varepsilon^2 x'\sum_A^P x\cos^2\phi\,\frac{S}{I_y} \\ & -\varepsilon^2\sum_A^P x^2\sin^2\phi\,\frac{\lambda S}{F} + \varepsilon^2 x'\sum_A^P x\sin^2\phi\,\frac{\lambda S}{F}\Big\} H \quad\ldots\ldots\ldots(42a) \end{aligned}$$

$$\begin{aligned} c_h = -\frac{1}{2}\Big\{ & \varepsilon\sum_A^P v\,x\cos\phi\,\frac{S}{I_y} - \varepsilon\,x'\sum_A^P v\cos\phi\,\frac{S}{I_y} \\ & +\varepsilon\sum_A^P x\,u\sin\phi\,\frac{\lambda S}{F} - \varepsilon\,x'\sum_A^P u\sin\phi\,\frac{\lambda S}{F}\Big\} H \quad\ldots\ldots\ldots(42b) \end{aligned}$$

$$\begin{aligned} f_h = -\frac{1}{2}\Big\{ & -\varepsilon\sum_A^P x\cos^2\phi\,\frac{S}{I_y} - \varepsilon\sum_A^P x\sin^2\phi\,\frac{\lambda S}{F} \\ & +\varepsilon\,x'\sum_A^P \cos^2\phi\,\frac{S}{I_y} + \varepsilon\,x'\sum_A^P \sin^2\phi\,\frac{\lambda S}{F}\Big\} H \quad\ldots\ldots\ldots\ldots(42c) \end{aligned}$$

and,

$$\begin{aligned} e_h = -\frac{1}{2}\Big\{ & -\varepsilon\sum_A^P x\cos^2\phi\,\frac{S}{I_y} - \varepsilon\sum_A^P x\sin^2\phi\,\frac{\lambda S}{F} \\ & +\varepsilon\,x'\sum_A^P \cos^2\phi\,\frac{S}{I_y} + \varepsilon\,x'\sum_A^P \sin^2\phi\,\frac{\lambda S}{F}\Big\} H \quad\ldots\ldots\ldots(42d) \end{aligned}$$

For symmetrical loading, $T_y = 0$ and $M_y = 0$. Therefore e_v and e_h need not be determined.

DISCUSSION

B. L. WEINER,[8] ASSOC. M. AM. SOC. C. E. (by letter).—Parts I, III, and IV of Professor Rathbun's paper are of as much interest to designers of right arches and other statically indeterminate frames as they are to the designers of skew arches. The author has presented a general method for analyzing indeterminate structures, which has a certain marked advantage over other methods known to the profession.

Generally speaking, a right arch has three unknown reactions for each span, which must be obtained by the solution of simultaneous equations. In a three-span arch, there would be nine unknowns, necessitating nine simultaneous equations, each containing all the unknown quantities. This, in general, would be the case, except for certain simplifications which are possible because of symmetry, or because such conditions as hinged bases make certain unknowns zero, or because of other conditions which assign known values to some of the reactions. For the skew arch, the various standard multiple-span analyses could be applied and Professor Rathbun's theory of single-span arches[9] could be extended to multiple spans. In the skew arch, however, there are six unknowns for each arch, and, in general, eighteen equations with eighteen unknowns in each would be required for the analysis of a three-span skew arch. While this is possible, the mere mechanical difficulty of the process would be great even though the solution of simultaneous equations is no particular hardship if determinates are not used.[10] The difficulty increases with the number of spans, and for n spans, there would be $6n$ equations, each containing $6n$ unknowns.

Professor Rathbun has shown a way out, since the method he proposes restricts the number of equations to be solved at any one time to that of one span, that is, in a right arch only three equations with three unknowns, and in a skew arch no more than six equations with six unknowns need be solved at any one time. This is an advantage even though the saving in the numerical work involved may not be very much, since a set of the six equations must be solved for each span and, except for the last span, the equations of one span contain constants which are the unknown reactions of an adjacent span. Furthermore, after the equations for one span are solved, giving the reactions of this span in terms of the reactions of an adjacent span, substitutions must be made to eliminate these reactions which have been obtained from the equations of the adjacent span. Finally, after the equations of the last (end) span have been solved, resulting in numerical values for the reactions of this span, a series of numerical substitutions must be made, working backword from the end span to obtain the reactions of the other spans. Furthermore, since the underlying principle of statically indeterminate analysis is that of deflections, the same deflections which appear as constants must be computed no matter what method is used.

[10] *Loc. cit.*, Vol. 96 (1932), Table 6, p. 1243 *et seq.*

However, even if there is no saving in direct labor, in Professor Rathbun's solution, the process is comparatively easy to follow. In this method, the effect of one span is apparent only in an adjacent span and is not directly carried over into other spans, thus making it possible to break the work up into a series of comparatively short steps. Besides reducing the number of simultaneous equations which have to be solved at any one time, this process has another important advantage.

The writer has found by experience in the drafting-room that even when the analysis of an arch is given in complete algebraic formulas, together with a numerical example, an enormous amount of explanation is required by the computers. Without complete algebraic formulas, the task of getting computers to follow through an analysis is made more difficult. While the standard methods of analysis lend themselves readily to expression in algebraic formulas, it is not generally possible to write one set of equations for an arch of any number of spans. Professor Rathbun's solution makes the process the same for any number of spans. The same procedure is repeated from the left-hand to the right-hand span regardless of the number of intervening spans.

It is unfortunate that the author has not given a set of deflection formulas for the case of abutments hinged at the base. Curiously enough, except for the single span with the footings at the same elevation, the assumption that the bases are hinged makes the theory more difficult, even though there are fewer unknowns. It seems to the writer that, for this case, the multiple-span frame will have to be broken up into fundamental types of structures other than cantilevers, and that a more "elegant" method of obtaining deflections will have to be used instead of that of the single cantilever. The cantilever method of obtaining deflections requires certain corrections when the bases are hinged and at different elevations. These corrections involve considerable laborious work and are difficult to apply.

The case of hinged bases is a very important one. The true state of the footings is that of partial fixity. When the first "Rigid Frames" of one span were designed by the Westchester County Park Commission, the analysis was made for both conditions, that is, with the bases fixed, and with the bases hinged. The sections were proportioned for whichever condition was the more severe. After several designs, it was found possible to design for hinged bases only, as the principal difference was found to be at the bottom of the posts where the dowels provided ample reinforcement for either condition. A similar procedure should be followed in the present case and both conditions taken into account.

In the derivation of the equations for the loading terms, the author has taken into account the effect of forces which are located unsymmetrically with respect to the spandrel walls. The only effect seems to be that the forces, T_z (or t_z), M_x (or m_v), and M_y (or m_u), are changed in the skew arch or introduced in the right arch. Taking the latter case, for simplicity, M_z remains unchanged if the load is shifted from a symmetrical, to an unsymmetrical, position. Since Professor Rathbun distributes the moment uniformly over the width of the section, it follows that as far as bending is con-

cerned, all parts of the section from one spandrel wall to the other are equally affected. The effect of the torsion moment is also symmetrical as far as horizontal shears are concerned, and the vertical shears are also of equal value, but of opposite directions at each face of the bridge. This does not seem possible to the writer, because the load will distribute itself in such a way that the area immediately adjacent to it will be stressed most severely. The question of load distribution on slabs and arches, which has not yet been solved, enters into this problem.

E. F. Gifford, Assistant Engineer in the Engineering Department of the New York Central Railroad, has made some tests on concrete models of rigid frames. The photographs showing the results and method of testing are reproduced herein through the courtesy of Mr. Gifford. (See Figs. 16 to 25, inclusive.) Fig. 26 is a sketch showing the location of the reinforcement, comprising $\frac{1}{2}$-in. square mesh of No. 14 wire, with two of every three cross-strands cut. The mortar mix was 1 part cement and 2 parts sand. The angle of skew was 45° and the scale of model to prototype was 1 : 64. The models were tested to destruction and no attempt was made to obtain any quantitative results. The first cracks appeared at the obtuse corners of the top slab and continued approximately perpendicular to the face of the bridge. It is obvious from the photographs, that the unsymmetrical load (Figs. 22, 23, and 25) produces a type of failure different from that of the symmetrical load (Figs. 16, 18, 19, 20, 21, and 24). The photographs seem to show that for the unsymmetrical load there are two types of failures: (1) A local failure in the vicinity of the load due to some still unknown factor; and, (2) a general failure which takes place at points far enough away from the load so as not to be affected by the local load distribution stresses.

The question might now be raised, "Is Professor Rathbun's solution incorrect, and, if so, what about the tests described in Part IV?." The answer, it seems to the writer, is that the proposed solution is correct as far as it goes, and that Professor Rathbun's tests prove only what they were intended to prove and no more. If the crown section is taken, for example, it is shown that three forces and three moments act on it, that is, T_x, T_y, T_z, M_x, M_y, and M_z. These stresses are resisted by the unit stresses developed in the material of the arch. No matter what distribution of these unit stresses is adopted, their summation over the section, or their resultants parallel to the three co-ordinate axes, and their moments about these axes, must be equal and opposite to T_x, T_y, T_z, M_x, M_y, and M_z, respectively. The tests described in Part IV give only the values of the resultants of the reactions and do not show of what unit stresses they are the resultants.

If a simple beam with a load at the middle were similarly tested, it would show that one-half the load is carried to each support. The vertical shear acting on any section would then be equal to either reaction, but the distribution of the shear is another matter. The test would produce the same result in the case of a rectangular beam in which the maximum shear at the neutral axis is 3/2 times the average, or in the case of a deep plate girder, where the shear at any point in the web is practically equal to the average shear.

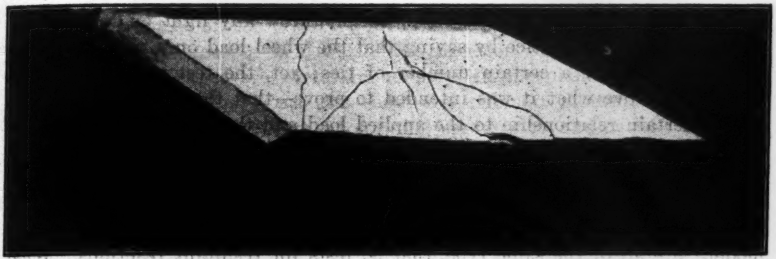

FIG. 22.—BASES FIXED, LOAD PLACED UNSYMMETRICAL AND AT CENTER OF SPAN.

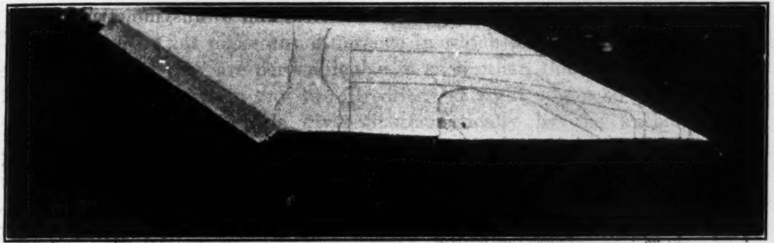

FIG. 23.—BASES FIXED, LOAD PLACED UNSYMMETRICAL AND AT CENTER OF SPAN.

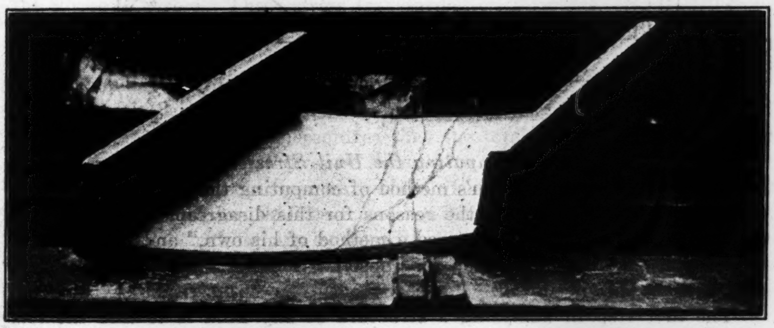

FIG. 24.—BASES FIXED, LOAD PLACED SYMMETRICAL AND AT QUARTER POINT OF SPAN.

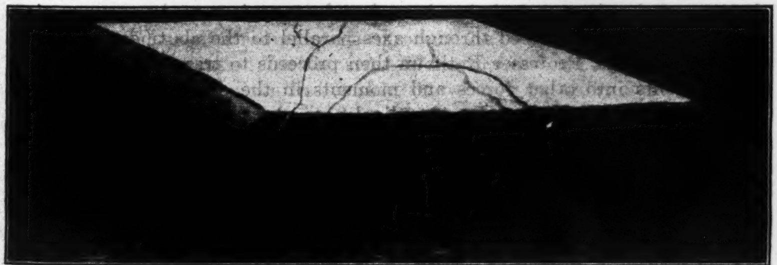

FIG. 25.—BASES HINGED, LOAD PLACED UNSYMMETRICAL AND AT CENTER OF SPAN.

Neither would the test of this simple beam throw any light on the problem which is solved in practice by saying that the wheel load on a railroad bridge is distributed over a certain number of ties; yet, the test would be correct and would prove what it was intended to prove—that the resultant reactions have a certain relationship to the applied load and that they satisfy the laws of equilibrium. The present case, it seems to the writer, is analogous. The tests described by Professor Rathbun in the present paper, those made on a plaster model and reported in a previous paper entitled, "Crown Stresses in a Skew Arch,"[11] and those made by him and Professor Beggs on a rubber model,[12] are all of the same type, that is, tests for resultant reactions. What is required now are tests to determine internal unit stresses and their distribution, and this applies equally to symmetrical and to unsymmetrical loads.

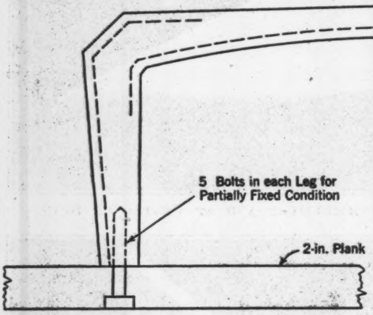

FIG. 26.

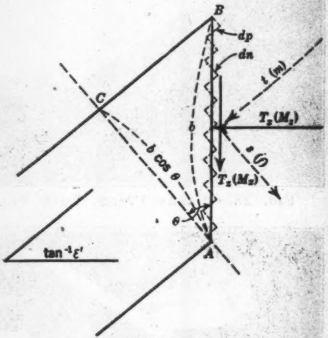

FIG. 27.

Part II.—Method of Computing the Unit Stresses.—The writer does not agree with Professor Rathbun's method of computing the unit stresses. It is not necessary to go into all the reasons for this disagreement in any great detail since the writer has proposed a method of his own,[13] and the interested reader can make the comparison for himself. Some of these differences, however, will be discussed.

The first step in analyzing a structure of any kind is to find the total or resultant forces and moments acting on the various critical sections. In the case of the skew arch, it has been found convenient to do so on sections cut by radial planes passed through axes parallel to the abutments (Z-axes). Having done this, Professor Rathbun then proceeds to transform these forces and moments into other forces and moments in the direction of and about axes, which are parallel and perpendicular to the faces of the bridge. In Fig. 27, the forces, T_x and T_z, are shown transformed into t and s, and the moments, M_x and M_z, into m and f. The author then assumes that the force and moment in the plane parallel to the face of bridge, t and m, act as a

---

[11] *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 135.

[12] *Loc. cit.*, Vol. 88 (1925), p. 1208.

[13] "Design of a Reinforced Concrete Skew Arch," *Transactions*, Am. Soc. C. E., Vol. 96 (1932), Part II, p. 1249 *et seq.*

thrust and moment on the projected area of the section on a radial plane perpendicular to the face of bridge (in the direction of the plane, AC). He similarly assumes that the force and moment in the plane perpendicular to the face of bridge, s and f, act as a shear and a torsion moment on this same projected area. No proof is given for this assumption and as will be shown later, it leads to incorrect results. If the zig-zag line, AB (composed of segments parallel and perpendicular to the face of bridge), and the dimensions, dp, dn, are considered, it might be argued that t and m produce tension and compression on the segments, dn, and shear on the segments, dp. Similarly, it might be argued, that s and f produce tension and compression on the segments, dp, and shear on the segments, dn. This is what actually happens, and the exact proportion of each kind of stress in each direction can be found. It does not make any difference in which direction the segments are taken, provided they are perpendicular to each other, thus giving a means of obtaining the stresses in any two directions at right angles to each other.

The operation which is given mathematically by the author's Equations (7), is merely a transformation of axes, but what is required is something entirely different. Textbooks on mechanics[14] derive formulas for finding the unit stresses on any plane when the unit stresses on any other two planes at right angles to each other are known. These formulas, when referenced to the principal planes, result in the equation of what is known as the ellipse of stress. These stress transformation formulas, or the ellipse of stress, apply equally well to moments and forces per unit width as to unit stresses.

A complete set of these equations in terms of the skew arch notation adopted by the writer is given in the paper previously mentioned[15] and need not be repeated. Their use requires that the total or resultant forces and moments on a section shall first be reduced to forces and moments per unit width, and that the stresses per unit width, if any, acting on a plane at right angles to the cut section shall be found. With these data, the stress per unit width on a plane making any angle with the cut section, and on the plane on which the maximum stresses occur, can be computed. This procedure gives a different result from that obtained by the method outlined by the author.

The writer's method based on the ellipse of stress requires that the total forces and moments first be distributed on the plane on which they are computed, that is, on the radial plane through the Z-axis. This distribution, as well as the derivation for the stresses on the plane at right angles to it, through the V-axis, is given in detail in the writer's paper.[16] Professor Rathbun has made a suggestion regarding the distribution of T_z on the plane on which it is computed, which shows that it can be done. He has stated that a portion of T_z equal to ϵT_x can be distributed uniformly and the remainder, parabolically.[17] This is proven by the writer to be correct and similar derivations are worked out for the moments.

[16] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), Equations (35), (36), (43), (44), (48), (49), (51), and (52), p. 1297.

As an example of the differences between the two methods, the numerical illustration given by the author under the heading, "Example 1,"[18] will be used. The value of m for which the main or longitudinal steel is designed, is 628 kip-ft. acting over a width of $b \cos 47° 41' = 45.6 \times 0.680 = 31$ ft. The moment per unit width is $\frac{628}{31} = 20.2$ kip-ft. The writer obtains two values for this moment per unit width: One at the face of bridge and another for the central portion. The first value equals $\frac{M_z}{b} \sec^2 47° 11' = \frac{534}{45.6} \times 2.16 = 25.3$ kip-ft. The moment at the face of bridge is chosen because the proof of its correctness[19] is simple and is not subject to the uncertainty surrounding the correct formula to use for the torsion moment. The torsion moment does not enter into this part of the problem in the solution proposed by the writer.

Incidentally, Professor Rathbun uses Merriman's torsion formula whereas the writer uses St. Venant's formula. This is a matter of minor importance as neither is correct, as explained in the writer's paper previously mentioned. As far as the writer has been able to discover from the available literature on this subject, there is no derivation which applies exactly. St. Venant's formula is the most accurate, and for large ratios of $\frac{b}{t}$, that of Merriman is the least accurate.[20] Unless a correct formula, when developed, reveals something quite unexpected, its results need only be substituted for those used herein, and the discussion remains the same.

The author has attempted to transform the computed moments and thrusts, T_x, T_z, M_x, and M_z, into the stresses, t, s, f, and m, respectively, because they are in the directions in which the steel is to be placed. This transformation is convenient, but the writer questions its correctness. Sections should be designed for the maximum moments and thrusts. The writer has referred previously to the stress transformation formulas which are a form of the equation for the ellipse of stress. These show that the maximum moments occur on one of the principal planes. The directions of the principal planes are determined by the relative values of the various moments, and, similarly, for the forces. It therefore happens, except at the face of bridge, that the steel will not be perpendicular to the principal planes. This fact requires a new set of reinforced concrete design formulas for the condition in which the steel is not normal to the plane on which the moments are computed.[21]

[20] *Bulletin No. 3*, Faculty of Applied Science and Eng., School of Eng. Research, Univ. of Toronto, Toronto, Ont., Canada.

[21] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1261, and pp. 1298 to 1320, inclusive.

The ellipse of stress shows that the maximum shearing stresses occur on a pair of planes at 45° to the principal planes. Here, again, the planes form an angle with the steel. It is shown by the writer[21] that where the steel is not normal to a section it resists shearing stresses and direct stresses (bending and thrust) simultaneously and the two types of stresses can be separated only where the steel is normal to the section. Leaving out the question of the correctness of the transformation formulas given by the author, the writer still does not agree with the design for torsion in "Example 1."[22] Besides the points already enumerated, no account is taken of the relative deformation of the concrete and the steel. Incidentally, in designing for the maximum or principal flexural stresses, the fact that the steel is not normal to the section and that, therefore, the concrete and the reinforcement do not deform in the same direction must be taken into account. The same applies to the shearing stresses.

The writer has found that if the longitudinal steel in a skew "Rigid Frame" is placed parallel to the faces of bridge, no transverse steel is required for skew arch action. The photographs (Figs. 16 to 25, inclusive) seem to prove this in a general way, since the failure cracks are perpendicular to the face of bridge. At the center, some of the cracks make a small angle with the perpendicular to the face of bridge, and this also is to be expected. In a design of a similar bridge (skew angle, 50°),[23] this angle is found to be 11° 50′ for loads symmetrical with respect to the faces of bridge. In a slab, it can be shown that for symmetrical loads, as understood herein, the principal stresses will be parallel to the face of bridge. Apparently, a rigid frame differs very little from a slab as far as a certain type of skew arch action is concerned. For other reasons, transverse steel, of course, should be used even in a right arch, but that is another matter entirely. The transverse steel can be placed parallel to the abutments (and, if found necessary, it can be designed that way) for simplicity in detailing. By the writer's method, the steel can be placed and designed in any direction desired, and the stress computed at any point and in any direction.

Conclusion.—Professor Rathbun's mathematics and the experimental work done by him and by Professor Beggs, demonstrate the relation between the load and the resultant reactions.

The mathematical demonstration of the relation between the reactions and the internal stresses is covered in Part II of the writer's paper.[24] The proportioning of the sections and design of steel, as suggested in this paper, are sufficiently accurate for design purposes, although certain factors which have not been experimentally demonstrated enter into the derivations. This experimental verification should be made so that no doubt will remain as to the exactness of the theory developed, even though a design based upon it, may be adequate for all practical purposes.

G. D. HOUTMAN,[25] ASSOC. M. AM. SOC. C. E. (by letter).—The writer has observed one bridge of several arches built on a pronounced skew, in apparent disregard of skew-arch theory, which shows no extraordinary crack or blemish. On the other hand, he has seen a lesser arch, built along lighter lines, showing a peculiar crack near the acute corner, as noted in Fig. 28. The direction of this crack is almost certain proof that the arch, near that crack, is not in compression, which confirms some of the current beliefs regarding skew-arch action.

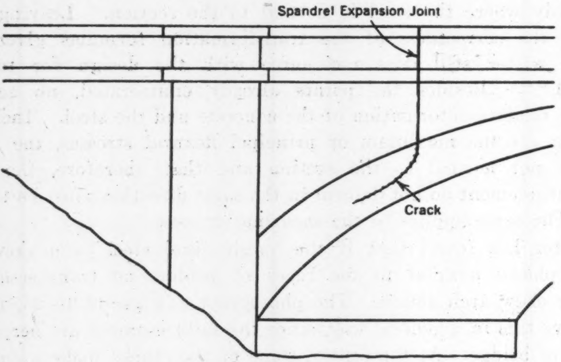

FIG. 28

CHARLES L. NORD,[26] M. AM. SOC. C. E. (by letter).—To any one familiar with the first paper[27] written by Professor Rathbun, it will be perfectly apparent that the method presented in this paper is, in the main, the same as that used in multiple right arches, in which the reaction of one is considered in the computation of the other.

The arch rings are divided into cantilevers, loaded with uniform and concentrated loads and with the reaction of the cutting plane or planes as in the case of the intermediate spans. The entire mathematical analysis of the single skew arch as well as the multiple arches is based on the flexure theory and can readily be understood and applied by engineers familiar with the elastic theory.

Other methods, such as "virtual work," or "least work," could be used. These, however, are too tedious and complicated for the average designer.

Professor Rathbun's mathematical analysis of the single skew arch is of primary importance to the profession since it has been proved by tests that, for vertical loads, the reactions are transferred to the supports along the lines parallel to the skew axis and not along those normal to the support. This, apparently, is contrary to the fundamental law of Nature that work is done by forces along the shortest lines and in the most economical way; although the writer fails to see where there can be an error in Professor Rathbun's method.

[27] "Analysis of Stresses in the Ring of a Skew Arch," *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 611.

That other authorities do not agree with the author may be seen from a paper[28] by Professor Oskar Muy, of the Technische Hochschule, Stuttgart, Germany, describing the design and construction of a reinforced skew arch bridge over the Saar River, near Voelklingen. In this paper it is stated that in a skew arch the stresses cannot follow the arch as far as the sharp angles at the haunches, but will run more in the direction of the plane normal to the abutments, and that, therefore, the tendency is to overstress the obtuse corners greatly, with the likelihood of breaking them. To meet this situation, these points were heavily reinforced in a transverse direction. Professor Muy advanced no theory to support his view, but based his assumption solely on what he called "common sense." This would seem to indicate that a theory or method of designing a skew arch was a universal need of the Engineering Profession.

TABLE 6.—COMPUTATIONS FOR AN 80-FOOT SPAN OF A SKEW ARCH.

Term	Value	Term	Value

* Terms in Equation (11) that may be eliminated.

The writer unintentionally checked Professor Rathbun's statement that certain terms may be eliminated and found it correct. Table 6 was prepared in the computation of a skew arch of 80 ft. span, at an angle of 30°, which, later, was checked by Professor Rathbun personally.

---

[28] *Deutsche Bauzeitung*, Nos. 14–18, 1915.

F. W. KEYSER,[29] ESQ. (by letter).—The importance of Professor Rathbun's mathematical achievement is obvious when one realizes the many grade separations made necessary by highways crossing other highways, railroads, and rivers. The constantly expanding public roads program and its accompanying economy has made, for the skew arch, a definite place in the world of structures.

The mathematical analysis advanced by Professor Rathbun in this paper and in his previous paper on skew arches, namely, "Analysis of the Stresses in the Ring of a Concrete Skew Arch,"[30] ends the long period of obscurity in which the skew-arch problem has rested.

The slow increase in bridge width has been greatly accelerated in recent years, and, in a very short time, the effect of eccentric loads on the right arch will be a primary and not a secondary factor in the design of right arches. This eccentricity of loads on right arches can no longer be neglected. Professor Rathbun's analysis with its accompanying fundamental assumptions definitely shows the effects of eccentric loads. Not only that, but it points the way to the solution of eccentric stresses in the design of arches in the future.

The fact that Professor Rathbun's analysis is an exact one and is based on simple fundamental assumptions does not eliminate the case in which the stresses, computed as such, would be only approximate at best. For example, he has assumed rigid supports which means absolutely unyielding foundations, since the reactions do no work. This condition is never quite encountered in practical cases because even rock has a certain degree of elasticity and will deform under the action of thrusts and moments (although the deformation is insignificant).

For most other soils the deformation will be greater and more permanent, and, therefore, the writer believes that it remains for the designer to decide how far to go in accepting soil conditions as found and, at the same time, consider the work of the reactions as zero. In other words, Professor Rathbun's analysis is based on an assumption that never actually occurs in practical cases, although it may be approached.

The deformations as calculated are comparatively small; they will have to be so, in order to apply the elastic theory. If a settlement of the foundation occurs, it can at best only be estimated; it certainly cannot be calculated. The calculated deformations and, therefore, the crown reactions which are dependent upon the rigidity of the support, will necessarily be approximate only. In regard to the author's assumption of rigid supports the writer would like to issue a solemn warning that the skew arch, as well as any other indeterminate structure, should not be considered unless absolutely reliable data on the subsoil condition are at hand, to be studied carefully and deliberately, so as to determine the exact degree of rigidity that can be relied upon. In other words, engineers are all too apt to equate the work of the abutment reactions to zero. In many instances this is not so, due to subsoil conditions that are not apparent until the excavation for the structure has started.

---

[29] New Haven, Conn.

[30] *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 611.

Then, spread footings, tie-beams, pile foundations, and other methods are used to make up for the lack of assumed rigidity. In such cases the indeterminate structure would not be economical and might even prove dangerous.

The modulus of elasticity is another factor to be considered. The writer is fully aware of the fact that common practice of present-day design is to consider this factor a constant when dealing with materials that follow the constant ratio of stress to deformation. Within the limits of stress commonly used, this assumption is correct; that is, if concrete is one of these materials. Tests made by Professor Emil Probst, in the testing laboratory in Zurich, published in 1906, give a different picture. Dr. Ing. Rudolph Saliger[31] has called attention to several tests made by Professors Bach, Wayss, and Freytag, of Berlin, which indicate that concrete is not one of these materials. The results of these tests show that the modulus of elasticity for concrete is a function of the stress, and, therefore, must be treated as a variable and not as a constant. However, the striking of an average stress deformation constant might be justifiable for an approximation except for another complication that enters in concrete structures, namely, the initial stresses induced in the steel and concrete during the setting process of the concrete. This subject has received little attention and much less investigation and, therefore, must be considered unsolved. These stresses may be of such intensity as to cause considerable variation in the stress computed by the elastic theory.

Another subject that has received very little attention and investigation is the behavior of large sections under torsional moments. Their behavior is most uncertain and this problem must be considered as unsolved.

These points have been cited to show why structures of the skew-arch type should be designed with conservative stresses, the judgment of experience as to conditions of site, and an absolute understanding of the analysis and its assumptions. The writer's views are those of the practicing engineer and not of the scientific investigator and mathematical expert. They are given in the spirit of co-operation to the end that a practical solution of the problem may be accepted by the profession.

With these points in mind, and under the assumption that they may be discounted, the writer has made a study of Professor Rathbun's analysis of skew arches by the Method of Virtual Work, or as it is more commonly known, the Principle of Least Work. He has checked his formulas for the single-span skew arch as outlined in Part I of the paper, but in the development of Equations (3) for the right side, sign differences were encountered because the directions of forces and moments were assumed to act as in Professor Rathbun's first paper,[32] where they are opposite in direction to those in the present paper. These sign differences occur in the writer's analysis only when based on his own interpretation of the method of virtual work and the sign system for the right half of Arch *A* (Fig. 3) as developed in Professor Rathbun's first paper.[32] By assuming that the directions of moments, forces, and crown deformations, as shown in Figs. 6 and 7, are correct, the writer has checked Professor Rathbun's analysis in sign and terms for both the right side and the left side.

---

[31] "Ueber die Festigkeit Veränderlich Elastischer Konstructionen," Leipzig, 1904.

[32] *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 613.

The method of virtual work is based upon Castigliano's first theorem:[33] "The derivative of the total internal work, W, with respect to any one load or external force, X, is equal to the displacement, Δ, in the direction of this load."

In other words,

$$\frac{dW}{dX} = \Delta \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(43)$$

The general formula for the elastic work is,

$$W = \tfrac{1}{2}\int \frac{t^2_v\,ds}{EA} + \tfrac{1}{2}\int \frac{m^2_z\,ds}{EI} + \tfrac{1}{2}\int \frac{t^2_u\,ds}{GA} + \tfrac{1}{2}\int \frac{m^2_u\,ds}{GI_p} \quad \ldots(44)$$

in which, $G =$ modulus of shear $\left(= \frac{E}{\lambda}\right.$ in Professor Rathbun's analysis); and,

$GI_p =$ factor of torsion $\left(= \frac{EF}{\lambda}\right.$ in Professor Rathbun's analysis).

Differentiation of Equation (44) by partial differentiation for the unknown elastic values, which is denoted by X, determines the virtual work; thus,

$$\frac{dW}{dX} = \Delta = \int \frac{t_v}{EA}\,\frac{\partial t_v}{dX}\,ds + \int \frac{m_z}{EI}\,\frac{\partial m_z}{\partial X}\,ds + \lambda \int \frac{t_u}{EA}\,\frac{\partial t_u}{\partial X}\,ds + \lambda \int \frac{m_v}{EF}\,\frac{\partial m_v}{\partial X}\,ds. \quad (45)$$

When the abutment deformation is neglected Equation (45) represents 1 × Deformation. The modulus of elasticity, E, considered constant, is next removed from the integrals and multiplied by the deformation.

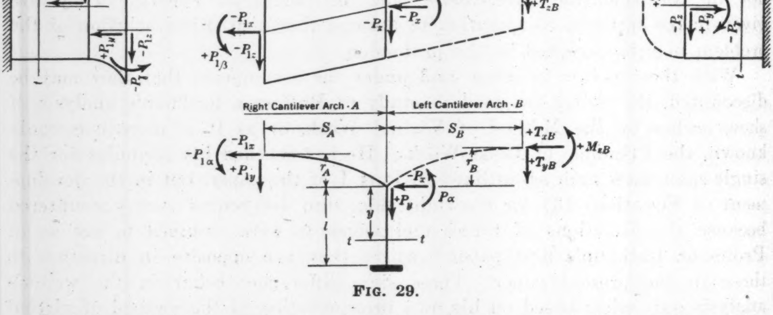

FIG. 29.

In his analysis the writer treated the problem as a single cantilever, the right cantilever of Arch A, acted upon by the forces of Arch B, as shown in Fig. 29. The P forces acting on the cantilever are due to the crown reactions of Arch B and their relationship may be demonstrated as follows:

---

[33] "Die Neueren Methoden der Festigkeitslehre und der Statik der Baukonstruktionen," and, "Die Graphische Statik der Baukonstruktionen," by Prof. H. Müller-Breslau. (Lectures by the same Professor as recorded by the writer during his student days.)

$$P_x = T_{xB} \qquad \text{(46a)}$$

$$P_y = T_{yB} \qquad \text{(46b)}$$

$$P_z = T_{zB} \qquad \text{(46c)}$$

$$P_\alpha = T_{xB}\, r_B - T_{yB}\, S_B + M_{zB} \qquad \text{(46d)}$$

$$P_\beta = T_{xB}\, \epsilon\, S_B - T_{zB}\, S_B + M_{yB} \qquad \text{(46e)}$$

$$P_\gamma = T_{yB}\, \epsilon\, S_B - T_{zB}\, r_B + M_{xB} \qquad \text{(46f)}$$

The P_1 forces are the unit forces applied in the direction of the deformations caused by the P forces. The relationship of the forces acting on the Section (t-t) of the pier is shown by the following formulas:

$$t_x = - P_x - P_{1x} \qquad \text{(47a)}$$

$$t_y = + P_y + P_{1y} \qquad \text{(47b)}$$

$$t_z = - P_z - P_{1z} \qquad \text{(47c)}$$

$$t_\alpha = - P_\alpha - P_{1\alpha} - P_x y - P_{1x} (r_A + y) - P_{1y}\, S_A \qquad \text{(47d)}$$

$$t_\beta = + P_\beta + P_{1\beta} - P_{1x}\, \epsilon\, S_A + P_{1z}\, S_A \qquad \text{(47e)}$$

$$t_\gamma = - P_\gamma - P_{1\gamma} + P_{1y}\, \epsilon\, S_A + P_{1z} (r_A + y) + P_z y \qquad \text{(47f)}$$

The partial differentiation of Equations (45) with respect to the P_1 forces are given in Table 7.

TABLE 7.—PARTIAL DERIVATIVES FOR USE IN EQUATIONS (45)

Terms	∂P_{1x}	∂P_{1y}	∂P_{1z}	$\partial P_{1\alpha}$	$\partial P_{1\beta}$	$\partial P_{1\gamma}$
∂t_x	-1	0	0	0	0	0
∂t_y	0	$+1$	0	0	0	0
∂t_z	0	0	-1	0	0	0
∂t_α	$-(r_A+y)$	$-S_A$	0	-1	0	0
∂t_β	$-\epsilon S_A$	0	$+S_A$	0	$+1$	0
∂t_γ	0	$+\epsilon S_A$	$+(r_A+y)$	0	0	-1

The P_1 forces are equated to zero, after differentiation, because they do no work. Then, the forces acting on the cantilever are:

Shear:

$$t_x = - P_x \qquad \text{(48a)}$$

Normal:

$$t_y = + P_y \qquad \text{(48b)}$$

Shear:

$$t_z = - P_z \qquad \text{(48c)}$$

Moment:

$$t_\alpha = - P_\alpha - P_x y \qquad \text{(48d)}$$

Torsion:

$$t_\beta = + P_\beta \qquad \text{(48e)}$$

Moment:

$$t_\gamma = - P_\gamma + P_z y \qquad \text{(48f)}$$

By inserting the values of the shears, normal force, moments, and torsion, as obtained from Equations (48), with their respective differential values, in the general formula for virtual work (Equation (45)), the equations of deformations in terms of the P forces are determined. By the proper substitution of the crown forces of Arch B (Equations (46), in the equations of deformation, the author's Equations (3) are derived except that, as noted previously, the signs are reversed completely in Equations (3*a*), (3*c*), (3*d*), and (3*f*).

It will be noted that the load terms have been neglected. The writer considered the cantilever unloaded. The load terms are independent of the elastic values and should be treated separately. Their omission will not affect, in any way, the equations as developed.

In closing, the writer wishes to acknowledge the assistance of Joseph D. Drury, a co-worker in the Engineering Division of the Connecticut State Highway Department, in checking the mathematical analysis and in the preparation of this discussion.

A. A. EREMIN,[34] ASSOC. M. AM. SOC. C. E. (by letter).—The author has extended the application of the deflection equations of a cantilever skew arch to the solution of a continuous multiple-span rigid frame.

The equations in the terms of the loading and their reactions at the cut planes developed by the author may be solved either simultaneously for all spans of the frame, or in the groups of six equations for each span, by substituting the unknown reactions in the terms of the reactions at the cut planes in the adjacent spans, as described by Professor Rathbun. In both cases, however, the arithmetic error in solving the equations accumulates with the number of equations connected by continuous properties of a structure.

If a frame is cut by the planes at the crown, as shown by Professor Rathbun in Fig. 3, the procedure of solution of the frame is the same, regardless of the variation in the relative elastic properties of the arches and piers. The solution of a frame may be simplified by placing the cutting planes at the skewbacks, as shown in Fig. 30.

The deflections, Δ_y, Δ_z, and $\Delta\gamma$, at the top of the piers are usually small and, therefore, it may be assumed that the reactions T_y, T_z, and M_x, at the cutting plane of one span (Fig. 30) will not vary with the changes in the loading and their reactions at the adjacent spans. According to this assumption fewer substitutions will be required to solve the equations.

If the frame and loading are symmetrical then one cutting plane in Fig. 30 may be placed symmetrically to the frame and the other sections at the skewbacks in the adjacent spans.

It is interesting to compare Equation (8), used by Professor Rathbun for computing the unit shear stress due to torsion moment, to Equation (49) which was experimentally developed by Professor Bach[35]:

$$v = \left(3 + \frac{2.6}{0.45 + \dfrac{b}{d}} \right) \frac{f}{b d^2} \qquad \text{.....................(49)}$$

---

[34] Asst. Designing Engr., Bridge Dept., State Highway Comm., Sacramento, Calif.

[35] "Deutscher Ausschuss für Eisenbeton," Heft 16, 1912, W. Ernst & Sohn, Berlin.

The numerical coefficients in both Equations (8) and (49) will be the same for the cross-section with the ratio, $\frac{b}{d} = 1.29$.

In his test, Professor Bach used beams of a square cross-section and the rectangular section with the ratio, $\frac{b}{d} = 2$. Therefore, his equation and, apparently, Equation (8) cited by Professor Rathbun, are true only in this range of the sections.

FIG. 30.—MULTIPLE-SPAN RIGID FRAME DIVIDED BY CUTTING PLANES.

The writer agrees with Professor Rathbun that the shear reinforcing steel should be placed at right angles to the main reinforcement. A very noticeable loss in the efficiency of steel reinforcement occurs if it is placed inclined to a force. This may be proved by simple geometrical relations.

In Fig. 31 is shown a steel bar, *AB,* inclined to the force, *P.* at an angle, α. If the length of a strand, *l,* changes to $l + \delta$, the strain in the bar will be:

$$\frac{\delta}{l} \cos^2 \alpha$$

Whence, the stress in the bar in the direction of the force, *P,* is:

$$E \frac{\delta}{l} a_s \cos^3 \alpha$$

Therefore, the effective area of the cross-section of the inclined bar is:

$$a_s \cos^3 \alpha$$

This area will be maximum if the angle, α, is equal to zero, or if the bar is placed in the direction of the force.

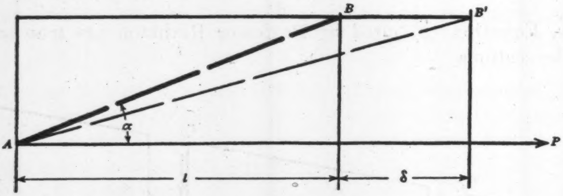

FIG. 31.—DEFORMATION IN STEEL PRODUCED BY DIRECT DEFORMATION IN CONCRETE.

Likewise, it may be proved that the tie-bars placed at right angles to the neutral axis of an arch in conjunction with the steel bars in the extrados and intrados, placed also at right angles to each other, will assist most effectively in carrying the variable stresses in the space.

Professor Rathbun deserves the high appreciation of the Engineering Profession for his excellent accomplishments in developing the theory of skew arches.

RICHARD M. HODGES,[36] ASSOC. M. AM. SOC. C. E. (by letter).—In Part IV of his paper, Professor Rathbun gives a simple and direct method of designing skewed arches after the forces and moments acting on any section have been found. In the writer's opinion this is the most valuable information, from a strictly practical standpoint, contained in the paper. It is also, probably, the only part of the paper that may be considered open to question.

As far as all external forces and reactions are concerned, the solution of skewed arches, whether fixed or hinged, single-spanned or multi-spanned, is no longer a matter of opinion. The correctness of Professor Rathbun's results has been verified by tests, and in the case of hinged skewed arches of one span, at least, has been checked by an independent analytical procedure,[37] as well as by the investigations of B. L. Weiner,[38] Assoc. M. Am. Soc. C. E.

However, when it comes to the matter of finding the distribution of stresses on any section, and of designing the arch and its reinforcement to withstand these stresses safely and economically, no such certainty exists. It seems evident that, whatever method is used, an exact design will be impossible until tests have been made to verify the fundamental assumptions of stress distribution which must be made at the outset, the correct value of the constant, K, in the torsion formula, $v = \frac{K f}{b d^2}$ (and the applicability of the formula itself to skewed arches), and the practical effectiveness of whatever method of torsion reinforcement may be proposed. Pending such tests, it will remain a matter of opinion as to what degree of analytical precision is required in deriving design formulas, and as to what degree of reliance can be safely placed on such formulas in practical design. The writer is of the opinion that the author's method, with the modification hereinafter suggested, is the best practical method yet proposed for designing skew arches, on account of its directness and simplicity, and because it leads to results which seem safe and reasonable for all ordinary skews.

---

[36] Asst. Engr., Westchester County Park Comm., White Plains, N. Y.

[37] "The Rigid Frame Bridge," by A. G. Hayden, M. Am. Soc. C. E., N. Y., John Wiley & Sons, 1931.

[38] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), pp. 1212–1229.

Luckily, after all, indications point to the probability that for moderate skews, the old method of designing a skewed arch as a rectangular arch for a span equal to the skewed span is fairly safe. In the writer's opinion, the author's method is applicable to skews up to 45°, more or less, which comprises the great majority of grade-crossing eliminations. Skews of more than 50° should be avoided, pending the results of tests.

In applying the author's method of design, the following modification is suggested. It is often found advisable from the standpoint of practical simplicity to place the transverse reinforcement parallel to the abutments. In such a case, the forces and moments, being resolved into directions parallel to spandrels and parallel to abutments, become:

$$t = t_v \sec \epsilon' \tag{50}$$

$$s = t_v \tan \epsilon' - t_z \tag{51}$$

$$m = m_z \sec \epsilon' \tag{52}$$

and,

$$f = m_z \tan \epsilon' + m_v \tag{53}$$

The remaining procedure then follows, as shown in the paper. This change seems to result usually in an increase in the longitudinal reinforcement, but sometimes a decrease, depending on the relative magnitudes of t_v and t_z, or m_z and m_v. Wherever the resultant, r (see Fig. 8), is in the exact direction of the arch axis, Equations (50), (51), (52), and (53) will lead to the same results as the author's formulas. It is suggested that, in practice, the design should be made in every case according to the formulas leading to the larger amount of longitudinal reinforcement regardless of the selected direction of the transverse steel. The increase in cost will be inconsiderable in comparison with the increased margin of safety.

The design of the transverse reinforcement becomes a matter of academic interest only, since the resulting steel is nearly always less than the transverse spacer rods which would be inserted in any case to tie the longitudinal steel. Inadvertently the author seems to have equated an uubalanced shear torque to an unbalanced resisting steel stress couple in order to find the required steel areas. A more correct procedure would seem to be to take moments first on one side of the neutral axis and then on the other. However, this correction leads to very small variations, in application, from the results obtained by doing it the author's way.

J. Charles Rathburn,[39] **M. Am. Soc. C. E. (by letter).**—Some of the points that have been brought out by those who have contributed to this paper are pertinent to the subject of arches in general rather than to the effect of the skew. As they add to the knowledge of arches and arch design the writer will give his contribution as well as discuss those points that arise in the design of skew arches only.

Mr. Weiner indicates that a set of deflection formulas should be worked out for the case of a multiple-skew arch hinged at the base. The paper contains, in Appendix III, the formulas for the skew arch when the abutments are free to rotate, as he suggests. The body of the paper gives the general method of extending the analysis from one to two or more spans. The writer feels that this constitutes a solution of the problem even if an example of application is not given. The extension of these formulas to include the multiple arch involves no new ideas that have not been brought out in this paper, in the writer's previous paper,[40] and in Appendix III. Working out and publishing these formulas would have involved considerable labor and would have lengthened the paper materially. The writer suggests to any one who may have use for these formulas and may wish to derive them that he divide the structure by cutting planes as shown in Fig. 32.

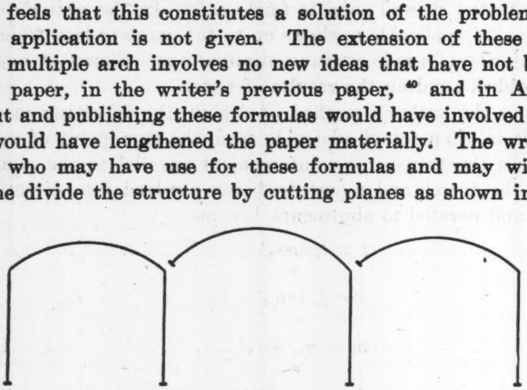

Fig. 32

The local load distribution due to a concentrated load, as demonstrated by tests made by Mr. E. F. Gifford (Figs. 16 to 25, inclusive),[41] shows that dangerous local stresses surround the point of application of this load. This very important problem arises in the design of arch rings where the load covers a comparatively restricted area and will arise in right, as well as in skew, arches.

The writer conducted a simple experiment which may add to the findings of Mr. Gifford. It also gives some idea of the lateral distribution over the ring of a concentrated load. Fig. 33 gives the general set-up of the experiment. A sheet of galvanized iron about 20 in. wide was bent to form an arch with about 5 in. rise and a span of 13½ in. The ring was a segment of a circular cylinder, quite wide and very thin. The ends may be considered fixed, because the sheet extended about 4 in. beyond each abutment. This 4-in. extension was placed under a 1 by 4-in. plank which, in turn, was nailed to the table. A concentrated load was applied by weighting a 60d nail which had been driven through a plank, as shown in Fig. 33. Weights were placed on this plank, but no attempt was made to evaluate the load.

---

[39] Associate Prof. of Civ. Eng., Coll. of the City of New York, New York, N. Y.

[40] "Analysis of the Stresses in the Ring of a Concrete Skew Arch," *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 611.

[41] See p. 50.

A central load was placed on the arch and the deflections along the crown from face to face were noted by means of an Ames dial placed on a carrier. There was some permanent set, as shown, when the load was removed. The load was then placed near one edge of the crown and another set of deflections taken. The deflection and permanent set due to the second load were taken from the final position after the removal of the first load.

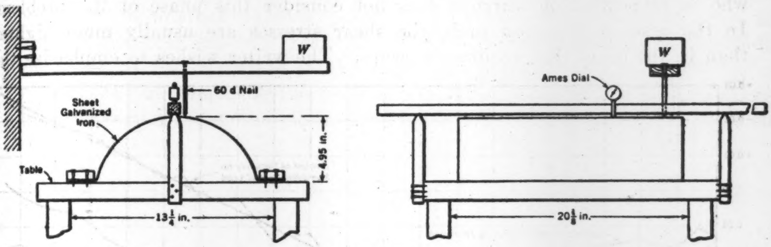

FIG. 33

Fig. 34 shows three curves for each load, first the deflection along the crown of the arch while the load is in position; second, the position after the load is removed (the permanent set); and, third, the difference between the two, which gives the distance that the crown rose after the load was removed. These curves show that there is considerable deviation from a straight line near the load. This simple experiment gives some emphasis to Mr. Gifford's work. A practical as well as a theoretical solution of this problem would be very valuable, but until it is made it is evident that designers should reinforce structures so as to avoid failures of the type indicated by Figs. 16 to 25.

Mr. Weiner takes issue with the writer because he does not use the ellipse of stress, and states that his Equations (7) are "merely a transformation of axes." This is evidently a misunderstanding because the writer has not transformed axes, as is done in the common method of deriving the ellipse of stress. The writer computes the components of a force and from them he finds that force, which is then broken up into other components that are more convenient to use in obtaining unit stress. The ellipse of stress that is found by considering these forces may have one axis equal to zero; that is, it may be a straight line. The properties of such an ellipse do not contribute to the understanding of the problem, as the writer sees it, and, therefore, he has not used it in his solution.

To make this point clear the stresses on a point near the edge of the ring will be considered. The line of force, or direction of force, must be parallel to the surface when it is a very short distance from this surface. This means that there is no shear across the plane perpendicular to the force and it is, therefore, one axis of the ellipse. The force perpendicular to it (if it is of any value) will be perpendicular to a surface. It is therefore zero, and the ellipse is a straight line. This is the point used by Mr. Weiner in the illustration in his discussion.

The writer feels that the problem of the ellipse of stress in the skew arch is somewhat the same as that in a reinforced concrete beam. It is interesting to study these ellipses at various points in a beam, but a designer who is proportioning stirrups does not consider this phase of the problem. In the case of the skew arch, the shear stresses are usually much lighter than in the beam that requires stirrups. The writer wishes to emphasize the fact that although T_x, T_z, and T_y are evaluated separately, they are only a part of the force, T. Combining components of a force to find the force is only one step in what Mr. Weiner refers to as the first part of the skew-arch problem.

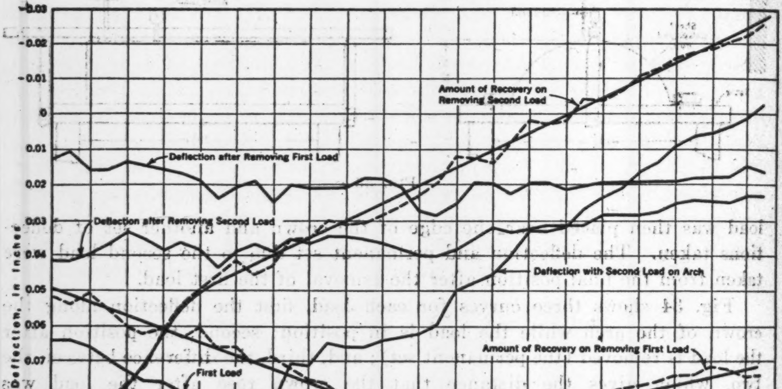

FIG. 34.—DEFLECTION ALONG THE CROWN OF A WROUGHT-IRON SEGMENTAL ARCH UNDER CONCENTRATED CROWN LOADS

Mr. Weiner takes issue with the writer on the method of computing unit stresses and shows by an example the difference between the results obtained by his method and that presented in this paper. He states that the writer is in error in claiming that the two methods are the same, which is admitted. As Mr. Weiner states, the one given by the writer has been used for several years and until carefully conducted laboratory tests or other demonstration proves the superiority of another method, he will consider it as close an approximation as has been found. The assumptions have been stated and are quite clear, the entire method is easy to understand and simple to apply. Mr. Weiner has presented a method which is based on assumptions of the same general character, slightly different from those given by the writer, but no more logical, and without proof. As his method has no better foundation than that of the writer and leads to a result with a shear on one plane and a thrust on another at each point, it is difficult to understand why the change has been made. Like Mr. Weiner, the writer does not consider the effect of the curvature of the arch ring.

One way of comparing the two methods is as follows: The writer assumes uniform thrust across the plane, *hi* (Fig. 35), in the direction parallel to the

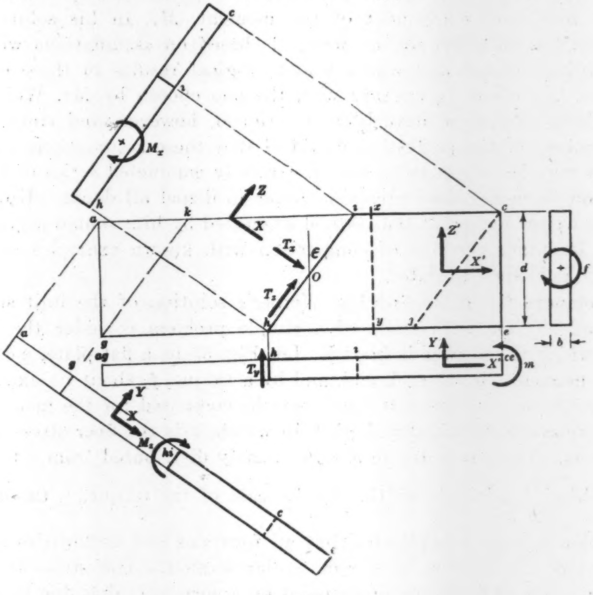

FIG. 35

X'-axis (in the direction of the major line of reinforcement), and a shear parabolically distributed at right angles to it or parallel to the *Z'*-axis. Mr. Weiner assumes uniform thrust across the plane, *hi*, in the direction of the *X*-axis. From this assumption he deduces the writer's assumption as to thrust. He also assumes a shear parabolically distributed in the direction of the *Z*-axis, on the *hi* plane. He then has at each point a thrust in the direction of the *X'*-axis across a plane parallel to the *Z'*-axis and a shear (along a different plane), parallel to the *Z*-axis. This shear has a component parallel to the line of thrust, the *X'* direction, which makes the thrust non-uniformly distributed although the thrust plus the component of the shear are so distributed. The writer considers the thrust and shear perpendicular to each other and thus avoids this phase of the problem.

Comparing the internal work of the shear and thrust the writer has uniform thrust against non-uniform thrust by Mr. Weiner, the former giving the less work. Both have parabolic shear at right angles to this thrust. Therefore, the writer's method assumes less internal work then that of Mr. Weiner. This is not a proof of the correctness of the assumptions, but does show they are more nearly correct than those submitted as a substitute.

In the problem chosen in the discussion by Mr. Weiner his method gives a result 25% in error and, therefore, the writer considers that the statement that "his method is sufficiently accurate for design purposes" is questionable. The writer feels that the assumptions made in his paper do not lead to such large errors. It is to be noted that Mr. Weiner did not take into account the very important component of the moment, M_x, in his solution. The stress distribution given by the writer is based on assumptions which have been definitely stated and which lead to logical results in those cases that the writer can check in another way, the one chosen by Mr. Weiner being one of them. As these have been questioned, however, and since, perhaps, some members of the profession may feel that these assumptions are unwarranted, it may be necessary to have a carefully conducted series of laboratory tests made on model skew arches in order to dispel all doubt. Until this is done, the writer feels that the method suggested by him should serve for arch design. It stands the test of comparison with known examples better than any other published to date.

To compare the results of Mr. Weiner's solution of the unit stresses on a diagonal surface with those of a simple problem consider the following case, in which the answer is known. Let Fig. 35 be a flat plate, *a c e g*, acted upon by moments, m, at each end, and by a torque, f, about its axis. At any right section (as xy) the unit stress may be computed for the moment, m, by the well-known formula, $m = \frac{1}{6} pbd^2$, in which, p is the fiber stress at the top and bottom. The stress due to m is uniformly distributed from x to y, and is expressed by $\frac{m}{b}$ per unit width. In the case of the torque, f, the unit stress distribution is more complicated, but all formulas and authorities agree that it is zero at the corners of a rectangular section. The stress then at the points, x, y, i, and h, or any other point on a corner, is that due to a moment of $\frac{m}{b}$ and is in a direction parallel to the corner line. This is true for all values of f. The force across a plane parallel to and near the vertical face, *ac*, is zero. The ellipse of stress has degenerated into a straight line. If this flat plate is cut by an imaginary plane, *hi*, making an angle, ϵ, with the right section, and if the portion to the right of the section is removed, it must be replaced by the moment and force produced by the removed portion. This moment may be broken up into three components, M_z, M_x, and M_y, while the force is broken up into T_z, T_x, and T_y. Taking the forces and moments about each axis equal to zero, six equations of equilibrium are evolved; $M_y = 0$; $T_x = T_y = T_z = 0$; while $M_x \cos \epsilon + M_z \sin \epsilon = f$; and, $M_z \cos \epsilon - M_x \sin \epsilon = m$.

If M_x and M_z are known, m and f may be found and the unit stresses computed. As m may be taken as uniformly distributed at the ends of the plate the stress at i must be $\frac{m}{b}$ and in the direction of ac no matter what the value of f. Taking the case chosen by Mr. Weiner in which $M_x = -361.9$; $M_z = 533.57$; $\tan \epsilon = 1.079$, and $d = 31$ ft. By computation, $m = 628.1$, and the unit stress at i and h is that produced by a moment of $\frac{628.1}{31}$, or 20.2 kip-ft. per lin. ft., and not 25.3, as reported by Mr. Weiner. The writer, therefore, does not wish to endorse Mr. Weiner's method.

Mr. Eremin and Mr. Hodges bring up the question of the reinforcement in the steel which is placed at an angle with the force. It is interesting to compare Mr. Eremin's equations with those given by Mr. Weiner[43] in Equation (60) of his paper "Design of a Reinforced Concrete Skew Arch," noting that his δ_z is zero when the ellipse of stress is only a straight line. The shear induced in the concrete by the steel placed at an angle tends further to reduce the load on the steel. In most cases the direction of the force follows the direction of the steel very closely, and the writer questions whether there is great error in the customary method of reinforcing for the parallel component of the force and then reinforcing for shear with bars acting somewhat as stirrups do in a beam. Of course, in extreme cases this point should be investigated.

Mr. Nord states that the direction of stresses in a skew arch are "apparently contrary to the fundamental law of Nature that work is done by forces along the shortest lines and in the most economical way." The latter part of the statement is most important, the former being assumed, at times incorrectly, from it. It is just this assumption that has made it difficult for engineers to believe the results of tests and the theory in the case of the skew arch. The equations used in this theory have been checked by the "method of least work" by the writer and by others, including Mr. Keyser. Such solutions as the one suggested by Professor Oskar Muy involve more internal work than that given by the writer. Although they under-estimate or neglect the force, T_z, and so make the force at the crown assume a direction nearer the obtuse corner, the resulting lateral bending of the arch produces more internal work than is gained by reducing the distance traveled by this force.

Mr. Houtman's discussion brings out quite clearly the fallacy of this line of thought. If an arch is divided into parts by a cutting plane all the forces across this plane should be considered. This includes thrust. Those who divide the arch by planes perpendicular to the abutment into two triangles and a rectangle (as viewed in plan) do not evaluate these forces and moments; nor do they even estimate this thrust. At least, the writer has known of no case in which the analysis has been carried through.

As Mr. Nord suggests, certain terms may be eliminated in the practical design of an arch. His Table 6 should be interesting and valuable as a reference to one who has an arch to analyze of the type studied by Mr. Nord. He can there see the relative value of the various terms.

---

[43] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1263.

Mr. Keyser calls attention to the fact that the stresses due to eccentric loads on a right arch can be worked out by the equations given by the writer. In this connection the local stresses caused by a concentrated load, as shown by Mr. Gifford's experiments, must be considered in the final design. Mr. Keyser's check of the writer's equations by an entirely independent method—the method of virtual work—has been very valuable and encouraging. His suggestions about foundation movement can well be enlarged upon. If the movement of a foundation is anticipated it may be assumed that it is proportional to the load, or that it is a definite amount. In the latter case the deflection at the crown section can be computed. Since the load terms are computed as deflections of this same section this added deflection can be used as a load term and the stresses can be found in the usual way. If the deflection of the abutment is assumed to be a function of the abutment load the pier may be assumed to be extended, the extension being of such dimensions that it will have the same elastic properties as those assumed for the soil. The wisdom of building an indeterminate structure on yielding foundations is questionable, unless due consideration is taken of the effect of the yielding; so Mr. Keyser's warning is a wise one.

Mr. Eremin suggests several simplifications which will doubtless shorten the work in the analysis of those designs when they do not create serious error. It has been the writer's policy to develop the equations without neglecting small terms, in order that these equations may be used in types of design where they may be of considerable influence. It is a comparatively easy task to drop small terms, but difficult to supply them if dropped in the original development and afterward found to be of importance. Mr. Eremin suggests that arithmetical errors may accumulate, but this can be avoided if one uses a mechanical computation machine. It involves little more labor to carry the work out to enough decimal points to keep the error well within the range of the accuracy required.

Mr. Hodges is correct in his statement that the theory of the two-hinged arch has been checked as to the algebra of the analytical solution. This check was made by Mr. Weiner and H. G. Babcock, M. Am. Soc. C. E., under the direction of A. G. Hayden, M. Am. Soc. C. E. Mr. Hayden has given this theory in the book referred to by Mr. Hodge, but not as a check on the theory. Mr. Weiner states quite clearly in the "Introduction" to his paper,[43] that he is simply presenting this theory as the writer developed it, but has "revised the form of the equations." No changes or additions affecting the theory were claimed (except for unsymmetrical skews), but the changes were made in order to simplify or clarify the work. As brought out in the discussion of that paper the writer does not think any of the changes an improvement and some were unwise because they were not consistent with accepted usage in mathematics, analytics, and the beam theory, and because they tend to confuse.

---

[43] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1213.

The writer questions the limitation of 45° placed by Mr. Hodges on the skew-arch theory. There may be some question as to the assumptions of the writer in calculating the unit stress, and Mr. Weiner has shown that other assumptions can be made that lead to different results. However, the general theory has been definitely corroborated. As Mr. Hodges states "the transverse reinforcement becomes a matter of academic interest only" and so this matter of the difference in the two methods of computing unit stress is not as great as might be supposed at first as far as transverse reinforcement is concerned.

In the case of unbalanced torque the writer has simply attempted to place steel in the form of stirrups that is an equivalent for the unbalanced concrete, as shown in the shaded triangle of Fig. 9. This steel must be an equivalent in moment as well as in thrust. As the force has a lever arm of 10.64 in. and the steel has only 8 in., the area must be changed accordingly. The direct thrust must also be checked if the change affects it, as it might where the lever arm of the steel is greater than that of the concrete.

FINANCING STREET AND HIGHWAY IMPROVEMENTS[1]

BY R. W. CRUM,[2] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. A. P. GREENSFELDER, C. R. THOMAS, J. C. CARPENTER, SAMUEL ECKELS, HORACE H. SEARS, AND R. W. CRUM.

SYNOPSIS

The Symposium on "Equitable Distribution for Highway Purposes of Motor Vehicle Licenses and Gasoline Taxes," conducted by the Highway Division of the Society during 1929, brought out the status of contemporary practice and opinion representative of the various governmental jurisdictions interested. The papers and discussions presented in this Symposium disclosed the fact that engineers in general concur in three basic principles.

In this paper the writer discusses from an engineering point of view, and without prejudice, some of the factors that appear to have a controlling effect in the equitable assessment of highway costs, and calls attention to some research projects that could aid materially in ascertaining the facts that are needed. These facts themselves will vary from place to place and from State to State, but the same methods of attack upon the problem should result in some uniformity in procedure.

IMPORTANT BASIC PRINCIPLES

In the separate papers presented by O. E. Carr, George B. Sowers, George H. Henderson, and Frederic E. Everett, Members, Am. Soc. C. E., and in the discussions elicited from all parts of the United States on this subject, there is evidence of concurrence in the following principles:

> 1.—Motor vehicle users should pay a fee to cover what is called, in public utility parlance, "readiness to serve." This may be considered to represent the motorist's contribution to the capital investment, and is generally collected through license fees.

---

[1] Presented at the meeting of the Highway Division, New York, N. Y., January 22, 1931.

[2] Director, Highway Research Board, National Research Council, Washington, D. C.

2.—Motor vehicle users should also pay some amount based upon their use of the roads. This amount may represent their share of the operating costs of the highways, and is universally collected at the present time through imposts on gasoline.

3.—No part of the funds raised by means of motor vehicle license fees or gasoline taxes should be diverted to any other use than the construction, maintenance, and control of highways.

These three principles, and especially the last, are of great importance. It will be noted that they do not touch upon the controversial question of the allocation of funds among the various classes of roads and streets, or governmental units. With respect to this question many well-considered opinions were presented by authors and discussers. In general, the engineers reasoned from their own experience with one or more phases of road or street work, although they recognized that the equities of the situation have not yet been defined.

Some emphasized the point that engineers should consider all the facts and should not favor any particular interest—the small town, the city, or the State highway department. This is obvious, and there is no doubt that if engineers could study the facts underlying the problem they could recommend an equitable procedure. The difficulty at present is that all the facts are not available for study.

Determining the Road Users' Share of Costs

The real problem is not how the funds being raised at the present time should be distributed, but rather what share of the annual expenditures on the various classes of roads and streets should be borne by motor vehicle users.

In order to determine correct amounts, sources, and distribution of funds for the construction, maintenance, and administration of any group of roads or streets, certain questions must be answered. Among such questions are:

1.—What are the roadway costs?
  (*a*) Cost of building; and,
  (*b*) Annual cost for administration, maintenance, and periodic replacement or renewal.
2.—What part of the costs should be borne by each of the various interests benefited?
  (*a*) Federal Government;
  (*b*) State government;
  (*c*) Local community;
  (*d*) Adjacent property; and,
  (*e*) The user.

Having the answers to these questions for all the various systems of roads and streets in a State, the grand total of what the users should pay, could be added up and assessed if it is within the "ability to pay." If the entire sum could not be assessed, consideration would have to be given to the allocation of the funds raised so that they would yield the greatest good to the greatest number.

The answers will vary widely, depending upon such factors as class, type, location of roads, and traffic. The classification of roads adopted by the American Association of State Highway Officials is adapted to discussion of these questions. This classification is: (1) Primary roads, comprising the Federal and State systems; (2) secondary roads, the principal county trunk highways, or State-aid highways; and (3) third-class roads, the purely local township roads. To these should be added city and town streets.

PRIMARY ROADS

Primary roads are the highways that provide for interstate, inter-city, and inter-county transportation which, it is generally agreed, should be built and maintained by the State with such aid as is contributed by the Federal Government. This system, as thus far defined, stops at city limits. However, the discussions in the Symposium indicate that a considerable number believe that the extensions of these roads into and through the cities should be considered a part of the State primary system. In so far as engineers are concerned, there can be no doubt that, in planning for the movement of traffic over primary roads, the city links cannot be neglected, therefore, these streets will be considered in connection with the primary roads.

In any business undertaking, public or private, there must first be an outlay of capital. Then, if the enterprise is to be on a sound basis, it must earn enough to pay interest on the capital, to pay the operating and fixed charges, and to provide for anticipated renewals and replacements. In the case of a public project, such as a system of highways, the soundness of the enterprise can be assured if the governmental unit concerned levies enough taxes upon the benefited parties to provide the necessary sum each year to cover the financing of the capital outlay and the annual cost.

The rate at which a system can be built will depend upon what the benefited interests can afford, and upon whether the payments for construction are to be made directly from the tax money or from borrowed money. The reasons why the issuance of bonds for road improvements under certain conditions is sound public policy have been ably presented[3] by T. R. Agg, M. Am. Soc. C. E. and John E. Brindley, Professor of Economics, Iowa State College, Ames, Iowa. The writer is principally interested in the determination of the total annual cost so that the necessary taxes can be levied.

NEED FOR CO-OPERATION

The building and operating of a highway system is a huge co-operative enterprise of the people of a State, for which they must first furnish the capital, and then must pay individually for the use of the facilities. Their profit comes in lowered vehicle operating costs and in other more or less intangible benefits.

At any given date, the money and time necessary to bring the entire system to the desired standard can be estimated. If the pay-as-you-go plan is followed, the tax levy for construction will naturally be whatever the benefited interests can afford each year; and if bonds are to be issued, the construction fund should be sufficient to pay them as they mature, as well as the accrued interest. By issuing serial bonds, these annual imposts can be made uniform over any number of years.

---

[3] Highway Administration and Finance," by T. R. Agg and John E. Brindley, McGraw Hill Book Co., First Edition, 1927, p. 160.

The determination of the amounts needed per year for operating expenses and for periodic renewals is more laborious, but there is no reason why they cannot be calculated on a sound basis for any highway system. This involves computation of the annual highway cost for those parts of the system that are already completed, and estimates of the probable annual cost of the remainder during and after the construction period.

Annual Roadway Costs

The Committee on Transportation of the Highway Research Board, National Research Council, has proposed a method for computing the annual roadway costs as of the date when the data are assembled, for any specific section of highway.[4]

The annual cost of a section of highway consists of the interest on the cost of construction, or value at the time of the analysis, plus the annual maintenance cost, including administration and engineering, plus the sum that must be set aside each year at compound interest to provide money for periodic renewal or replacement. This is expressed in a formula, as follows:

$$C = r\left(A + \frac{B}{r} + \frac{E}{(1+r)^{n}-1} + \frac{E'}{(1+r)^{n'}-1} + \ldots\right) \ldots\ldots (1)$$

in which, C is average annual cost; A, the cost to construct; B, the yearly maintenance cost; E, the expenditure for periodic maintenance every n years; E' the expenditure for reconstruction every n' years; and r, the rate of interest prevailing in current financing.

An estimate of the total annual cost of a highway system would have to be built up piecemeal since the factors would vary on different roads. On those sections of the system included in the construction program, the annual cost would be calculated for the date on which the analysis was made, and then could be estimated for each year in advance, until the end of the construction period. The result of such calculations would be a tabulation showing the amounts that the system would actually cost the people of the State for capital investment and for annual cost.

If this annual cost should be collected through some form of taxes, the revenue would be in excess of the expenditures, at least to the extent of the interest factor. This excess would no doubt be needed for those changes and betterments in the system, that would appear from time to time.

Knowledge of Costs Helpful

Although it might not be feasible, for administrative or legislative reasons, to assess the interest and carry a sinking fund as provided in these calculations of costs, a knowledge of the actual annual cost of providing the roads would be helpful in planning both revenue measures and expenditures. These costs, after deductions for Federal aid, would be the amount that might be fairly assessed against the vehicle operators, if a State highway system were to be built and operated on money raised by license fees on motor vehicles and taxes on gasoline.

---

[4] Ninth Annual Proceedings, Highway Research Board, National Research Council, p. 360, and Tenth Annual Proceedings, Highway Research Board, p. 329.

Anticipating the acquisition of fundamental data for use in this motor-vehicle tax-distribution problem, it would be a worth-while research project to have the annual highway costs computed for all or for part of a State highway system. This would be a laborious job, it is true, but how else can such basic data be secured?

SOURCES OF FUNDS

The parties that would be benefited by the completion of a State highway system are: (1) The United States; (2) the State; (3) the local communities; (4) real estate; and (5) the road users.

The Federal Government recognizes the value to the Nation of roads that are needed for interstate transportation and National defense. Hence, Federal aid on the construction of these highways is well established and will probably continue for some time.

Since it is generally realized that the State is the principal beneficiary of the primary system of rural highways, it is a well-established principle that these roads should be built and maintained by the State organization, on money raised by the State. As the entire population is affected to some degree by the use of the main highways, it seems equitable to spread the cost over the population by means of taxes borne by motor vehicles, consisting in part of a service charge and in part of a payment proportionate to the amount of use. As far as can be determined, this arrangement appears to be acceptable to the users.

It is probable that the benefits to the local community and private property are relatively greater on extensions of primary roads into and through towns and cities than in the rural districts. Little information has been assembled to show the true relationship existing between community interests, private property, and road users. As a matter of fact, this relationship undoubtedly varies from place to place and from State to State, but a thorough study of even one case would be of immense value in pointing the way to a profitable solution in other places, and in establishing some principles of general application.

Factors needing study are: (*a*) The volume of through traffic, local traffic, and public carrier traffic; (*b*) the effect of through and local traffic upon the design of pavements; (*c*) the use of streets for parking, this being an extensive street use that cannot be measured by a tax upon fuel; (*d*) the relation of the highway to local business; and (*e*) the effect of street improvement upon property values. Many data and painstaking analyses are required. If the interests of the various parties could be evaluated, it should not be difficult to secure a fair share of the cost from each.

SECONDARY ROADS

Secondary roads are the principal county trunk highways, mainly important to the immediate agricultural regions and market centers which they serve. An analysis of annual highway costs would also be valuable on roads of this class. Some of the States, recognizing that these roads are necessary to general prosperity, grant aid on important secondary projects; others take them over into the primary system when funds for extensions become available. As State money is ordinarily derived from user taxes, these methods can be adapted to take care of that portion of the total cost of secondary roads that should be borne by the road user.

As the communities served are the chief beneficiaries of the secondary roads, it is usual to finance them by general property taxes. Benefits to adjacent property by secondary road improvements depend upon such factors as the extent to which the entire region is served, the character of the traffic, and the character of the improvements. Although improvement is undoubtedly a benefit to farm land, it may not be of value beyond a certain degree of all-year usableness. When the residents along a particular stretch of road desire to expedite the improvement of it, financing by means of an assessment district may be advantageous. As many secondary roads have considerable transient traffic that is of no value to the local district, the only way to get a contribution from this traffic is through State taxes affecting the user.

Studies of land values, land income, and the amount, character, origin, and destination of traffic are needed to arrive at the proportion of secondary road costs that should be borne by the various interested parties.

An investigation of secondary road conditions has been conducted by the United States Bureau of Public Roads, the North Carolina State Highway Commission, and the Tax Commission of North Carolina. Their report[8] is entitled "North Carolina County Road and Finance Survey." According to the finding of the Committee on Highway Finance of the Highway Research Board:

> "The report of North Carolina goes far to point out the reasons why no faster progress is being made in the improvement of secondary roads, and the principles that must be made effective if, within any possible expenditure, adequate secondary roads are to be secured."

THIRD-CLASS ROADS

Improvement of third-class roads, which exist primarily to give access to the farms of the country, constitutes one of the most pressing and difficult of highway problems. The principal beneficiary of these roads must be the farmer, because an outlet is essential to his success. However, the interest of the community in them can scarcely be less than his, because successful farms are necessary to its prosperity, and the general property tax touching both is probably fair.

In particular cases the improvement of certain roads by means of special assessment districts may be profitable to the land owners. Traffic is light and the relative share of the users, as such, in the costs is slight.

---

[8] *Public Roads*, Vol. II, No. 12, February, 1931, p. 237.

CITY STREETS

In the cities, besides the extensions of rural through routes, there are residential streets, business streets, and intra-city through routes. The residents are the greatest beneficiaries of improvements on strictly residential streets, and the practice of assessing the major part of the cost against the real estate benefited has become established as equitable.

The city at large and the users, especially public carriers, have considerable interest in business streets, which are also vitally necessary to the business houses using the adjacent property, so that their share of the cost is probably relatively large. The street railways pay for their share of the pavement and upkeep, while buses, taxicabs, and public carrier trucks have an interest that can be assessed by the city in various ways. It is true that many of these vehicles do not operate outside the city limits although they contribute, through license fees and gasoline taxes, to the primary road system. It can be claimed in justification that the prosperity of the city is enhanced by the existence of a good system of tributary roads.

On business streets, the problem of who should pay for that portion used for parking space is perplexing. It is probable that the subject is of greatest interest to the vehicle users, although the city at large, or the adjacent property, may have to bear the burden. The value of street parking to business houses needs to be evaluated, and there is much evidence relative to this problem in the traffic data that have been collected in many of the larger cities.

The intra-city through highways may be a detriment to the abutting property although benefiting a zone of some width. The city at large and the public carriers have considerable interest in these streets, and it may be that the interests of the private users and the city coincide. Study of the available data, to evaluate these factors in terms of benefits to the various parties concerned, is needed as well as a study of property values and the earning capacity of real estate in the zone benefited by these streets.

NEEDED RESEARCH

This Symposium has brought out the need for factual studies before sound conclusions can be reached as to the relative parts of the cost of each road or street system that should be paid by the State, the community, the adjacent property, and the users. Although it does not appear probable that the relationships can be reduced to formulas, an engineer finds such studies essential to the exercise of judgment.

Four needed research projects may be mentioned:

1.—Calculation of the annual cost of all or part of a State highway system. It is expected that the Committee on Transportation of the Highway Research Board will continue its work in this field.

2.—A study of the amount, character, origin, destination, and purpose of traffic on city streets that are extensions of the State primary road system.

3.—A study of real estate values and earning capacity in the vicinity of through streets in cities as affected by street improvements.

4.—A study of the effect of road improvements upon rural property values and earning power.

CONCLUSIONS

As a result of this study, the following conclusions have been drawn:

1.—Motor vehicles should pay a "readiness-to-serve" charge.

2.—Motor vehicle users should pay for roads in proportion to the extent of their use.

3.—Funds raised through special taxes on motor vehicles or motor-vehicle users should be used only for highway improvement.

4.—It is not possible, from the information at hand, to determine what proportion of road costs should be paid from user taxes. General practice concedes that the major part of the primary road costs shall be paid from motor-vehicle license fees and taxes on gasoline.

5.—The State should be the sole agency levying special taxes upon the motor vehicle or highway user.

DISCUSSION

A. P. Greensfelder,[8] M. Am. Soc. C. E. (by letter).—An analysis of the broad principles involved in financing highway improvements has been ably presented in this paper.

There would seem to be no worthy reason for diverting for other than highway use the funds levied on motor vehicles and fuel. In spite of the equity in the case, a number of States are using gasoline tax money for a variety of other purposes. To date, however, motorists have been found willing to support these taxes because of their desire to secure ample highway facilities. If American legislators break faith and use such gasoline funds derived from motor vehicles for other than motor highways, there is likely to be "back fire" which they will not enjoy. America has needed, and still needs, thousands of miles of major highways. The user of these highways should be given every consideration because he is paying the major part of the bill.

In determining the road user's share of costs, it would seem essential to consider the separation of highway bond funds into road-bed bonds and paving bonds. The road-bed bonds should include costs of right of way, drainage, and grading. These costs might be allocated to the various political subdivisions of the Government, and might be issued for a term of thirty to fifty years. Serial bonds should be issued only for the estimated life of the particular pavement and then might be allocated logically to the users, including amortization, interest, and maintenance of the highway.

Just as it is logical to tax motor vehicles for highways, so it would seem only equitable that fuel tax from inland vessels be allocated to the cost of providing navigable inland waterways, and the fuel tax from aircraft should be allocated to airport and airway lighting.

Relative to primary roads, it would seem that the community benefits derivable from private trucking and buses should be weighed against the very probable damage and heavier pavement costs which these vehicles will presently cause. Railways are required to have private rights of way and yet State and interstate truck and bus traffic is permitted to block the highways without regard to other vehicles. Perhaps long hauls by rail upon private rights of way and local distribution from pivotal centers by trucks on public highways will be found to be the economic answer. The writer agrees with Mr. Crum that there is need for co-operation between all transportation groups. There is danger, however, that highways may be damaged by fast heavy truckage of low-class freight more than the gain in freight charges or the value of time saved in delivery.

There is little doubt but that automobile transportation of individuals is extremely expensive per capita per mile. That the saturation point per capita has been temporarily reached is evidenced from the 1931 automobile sales. Whether individual passenger automobiles per mile per capita will increase or decrease is debatable.

---

[8] Pres., Fruin-Colnon Contr. Co., St. Louis, Mo.

In considering sources of funds, it is interesting to recall that in 1880 when local highways were desired, the benefited parties were frequently required to pay direct toll. While toll highways have been practically eliminated, toll bridges are still being constructed for the same obvious reason, namely, that the toll charge is more than justified in the time and mileage saved. Tolls are merely direct taxes paid by the benefited users, whereas the gasoline fund is an indirect tax.

Federal aid may have been more justifiable in former times than at present. It is easier to educate from the top down than from the bottom up. Federal aid served as a bonus to stimulate State and county highway construction. Just how long and how much the National Government should continue to contribute would seemingly be a function of interstate vehicular traffic.

It seems only equitable that both primary and secondary roads should be paved through a city or village as a continuous highway. That this was not done originally was due to the fact that county legislators overwhelmingly predominated the representatives of the urban centers in any plan. In justice to the city taxpayers who collectively contribute a very large sum for highway construction, the through highway should be continuous. It seems equally vital that the expenditure of funds for through highways in cities should be under the control of the State Highway Department, the same as it is throughout the counties. If the State Highway Department can design, contract, maintain, and pay for the highways in the counties of the State, it would seem perfectly reasonable that they should do the same thing through the cities of such counties, since both are political subdivisions of the same State.

There is another type of highway which Mr. Crum does not mention, namely, those that go to and through various State Parks. American citizens to-day demand outdoor recreational facilities and are increasing the number of National, State, and County Parks, which, in turn, increasingly require highways to reach them. In a bond issue of $75 000 000, in Missouri, several million dollars were thus allocated in 1928.

In connection with third-class roads the author questions just how much the land owner should contribute. It seems fundamental that the least the farmer can furnish is a fair amount of right of way for the highway which will undoubtedly benefit his farm. Perhaps a tax for advertising signs per square foot per 1 000 passers-by per annum would furnish a considerable sum for highway improvements, since without the highway the signs are worthless. Signs are distasteful to most motorists and to tax them thus would minimize their area.

In discussing city streets, the author very appropriately presents the problem of parking space. It would be interesting if the cities would consider providing parking space on unpaved city blocks rather than on the paved street itself. Perhaps it would decrease traffic congestion and, at the same time, be considerably less expensive per car parked. In the down-town section the city might make inducements to private capital for the construction of multi-story garages.

The writer concurs with the author that continuous research along these lines is imperative. The traffic surveys made in the City of Cleveland, Ohio, and in the State of Connecticut during the years 1928, 1929, and 1930, are splendid examples of what can be done. City, county, and regional planning must be based on adequate information.

C. R. THOMAS,[7] M. AM. SOC. C. E. (by letter).—The largest single factor in the stabilization of highway programs is the relative continuity of the income from motor vehicle taxes used for highway purposes. The marked diversion of such funds to purposes other than roads and streets would be a great blow to stabilization of income that permits budgeting of funds several years in advance, and to the amount of road building now (1931) in progress. As Mr. Crum states, the problem of allocation of the motor vehicle taxes among various classes of roads and streets or governmental units, which is controversial, is overshadowed by the greater problem of stopping diversion to purposes other than highways.

The principal reasons advanced for the diversion of the motor vehicle taxes to other purposes than roads are: (1) Other State activities need money more than roads; (2) the road system is well advanced toward completion, and the funds raised by motor vehicle taxes should go to other purposes; (3) motor vehicle taxes belong to the general funds of the State and can be used as the State Legislatures desire. These reasons are advanced with the object of influencing Legislatures so that appropriations may be obtained for many purposes foreign to roads and streets. Back of these reasons may be the desire of property owners to use motor vehicle taxes as a substitute for levies on real estate.

The original purpose of motor vehicle taxes, which include both gasoline and license taxes, was to provide roads for motor vehicles. Taxes are assessed for schools and other special purposes and diversion of such taxes is not generally considered. The justice of the motor vehicle taxes (which are really "use" charges in lieu of tolls), like telephone charges, has been proved by the apparent popularity of the tax and the lack of opposition to repeated increases. However, some opposition to the motor vehicle taxes has developed since diversions have taken place in seventeen States, so that the motor vehicle drivers no longer receive full benefits. The growth of the idea for diversion has followed the increase in returns which amounted to $850 388 000 in 1930, and the demands of other State interests for a part of this large sum of money. Diversion to purposes other than roads amounted in 1930 to 3% of the gasoline tax income. Practically all the diversion is from the gasoline tax.

The reason advanced that other State activities need the money more than roads opens up the whole field of discussion of the value of highways, both tangible and intangible, as compared with the public value of other State activities. The subject is too broad for discussion here. It is sufficient to state that the savings in transportation costs alone to the public more than pays the cost and sinking fund for replacement of heavy traffic highways.

---

[7] Alexandria, Va.

No other State activity appears to be on such a sound financial basis. The danger of changing from an investment that is returning such tangible dividends is at once apparent.

While more roads are being paved in 1931 than a few years previously, the highway system is by no means approaching completion for several reasons. There are 3 000 000 000 miles of public roads and only 700 000 miles have been surfaced. New developments in vehicles, such as the change in the few years preceding 1931 from low to high road speeds, bring new burdens on the roads that call for complete revision of highway-design practice. The rapid increase in the number of motor vehicles has led to congestion on the highways with resulting costly delays and accidents. Highway facilities are far behind the motor vehicle facilities both as to rate of production and mileage of improved roads. It has been stated that in Cook County, Illinois, if all the vehicles in the county were on the improved roads at one time, they would be two deep.

The idea that motor vehicle taxes belong to the general fund of a State is perhaps sound in some States, due to constitutional provisions, but the use of such funds for purposes other than roads and streets is undoubtedly a violation of the intent of the motor vehicle taxes as originally imposed, and is contrary to the public understanding of the purpose of the taxes. It is certain that opposition to motor vehicle taxes will develop in almost direct ratio to the amount of the diversion to illegitimate purposes.

J. C. CARPENTER,[8] M. AM. SOC. C. E. (by letter).—The problem involved in this paper is the determination of the most equitable method of obtaining highway funds in such a manner that the burden may be adjusted according to ability to pay and the funds distributed according to the needs of traffic. This determination has been made customarily by legislative bodies with very little advice from engineers. Several years ago a legislator made a public statement that it is the function of the Legislature to decide on the amount of funds necessary as well as to determine the method of collection, and all that will be expected of the engineer is proper expenditure.

It is becoming more and more evident that the engineering and financing are so intimately connected that they cannot be considered separately, and engineers are being called upon for advice as to methods of financing. When times are good the average citizen is too busy to inform himself on routine governmental action. He grumbles about payment of an excessive tax, but does not bother to look into the use that is made of his funds. When times are not so good, however, the taxpayer takes an active interest in knowing just what use is made of his hard-earned dollars and also inquires as to the functions performed by those entrusted with his money. Equitable collection of funds and proper distribution of the finances so as to furnish satisfactory service for those who provide these funds are necessary if the public is to remain satisfied with results.

The classification of highways into the three groups outlined by Mr. Crum is commonly accepted. The primary roads, as defined, cover the State highway systems as now laid out. The Federal Aid Act provides for a system not to exceed 7% of the public highway mileage of the State, at the time of the passage of the Act, and divides the highways thus designated into primary (not to exceed three-sevenths of the system) and secondary. Since this law was passed the American Association of State Highway Officials has mapped out a system of numbered highways extending across the country in all directions. The established primary highways in all cases, do not follow the numbered highways, and there are a few isolated instances in which the numbered highway may not be a part of the Federal Aid System. The Association, in establishing this system of marked highways, performed a service of inestimable value to the traveling public. In the writer's opinion, the highways on this system should be considered the primary highways of the country.

---

[8] Fort Worth, Tex.

Secondary highways should include those of enough importance, outside of the primary system, to be included in the State highway system. Any highway within the description given by Mr. Crum for secondary highways should be a part of the State highway system.

Tertiary highways, or third-class roads, should include all other necessary public highways, except city and village streets. If a highway is open to public travel and serves one or more individuals, it should be included in the classification.

Changing conditions make reclassification necessary as is obvious from the many changes in the Federal Aid System since the first system was adopted after the passage of the Federal Road Act in 1916. A highway that is in the secondary class to-day may be a primary highway five years from now, or *vice versa,* by change of traffic trend, a primary highway may become a secondary or even a tertiary highway to-morrow. Nevertheless, with careful planning and far-sighted determination of the location of routes, the systems will finally become established and the changes which could not be foreseen in the early days of highway planning will become much less extensive and of minor importance. This condition is eminently desirable from the standpoint of economical expenditure of highway funds.

The problem of determining just what portion of the cost should be paid by each individual on a complete highway system for the entire country is by no means simple. Consider the case of the farmer who lives at the end of the third-class road. When he leaves his garage he travels to the farm gate over a right of way which is reserved for his special use to the exclusion of all others. Obviously, he should pay the entire cost of any improvement on this location; but when he passes his gate and enters the third-class highway he may mix with trucks hauling farm products to the community center, tax assessors from the county seat, State officials on business for the Commonwealth, and the United States mail carrier on his regular round of duty. He may legitimately expect this traffic to help him finance the improvement and maintenance of the roadway in proportion to the service it receives. After he emerges into the secondary system he finds a well-paved road which may be provided by the State, and this service may be of more value to him than the service his tertiary road affords to the occasional State officials who may use it. If he visits his cousin in the next State he uses the primary highway system. With Federal Aid on this highway this farmer is receiving some return for the use of his tertiary road by the United States in carrying the mail. This simple example illustrates the complications that surround a solution of the problem of financing and service.

During 1930 almost $2 000 000 000 were provided for State highways and local roads. A study of available statistics for 1931 indicates that there is much variation in the amounts collected and the methods of distribution in the different States. There are almost as many different schedules of license fees as there are States. Gasoline tax rates run from 2 cents to 6 cents, with an average of 3.35 cents for the entire country. One of the States with the lowest rate of 2 cents has the largest total mileage of a high type of surfaced highway. The income for State highways was $1 136 673 437 and for local roads, $818 379 508.

The following figures are for the entire United States. There are many variations for the individual States, but these divisions are representative of the entire situation as far as collections and distribution are concerned. For State highways the total funds were derived in the following manner:

	Percentage
State tax levied	1
Appropriation by States	2.9
Motor vehicle fees, etc	25.5
Gasoline tax receipts, etc	36.2
Miscellaneous income	1.5
State bonds and notes	19.5
Federal Aid post roads fund, allotment used	8.1
Funds transferred from local authorities	5.3

State highway disbursements total $1 139 676 601, and disbursements by local authorities, $851 686 625. State highway disbursements were distributed as follows:

	Percentage
For construction and right of way	62.5
For maintenance	16.9
For miscellaneous expenses	0.2
For equipment and machinery	2.0
For interest payments on bonds and notes outstanding	4.4
For principal payment on bonds and notes	6.1
For transfer to county or town for local roads	5.9
For other obligations assumed	2.0

These figures show that construction and right of way absorbed the equivalent of all receipts from Federal Aid, State bonds and notes, motor-vehicle fees, and 9.4% of other receipts. After deducting this 9.4% from the gasoline tax receipts there remains 26.8%, which is almost enough to pay the total cost of maintenance and the principal and interest payments on bonds and notes.

With the increase in constructed mileage of the State systems there will be, of course, a reduction in the percentage spent for construction and an increase in the percentage paid for maintenance.

The grand total of collections from gasoline taxes for 1930 was $494 683 410. This was distributed, as follows:

	Percentage
Collection cost	0.2
Construction and maintenance of State highways	68.5
Construction and maintenance of local roads	19.5
State and county road bond payment	6.3
For miscellaneous purposes	5.5

The total for miscellaneous purposes is $27 378 986. It is encouraging to note that $13 509 516 is transferred to cities for expenditure on streets, aviation, free bridges, highway administration, and refund reserve. These amounts are expended for purposes indirectly related to rural highway traffic. Some States recognize, in this way, that city streets carrying highway traffic are entitled to a portion of the revenues from gasoline taxes. For school purposes Texas, Florida, and Georgia divert $13 423 880, or 2.7%, of the entire fund collected; and an additional 0.1% is used for purposes that have no connection with highways. While it is generally admitted that the diversion for schools of $7 381 774 from the Texas gasoline tax receipts is not equitable, there is some consolation in the fact that the State Highway Department receives in transfers from local authorities $10 037 600. The $355 704 860 received for license fees, registrations, etc., is distributed as follows:

	Percentage
For collection and administration	5.4
For State highways	62.4
For local roads	19.3
For State and county bonds	10.2
For other purposes	2.7

The larger part of the 2.7% for other purposes is expended for motor patrols. This tabulation indicates practically the same major distribution as for gasoline taxes.

There is need for a thorough study of all legislation providing funds for highway work, such as is now being undertaken by a committee of the American Road Builders Association. This will be valuable in promoting uniform laws throughout the country. The results of such a study when presented to a legislative body would be convincing and no doubt would be welcome to those who formulate the laws. The Tax Commission of Wisconsin has been authorized under an Act of the Legislature of 1911, to collect information on tax assessment, receipts, and expenditures, and the reports have been found exceedingly valuable by legislatures and economists.

The 1930 joint survey of the North Carolina State authorities and the United States Bureau of Public Roads is a valuable contribution toward the solution of problems of financing. This indicates that all *ad valorem* taxation is not a just method of collecting funds for highway purposes. It also makes clear that the county unit is unsatisfactory as an administrative division. Among the 3 000 or more counties of the United States, there are numerous instances of competent engineering and administrative organization, but almost one-quarter of all the counties have no definite, organized, engineering control over their highway work. The centralization of highway authority for several counties would undoubtedly result in more efficient and economic expenditure of funds.

Before the annual cost of all or parts of any State highway system can be calculated there must be careful study of the adequacy of the system as at present adopted. The systems now in use (1932) were laid out about 1922 and were generally well suited for the needs of the various States; but in ten years there has been a marked change in traffic conditions, industrial and agricultural communities, etc. In addition, it was necessary, in the early days of highway construction, to locate the highways so as to meet the needs of individual communities of small size. With the "nation on wheels" the public is now interested in, and demands, direct routings, good alignment and grades, smooth surfaces, and freedom from congestion. The highway engineer can now, with public support, use correct engineering principles in location.

A revised system should be laid out in such a manner as better to serve local and through traffic for the entire country. It is important that such a system be developed at an early date. Based on present and probable traffic trends, on the development of the industrial and agricultural sections of the country, the growth of cities, and the controlling topographic features, a careful study should be made in each State and a major system laid out and filed for use on new work. It will be necessary to consider, carefully, entirely new locations, extending across the State, in some instances. The location through and adjacent to cities, the distance between the highways and other utilities, such as railways, etc., should be carefully determined in considerable detail.

While it would be impossible to change at once from the present system to an entirely new one, the data should be collected and the system developed and placed on file with the expectation of utilizing the ideal locations for construction of parts of the system as funds become available. Under the present policy, large outlays of money are required to reconstruct old projects on narrow rights of way with undesirable alignment, and traffic congestion is increased, rather than diminished. With these same funds a new highway can often be built on good alignment, with adequate width of right of way for future development, and with much better planned surfacing, leaving the old road to serve local traffic, with a much smaller maintenance cost for the two routes.

The new location serves and develops an additional local community, and also provides ample room, at low ground rental, for commercial activities necessary for highway traffic (such as garages and hotels) without interfering with established stores and other services essential to the community, on the old road.

Most of the State highway departments now have a large volume of information on costs of all the elements of highway construction and maintenance. After having laid out the system, it should be possible for a department to work out the cost of construction and with it the annual cost of systems to the States.

There are in excess of 2 400 000 miles of local roads in the United States. Not more than 300 000 miles have been graded, drained, and surfaced. With the increased demand for "farm to market roads" and consequent increase in the amount of funds being expended for local roads, many more of them will be improved and surfaced. Logical co-ordinated planning is essential for economical and efficient expenditure of these funds. In addition to combining and re-routing local highways so as to furnish the best service for the fewest miles, the well planned system will be comprehensive and will be based on proper consideration of such factors as correct utilization of farm lands (such as prospective abandonment of some farm lands which are being worked without profit and probable change in population density after a soil survey to establish correct utilization of the land), re-adjustment of so-called marginal or sub-marginal lands, etc.

The information and plans established by regional planning boards and commissions should be correlated with the plans for the system of primary, secondary, and tertiary highways. The establishment of regional planning areas in rapidly growing communities is desirable. Any form of governmental organization which tends to ascertain regional requirements officially is better than no organization at all. Such an organization will create an informed body of public opinion on the subject. The success of regional planning depends on the extent to which those who furnish the funds are convinced of its practical utility. Enabling acts are desirable in those States where regional planning has not been sanctioned by law.

Traffic studies are essential in the planning of any system of highways. Many States have traffic records extending over a period of years and find them valuable in prophesying future construction. A study of city streets traversed by rural traffic, compared to that on other streets of the city, should furnish a basis of determining the portion of the cost of improvement to be paid by rural traffic.

A study of real estate values as affected by road improvement would prove valuable, but there are so many other elements which change values that it is difficult to apply any factor of assessment derived by this means. The existing governmental agencies organized for the purpose of assessing property should be utilized to furnish these data and any adjustments in values should be determined by the regularly constituted assessors. There is no doubt that improved highways change property values and those benefited should pay a part of the original cost, but as previously stated, the North Carolina survey indicates that the *ad valorem* tax is not an equitable method of financing all improvement costs.

The necessity for careful and extensive planning of locations for highways is much more obvious than ever before. In issuing bonds for highways it has been considered sound to assume that the location, grading, and drainage structures are permanent features, but numerous instances are found in which modern traffic demands locations which mean the abandonment of considerable sections of these old roads. The planning cannot stop at county lines, but must be extended to develop locations which will not be subject to change.

The magnitude of the problem is difficult to grasp, because there are many elements to be considered in proper planning, and failure to include all essentials will mean that the entire scheme will be temporary rather than permanent. This is a certainty: Planning must precede any scheme of financing and only such financing programs as are based on a carefully worked out plan will be successful and result in satisfaction for the individuals paying for the work.

SAMUEL ECKELS,[9] M. AM. SOC. C. E. (by letter).—This presentation of contemporary practice and opinion, representative of various governmental jurisdictions connected with the financing of street and highway improvements, is interesting and is particularly meritorious in pointing out quite clearly the need for factual studies before sound conclusions of great importance can be reached.

Until recently financing methods have been predicated upon the theory of localized use. Improvement of streets and highways has been considered to benefit adjacent properties, and, generally, within limits of ability to pay, such improvement has been considered largely chargeable to adjacent properties. At present (1932), there are some modifications of method recognizing changed traffic conditions, but traffic interest and acceptance of public responsibility for costs are naturally to be measured by the extent of public use, other than local, and, in this regard (particularly with respect to improvements other than on State highways), there is deficiency of reliable information.

The most conservative theories of financing public improvements may be stated as: (1) Financing responsibility coincident with property rights and authority; (2) public contribution from public general funds; and (3) public general funds from general tax.

(1) Financing Responsibility Coincident with Property Rights and Authority.—With careful location, extensive grading, construction of artificial surfaces, erection of structures, and intensive public use, private ownership of public right of way becomes a legal myth. Facility of motor-vehicle movement nullifies boundaries. In many cases, with respect to rural roads and busy streets, there is overburdening of local responsibility, and adjustment by public contribution is under way.

(2) Public Contribution from Public General Funds.—Historically, public improvements have lagged behind demand; transportation facilities have been incommensurate with traffic requirements; and demands for public contribution, especially with reference to State highways, have been so great that an extraordinary increase of State revenues has been required.

(3) Public General Funds from General Tax.—The urgent demand for public contribution, together with opposition to an increase of a general tax levy, and the recognition of special benefits to the operation of motor vehicles, has led, throughout the country, to special levies on motor fuel and motor

---

vehicles that are remarkable for lack of uniformity. Table 1 was arranged from data given in a *Bulletin* of the Motor Vehicle Conference Committee, issued in January, 1931.

TABLE 1.—SUMMARY OF MOTOR-VEHICLE TAX RATES

Item	MOTOR-FUEL TAX		MOTOR-VEHICLE LEVIES ON PRIVATE PASSENGER CARS	
	Rate, in dollars per gallon	Number of States	Basis of tax	Number of States
(1)	(2)	(3)	(4)	(5)
1	0.020	7*	Flat rate	2*
2	0.030	10	Value	3
3	0.035	1	Weight	20
4	0.040	17	Horse-power †	14
5	0.060	3	Flat rate and weight	2
6	.....	....	Value and weight	1
7	.....	....	Weight and horse-power.	5
8	.....	....	Value, weight, and horse-power	1

* Also, the District of Columbia.

† Including also cubic-inch displacement in one State.

Thirty-four States and the District of Columbia tax motor vehicles as personal property, in addition to charging annual fees, computed variously as indicated in Table 1, Columns (4) and (5).

Important Basic Principles.—Variations in the rate of gas taxes and registration fees are unfortunate, of course, particularly with reference to adjoining States, but the extent of the need of revenue and the degree of ability or willingness to pay are not uniform throughout the States. It would seem, however, that there might be some elimination of differences in the bases of computing license fees.

From the Symposium on "Equitable Distribution for Highway Purposes of Motor Vehicle Licenses and Gasoline Taxes," conducted by the Highway Division of the Society during 1929, Mr. Crum draws three principal deductions, as stated in the paper under "Important Basic Principles." The following comments apply to these deductions in the order given by the author.

Principle 1.—License fees are readily defensible in so far as they are designed to cover costs of necessary supervision, protection, and exclusive or special benefit. In excess of these indicated limits, license fees are discriminatory, and are explainable only as the product of necessity or policy. The statement that motor vehicle users should pay a fee to cover "readiness to serve," is open to argument inasmuch as road construction constitutes a public improvement, as logically chargeable to public general funds as education, for instance. Considered in the light of expediency rather than equity, argument is avoided. There is apparent difference of opinion as to whether the license fee should be in lieu of other direct tax, and the answer to this question is a prerogative of the State Legislatures. Where the motor vehicle is exempted from personal property assessment it would appear that the license fee to some extent should be based upon valuation. Other bases of computation of the license fee logically are horse-power and weight.

The collection of license fees computed on valuation, weight, and horsepower might appear difficult, but this idea has been used in North Dakota for some years and appears to be practicable. The component part of the registration fee based on valuation—when the motor vehicle is exempted from personal property assessment—is reasonably equivalent to the State average of personal property tax exemption. The horse-power and weight components of the fee are computed supposedly with reference to the highway surface requirements of motor vehicles. The influence of weight is of particular importance with reference to heavy wheel loads, but unfortunately there is a general lack of sufficient information in this regard. The graduated fee in accordance with horse-power is quite reasonable with reference to incurring maintenance costs and to ability of car owners to pay; but it might be injudicious in favoring under-powered freight carriers.

Traffic conditions as well as physical characteristics of surface should be studied in connection with the proportioning of license fees and the theory of the "readiness to serve" charge. Large or slow vehicles might not exceed the width capacity or the carrying capacity of a road surface, but still might interfere seriously with the usefulness of the road to the preponderant class of motor vehicles of moderate dimensions and moderate weight. The speeding up of large heavy vehicles would not make them entirely unobjectionable, especially in mountainous districts where they might get out of control.

Principle 2.—The fact that all the States and the District of Columbia collect gas tax is evidence of the popularity of this form for the production of revenue. Since gasoline consumption increases with weight of load and with speed of travel, it would seem that this tax might be depended upon for total revenue for road construction and maintenance in States where motor vehicles are not exempt from personal property assessment. From a practical standpoint the revenues from gas tax should not be set aside exclusively for maintenance because separate funds for separate purposes frequently hamper administration.

The argument that no part of the funds raised by motor-vehicle license fees or gasoline taxes should be diverted to any use other than the construction, maintenance, and control of highways, is an effort toward consistency in the application of the theory of special fund for special benefit development. This argument is more reasonable in States where the motor vehicle is taxed as personal property than in other States. Such theories, however, should be considered with respect to necessity and expediency and with the recognition that there is less objection to the determination of levies or imposts on ability to pay than in consideration of ability to resist payment.

Determining the Road Users' Share of Costs.—The problem as to what share of the annual expenditures on the various classes of roads and streets should be borne by motor-vehicle users is unavoidably a problem of compromise. The determination of roadway costs, including cost of building and annual cost for administration, maintenance, and periodic replacement or renewal, simply shows a total that has been fixed by practical limits. What part of the costs should be borne by each of the various interests benefited, namely, the Federal Government, State Government, local community, adjacent property, and the user, is a problem of voluntary contribution and adjustment.

Under present conditions this country has a Federal Aid System, other State highways, county roads, township roads, and streets of incorporated municipalities. The designation of Federal Aid and State highways has very probably been judicious, but it has not been based on qualifications that furnish factors for accurate apportionment of costs. Briefly, the Federal Government has encouraged the development of correlated State highway systems by Federal aid apportioned among the States, one-third by area, one-third by population, and one-third in proportion to the total mileage of all highways at the time of the passage of the Act. The various States have relieved counties or townships as the case might be of responsibility for construction and maintenance of certain principal roads, and have set aside motor funds for State highway purposes. To some extent the Federal Aid highways enter the jurisdiction of municipalities, and to some extent motor funds have been distributed among counties, townships, and municipalities for highway purposes. The conditions involving the designation of Federal Aid highways and State highways and of the apportionment of Federal, and the distribution of State, motor funds are scarcely capable of analysis with respect to interests benefited, or to proper allocation.

Primary Roads.—It is established practice that the State (with Federal aid, as it becomes available) construct and maintain the principal rural roads and the State highway system, including the Federal Aid System. The discontinuance of State responsibility and Federal aid at municipal corporation lines has been considered impractical. The Federal Aid Act has recognized the importance of assisting in the development of streets in municipalities of small population and in the scantily developed sections of the more populous municipalities, and, in some cases, the burden of carrying large volumes of State highway traffic into and through boroughs and cities has been accepted in part as State responsibility. Future development of by-passes will not entirely eliminate the State highway significance of connecting streets.

There is force to Mr. Crum's statement that "the rate at which a system can be built will depend upon what the benefited interests can afford, * * *." This is especially true with reference to streets carrying through traffic with limited assistance of Federal Aid and State contribution.

Need for Co-Operation.—Viewing a highway system as a co-operative enterprise of the people of the State and considering the relative advantages of the "pay as you go" plan and the issuance of bonds, it may be stated that the use of bond funds has appeared desirable where the expected value of contemplated improvements has been greater than the anticipated total of annual costs and when rate of increase of annual revenue indicated future sufficiency for amortization of bonds, without impairing working-fund requirements. The present approach of motor vehicle registration to stabilized totals lessens regard for bond issues as a means of financing highway improvements. When there is recourse to the sale of bonds for financing highway improvement, however, the advantages of serial issues are important. A serial issue can be designed to develop equal annual costs, the loss by difference between interest rate on sinking fund and interest rate on bonds is overcome, and the responsibility for custody of the sinking fund is avoided.

Annual Roadway Costs.—On the basis of expenditure from current funds, actual road costs are chargeable to depreciation and maintenance. Actual annual road charges, then, may be stated as average annual depreciation plus average annual maintenance cost.

When the proceeds of bond issues are used for financing improvements, and in studies of costs where various rates of initial investment and depreciation are to be taken into account, annual interest on the investment is to be considered as well as depreciation charge and maintenance cost.

The formula mentioned by Mr. Crum as having been developed by a committee for the Highway Research Board differs slightly from the method that has been used in the Pennsylvania State Department of Highways for a number of years. Equation (1) charges simple interest on construction cost; it indicates perpetuity of initial investment, and capitalizes cost of periodic maintenance.

The Pennsylvania method charges off all investments in an estimated period of economic life and enters periodic maintenance cost as a simple annual average. The Pennsylvania formula uses as a factor the expression, $\frac{i}{(1+i)^n-1} + i$, values of which are directly obtainable from tabulations in handbooks of accounting and financing, known as "the annuity 1 will buy," or "the annual sinking fund which will accumulate to 1 at the end of n years" plus interest.

The Pennsylvania formula is as follows:

$$F = Gg + C'c + Dd + M + N \dots\dots\dots\dots\dots\dots (2)$$

in which, F is the average annual total charge; G is the grading and drainage cost; g is the annual sinking fund rate for the period of years in which the grading and drainage cost is to be charged off, plus interest; C' is the cost of a durable type of surface, or the salvage value anticipated in temporary or semi-durable type surface; c is the annual sinking fund rate for the years of economic life of the surface, plus interest; D is the re-surfacing cost, including initial surface treatment; d is the annual sinking fund rate for the years of period preceding re-surfacing, plus interest; M is the average annual cost of general maintenance; and N is the average annual cost of periodic maintenance.

Knowledge of Costs Helpful.—A method tried for a short time by the Pennsylvania State Department of Highways to show annual road-mile and car-mile costs, made use of records of costs of construction and maintenance and estimates of depreciation or salvage value and anticipated further economic life of improvements. For each year the cost was computed as the depreciation for the year, plus interest on the depreciated value, plus maintenance costs. This method required two charts for each section of road: One for recording traffic, itemized maintenance costs, depreciation and interest, total annual cost, average annual cost per mile, and average car-mile cost, with expectation of adjustment for relative weighting of truck-mile costs; and the other for special use to show annual costs of pavement only, including a column for reporting traffic, current value of pavement, depreciation and interest, maintenance costs, annual pavement-mile costs, and average pavement costs per car-mile.

Source of Funds.—Explanation of absorption of costs of highway improvements by the Federal Government, the States, local communities, real estate, and road users, in terms of respective benefits, suggests the need of extensive studies of classification and of source and destination of traffic. It is to be remembered, however, that ratios of allotment of cost are not to be fixed definitely for long terms. The public serviceability and use of the principal roads of the nation at the present time (1932), for instance, are very different from what they were in 1916 when the first Federal Aid Road Act was approved, and the mapping of State highway systems is carried out with such flexibility of purpose and standard that classification of roads as to jurisdiction can only be considered a matter of expediency.

Secondary and Third-Class Roads.—The distinction between primary, secondary, and third-class roads by definition is difficult. In some cases, there might be classification of highways in a State such that the Federal Aid System was identical with the State highway system. This might be described as the primary system; a recognized system of other roads under county supervision, eligible to certain State-aid benefit, might be termed secondary; while the remaining roads might be identified as third class. There might be still other cases of more extensive State highway systems, including secondary roads as well as primary roads, in the Federal Aid System. If there is any effort to classify highways on a basis of traffic counts, it is evident that there must be a sliding scale, because the distinction between primary and secondary roads in one State might be an absurdity in another. From a practical point of view classification of highways must be more elaborate than "primary, secondary, and third-class" roads; that is, in accordance with present conceptions, more than three traffic ratings are required. The principal consideration is in the question of roadside surface, width, and type, although there are questions of relocation and grading for reduction of curvature and gradient that cannot be settled without consideration of traffic classification.

A tentative road classification based on traffic is suggested, as follows:

Class	Traffic, in vehicles per day	Class	Traffic, in vehicles per day
1	More than 3 000	4	250 to 500
2	1 000 to 3 000	5	100 to 250
3	500 to 1 000	6	Less than 100

In addition to traffic, each class would be defined as to: Width, grades, alignment, sight distance, and depth of pavement.

City Streets.—The greatest difficulties in the problems of planning and financing street improvements are traffic congestion and relief. After giving some recognition to corporate limits and corporation rights, and assuming that by-pass routes are furnished for so-called through traffic, the street problem is largely localized, and the consideration of special benefits and users' costs by special license fees appears to be possible. The task is difficult, however, and requires careful investigation and consideration.

Needed Research.—The city street problem is acute in many cases and it is probably the most important field for investigation at the present time. In addition to other lines of investigation suggested by Mr. Crum, another of great importance is to determine the responsibility for carrying all classes of traffic at all times on all public roads. At present, it is generally recognized to be impracticable to build and maintain all the public roads to sustain maximum, generally permissible, loads in all seasons. Adverse conditions are snow, grades, curves, and surface bearing capacity. Where local use does not justify high type construction and all-year maintenance, and where local ability to pay does not permit it, the determination of facts of other than local use offers a wide field of study.

HORACE H. SEARS,[10] M. AM. SOC. C. E. (by letter).—A serious phase of engineering design and construction is discussed in this paper. Future financing of these improvements is dependent upon the sale to private investors of millions of dollars in new and refunding securities. These securities are issued by highway districts and special assessment districts in the form of bonds, notes, and warrants. Each of the securities is a promise to pay by the district, as a corporation, for these improvements. The improvements become the property of the district when installed; yet they cannot be attached or sold to satisfy the costs for labor and materials as is the case in constructing improvements for private corporations.

The intent of this discussion is to call the attention of engineers to the need of recognizing the financial limitations of these highway and special assessment districts under the limited powers which the Legislatures of various States have conferred upon them. The design of roads, the appropriation budget, and the prospect of securing funds are radically different for the city special assessment district as compared with the county road district or the State highway district. It is of no avail to design highways unless funds are permissible under highway district powers and unless authorized securities can be sold to investors. The payment for construction and for engineering services comes from the sale of corporate securities. Repayment of these loans must be assured or no funds will be forthcoming.

The sale of securities for city street improvements is best assured when bonds are voted and payable from *ad valorem* taxes. Preliminary engineering designs and costs must be determined in advance of the actual authorization of these voted bonds. To-day, more than previously, the city special assessment district is a corporate form of State agency which must give the engineer cause for thought. The sale of such securities for many cities meets with a great deal of sales resistance from the investing public. The city credit may be stated on the bonds, but experience shows that the repayment to the investor is dependent upon collection of assessments against the property in the district benefited.

---

[10] Cons. Engr. and Attorney-at-Law, Hastings-upon-Hudson, N. Y.

The sale of securities for county road districts and for State highway district improvements is direct to the purchaser, without the intermediary of a city to supervise collections. This form of security is dependent for repayment, in the event of delinquent tax collections, upon foreclosure proceedings against delinquent property in the district. These district corporations are agencies of the State, created for a special purpose by the Legislature. They have limited powers in the matter of issuing securities, which are, therefore, not as readily sold to investors as the *ad valorem* tax bond voted by cities. In view of the present financial stringency, the design of renewals, repairs, and new road construction requires a knowledge of the probable financing of construction in the present securities market, as well as a knowledge of the corporate powers of the district. The legislative powers may be examined by attorneys for the engineer, but if funds are not forthcoming in the desired amount, the design and budget should be shaped accordingly. The resourceful engineer will prove his value to the community in maintaining traffic under these limited sources of funds. Highway districts must economize as many such corporations have reached the statutory debt limit.

District financing and special assessment financing for cities are very different so far as securing funds from the investor at the present time (1932). The engineer should investigate the terms, "highway district bond," and "special assessment bonds," and note the exact promise of the debtor corporation. Funds are secured at less cost when the credit of a city is back of the special assessment bond, than in the case of the district bond. The district road warrant, note, or tax anticipation certificate, should be studied with care. These securities are restricted, as a general rule, to payment for an existing indebtedness. When issued for loans and based on the future credit of the district, the enabling act of the Legislature should receive special attention from attorneys who specialize in municipal securities.

The investor has learned, and the engineer should know, that the district corporation is termed in law a quasi-municipal corporation, which is of limited character when compared with the municipal corporation, which is usually designated as the city. An approving opinion by a bond attorney, on procedure for a district security proposed to be issued, is in the nature of a preliminary statement. The final approving opinion of the attorney may not be given. Engineering designs, both preliminary and final, may be tied up with insufficient funds because of the failure to secure a final approving opinion, or because litigation is pending over the proposed issue of bonds. Highway construction may be imperatively needed, but if funds are not forthcoming the traveling public may detour for months because of incomplete paving. In such cases alternate highway plans must be provided until securities are sold.

The need for further assurance in this matter of financing by sales to the investor of special assessment securities and of district bonds has resulted in the recent publication by The Investment Bankers Association of

America of proposed Uniform Assessment Laws which will be submitted to the various State Legislatures for consideration and adoption. The State, through the Legislature, subject to constitutional limitations, has authorized these quasi-municipal corporations of limited powers to act as its agents. The customary legal liability of the State as principal for its agent's authorized acts in issuing securities does not result in the State becoming liable for the debts of these corporations. The State Constitutions limit the powers of municipal corporations in the matter of incurring debt, and, to a greater degree, the indebtedness of district corporations. The issue of securities to pay for a present debt, such as a warrant represents, differs greatly from the future pledging of district credit. A warrant promises to pay when funds are available, while a bond is a future promise to pay for funds presently loaned by the purchaser.[11]

The cost of designed roads must be financed from funds secured by the sale of district securities to the investor. The engineer must consult with his attorney and his district's banker before he can be assured of financing his projects. He must have an understanding of the corporate financial powers and the sale of its securities to the same extent that he has materials tested and traffic conditions analyzed.

In conclusion, it may be stated that the estimated annual revenues from motor vehicle users in the nature of automobile licenses and gasoline tax will prove most valuable as collateral assurance that the original sources of financing construction through municipal corporate securities will be performed. These license taxes are operating revenues and should be distinguished from highway district bonds, which are in the nature of first mortgage liens on benefited real estate. The highway engineer must not ignore the funds from bond sales, which make the original cost of construction possible. It is the finished structure that creates the "readiness to serve" the public (mentioned in Mr. Crum's paper), which is productive of annual revenues from motor vehicles. The owners of the latter, in turn, pay the State license and gasoline tax.

R. W. CRUM,[12] M. AM. SOC. C. E. (by letter).—By common consent some of the factors of the problems of highway financing are becoming settled. For instance, the principle that the users should pay directly the entire cost of the main roads (except that part borne by the Federal Government) has been widely adopted, and the States generally finance their primary road improvements and maintenance by means of license fees on vehicles and taxes on gasoline.

Of course, a part of the total sum raised by these imposts is derived from travel on roads and streets not included in the self-supporting system. However, the determination of that part of the total sum raised that is derived from travel on the main highways does not appear to be impossible. In a given case the data needed are the car-miles of traffic on the system in question and the total traffic on all roads and streets in the jurisdiction. Since the primary system is definitely located and limited in extent, traffic surveys will give that part of the needed data.

---

[11] Dillon, "Municipal Corporations," Chapters XIX and XX.

[12] Director, Highway Research Board, National Research Council, Washington, D. C.

The total traffic can be estimated from the gasoline consumption, as revealed by the tax returns, or from the total number of trucks and passenger cars registered, together with the average annual mileage per vehicle, and valuable data for use in making such estimates have been compiled.[13] The ratio of primary road traffic to total traffic will also be the ratio of the tax derived from primary road use to the total tax, and can be utilized in making an equitable allocation of the funds.

This ratio, in connection with the annual cost of the primary road system, should indicate also the total money that can be equitably raised by taxes on users of vehicles. As an illustration, consider some data from a certain State: The average daily traffic during 1929, at 360 stations, covering the 3 490 miles of the State primary highway system, was found to be 732 vehicles. The total average traffic per day on these roads was, therefore, 3 490 × 732, or 2 554 860 car-miles.

An estimate of the total traffic on all the roads and streets of the State was made from the returns of the gasoline tax. In 1929, this tax produced $6 794 000, which means that at the tax rate of 5 cents per gal., 135 880 000 gal. of gasoline were consumed during the year, or an average of 372 274 gal. per day. Assuming that an average vehicle in this State will go 14 miles on 1 gal., the total average car-miles per day were 5 211 836. Of these daily car-miles, the 2 554 860 on the State Highway System amounted to 49 per cent.

The total revenue from motor vehicle fees and the 5-cent gasoline tax in this year was $9 334 000, of which 49%, or $4 573 660, was derived from travel on the State Highway System. Allowing for reasonable increase in traffic over a 30-year period, the amount derivable from the traffic on this system, without change in tax rate, was estimated to be about $5 300 000 per year.

An estimate of the average annual cost over a 30-year period of improving and maintaining this road system was $5 239 000, exclusive of the Federal Aid to be expected during construction. The amount to be realized, therefore, was just about equal to the demand.

If the amount derivable from the traffic on the primary road system was insufficient to cover the annual road costs, the State would be faced with the necessity of deciding between the alternate policies of increasing the tax rates, or of using some money on the primary system that was generated by traffic on other roads and streets. The justice of the latter procedure would depend largely upon the need of the State as a whole for improved highway transportation facilities.

This discussion is offered merely as an illustration of an attempt at a rational analysis of one phase of the problem. In addition to the list of needed research projects in the paper, it is suggested that a detailed study of the various comprehensive traffic surveys that have been carried on in numerous States would probably shed considerable light on the fixing of rates of taxation on motor vehicle users and the equitable allocation of the funds raised by these taxes.

DESIGN OF LARGE PIPE LINES

BY HERMAN SCHORER,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. L. J. MENSCH, W. P. ROOP, JOHANNES SKYTTE, DONALD E. LARSON, RAYMOND J. ROARK, F. W. HANNA, PAUL BAUMAN, L. J. LARSON, C. M. ORR, EDWARD J. BEDNARSKI, H. C. BOARDMAN, R. L. TEMPLIN AND R. G. STURM, F. KNAPP, C. P. VETTER, L. E. GRINTER, OREN REED, ROBERT E. GLOVER, AND HERMAN SCHORER.

SYNOPSIS

The object of this paper is to present an exact theory for the design of large pipe lines and their supports, which may also be used for the design of horizontal tanks, under-water tubes supported on piers, etc. Instead of the saddles commonly used, the pipe is supported and kept in shape by full ring girders which were first introduced in Sweden.

The ring girders act as stiff, disk-shaped members, preventing large distortions over the supports and their transmission into the pipe shell proper. Under these conditions stresses can be analyzed by the modern elastic theory of thin shells. It is found that the shell then is mainly subject to direct beam and ring stresses, the loads being transmitted to the supporting rings by shearing stresses. A narrow zone of secondary bending stresses occurs in the shell portions adjacent to the supporting rings, induced by the restraining action.

Theory and experience show that a pipe line so designed does not require any intermediate stiffening angles, even in case of comparatively thin shells. Much larger spans than those permitted by the customary saddle supports are entirely feasible, and considerable savings in steel and excavation may be realized with a larger factor of safety. The governing design stresses in the shell are derived and, for completeness, the stress analysis of a circular supporting ring is also given.

NOTE.—Published in September, 1931, *Proceedings*.

INTRODUCTION

Large steel pipe lines of usual design, supported on saddles and subject to beam action, are typified by short spans and a large number of circumferential stiffeners. Although the cost of such conduits is by no means small, present design practice is still largely based on crude, empirical rules, derived from observations on the unsuccessful behavior of some of the earlier structures, especially during filling and when operating under low pressure.

A radical departure from the old type saddle support, first introduced in Sweden about 1911, has been described by K. I. Karlsson[2] in an interesting paper. The pipe shell is riveted to and supported by circular girders, which transmit the load to the ground through a two-point support near the ends of the horizontal diameter. Tests and observations made on pipe lines thus supported have demonstrated the remarkable stability of the thin pipe shell built without any intermediate stiffening rings, and combined with unusual spans. For instance, the Kungfors line, built in 1921, has a shell thickness of $\frac{1}{4}$ to $\frac{5}{16}$ in., a diameter of almost 11 ft., with 41-ft. spans, and no stiffening angles between the ring-girder supports.

During the development stage of the Swedish type of support the elastic theory of thin shells had not advanced sufficiently to furnish a theoretical explanation for the small shell deformations under low heads. Although Karlsson has made an attempt to analyze the bending stresses in the thin shell, for the pipe full and half full, his assumptions were necessarily of a rather arbitrary nature, so that the uncertainty concerning the actual stress condition in the pipe shell was probably one of the reasons why the stiff-ring girder support has not replaced the saddle support in other countries.

Since the publication of Karlsson's paper, the general theory of shells has progressed to such an extent that the exact stress condition can be derived in a fairly simple manner. In the following analysis the pipe is considered as a thin shell, unsymmetrically loaded.

NOTATION

The following notation is used throughout this paper. Units must be consistent, for instance, inches, pounds, pounds per square inch, pounds per cubic inch, etc.

a = eccentricity of reaction, $\frac{Q}{2}$ (see Fig. 6), from a tangent to the center of the pipe shell.

b = moment arm of the tangential shear, s, from Point D in Fig. 6.

c = width of circular girder ring (see Fig. 4 (*a*)).

d = radial deflection:

- d_H = radial deflection accompanying the radial thrust, H, on the free cylinder rim.
- d_M = radial deflection caused by a radial moment, M, at a free rim.

e = 2.7183 = base of natural logarithms.

---

[2] "Ueber Schwerkraftspannungen in Rohrleitungen von grossen Durchmessern und deren rationelle Konstruktion," by Karl I. Karlsson, *Schweizerische Bauzeitung*, Vol. 80, September 2, 1922, p. 105.

f = unit stress:

f'_r = maximum ring stress in shell, pipe precisely full.

f_r = maximum combined ring stress in shell, pipe under pressure.

f_{bx} = unit longitudinal bending stress in the rim at a distance, x, from the rim (see Fig. 4(*b*)).

f_L = combined maximum longitudinal beam stress.

f_{bo} = maximum longitudinal rim bending stress in the shell.

f_{bm} = absolute maximum value of the longitudinal rim bending stress.

h = head.

l = elementary length; $d\,l$ = segment lengths of a ring element (see Fig. 2).

m = Poisson's ratio.

p = variable pressure on the inside of the pipe circumference.

q = unit weight of the fluid flowing in a pipe.

r = mean radius of a pipe.

r'_p = increase in radius, r, at unrestricted sections of pipe.

r'_d = increase in radius, r, of the ring disk.

s = tangential shearing force per unit width of shell element.

t = thickness of shell.

u = angular location of a cylinder element, in the cross-section of a pipe, measured from the vertical (Fig. 2); du = angle subtended by the arc element, $d\,l$.

v = angular location of the point of tangency of s, measured from the vertical.

w = weight of pipe shell per unit of area.

x = distance from shell rim (see Fig. 4(*b*)).

x_1 = abscissas in the cross-section of a pipe, to any point (D, Fig. 5) in the supporting ring.

x' = distance along the center line of the pipe to any point measured from the origin, O (see Fig. 1).

dx' = length of an arc element, $d\,l$ wide, measured along the axis of the pipe.

y = ordinate of any point (D, Fig. 5) in a supporting ring.

z = a constant for the cylindrical shell $= \dfrac{\sqrt{r\,t}}{\sqrt[4]{3\,(1 - m^2)}}$.

A_r = area of supporting ring in a plane along the axis of the pipe.

D = diameter of pipe = $2\,r$ (see Fig. 3).

E = modulus of elasticity.

H = uniformly distributed radial thrust (see Fig. 4), measured per unit width of rim.

L = length of span, from center to center of ring-girder supports.

M = bending moments in ring girder:

M_e = moment of external forces.

M_s = moment due to tangential shearing forces.

M_A = moment due to left reaction (Fig. 6); M_B = moment due to right reaction.

M_0 = moment at the top of the ring when u = zero.

M_a = ring moment at $u = \dfrac{\pi}{2}$.

M_1 = ring moment in the first quadrant; M_2, second quadrant; etc.

M_i = maximum intermediate moment.

M_s = moment at the elastic center of the supporting ring.

N = normal forces in ring girder:
  N_0 = radial force at top of ring, when u = zero.
  N_a = maximum ring force due to the shearing forces, s.
  N_t = total tension in the ring caused by the combined loads, p and H.
P = external forces acting on a pipe.
Q = total load of the pipe shell, transmitted by shear to one supporting ring.
R = radius of curvature of a cylinder element (see Fig. 2).
S = section modulus of pipe, acting as a beam.
S' = section modulus of shell element.
T = stress components on shell element, measured per unit width:
  T_1 = acting in a longitudinal direction.
  T_2 = acting in a tangential direction.
X = longitudinal load component on shell element.
X_1 = horizontal force applied at the elastic center of supporting ring.
Y = tangential load component on shell element.
Y_1 = vertical force applied at the elastic center of supporting ring.
Z = radial load component on shell element.
δ = angular change:
  δ_H = change that accompanies the deflection, d_H.
  δ_M = change that accompanies the deflection, d_M.

DIRECT STRESSES IN PIPE SHELL

Fig. 1 shows a horizontal pipe section connected to, and supported by, two stiff, disk-shaped members, which prevent large deformations of the rim and their transmission into the shell proper. Under such rim conditions the theory of thin shells shows that continuous surface loads, applied over the shell area, will cause mainly direct stresses in the pipe walls. The cylindrical shell acts as a membrane, free from bending stresses normal to its surface, except for a narrow zone of secondary transverse stresses at the restrained rims. This behavior is quite in accordance with Castigliano's theorem of least work. Since a direct stress system is possible, much less internal work is required than with a system of large bending stresses in the pipe walls.

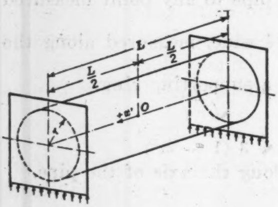

FIG. 1.

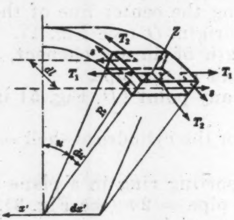

FIG. 2.

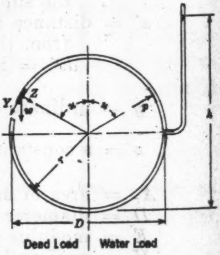

FIG. 3.

The following derivation of the direct stresses is based on the general theory of cylindrical shells, developed by Bauersfeld, and, later, independently by Finsterwalder, for the purpose of analyzing the stresses in the Zeiss-Dywidag, barrel-type roof, as described by Dischinger.[3]

---

[3] Handbuch für Eisenbetonbau, Vol. 6, Fourth Edition: "Dachbauten Kragdächer, Schalen, und Rippenkuppeln," by H. J. Kraus and Franz Dischinger, p. 269, Wilhelm Ernst & Sohn, Berlin, 1928.

Fig. 2 shows a small element of the pipe shell, loaded by the external force components, X, Y, and Z. The element is held in equilibrium by the stress components, T_1, T_2, and the shearing forces, s, which act in pairs of equal magnitude on all four faces. Designating tension by the positive sign, and the radius of curvature of the cylinder element by R, Bauersfeld (as mentioned by Dischinger[3]) has derived the following general differential equations,

$$T_2 = -RZ \quad \text{.........................} (1)$$

$$s = -\int \frac{\partial T_2}{R\,\partial u}\,dx' - \int Y\,dx' + f_1(u) \quad \text{..............} (2)$$

and,

$$T_1 = -\int \frac{\partial s}{R\,\partial u}\,dx' - \int X\,dx' + f_2(u) \quad \text{..............} (3)$$

The functions, $f_1(u)$ and $f_2(u)$, depend on the origin of the co-ordinate system and the conditions at the supports. With the origin at the center of the span, as shown in Fig. 1, $f_1(u) = 0$. Assuming that any inside pressure on the end disks is resisted by corresponding forces in the opposite direction, then, in the case of Fig. 1, the stress component, T_1, must become zero at the supports, which condition determines $f_2(u)$.

Equations (1), (2), and (3), can be integrated if the radius of curvature and the load components can be expressed as trigonometric functions of the angle, u. For a circular pipe shell, $R = r$ is constant.

The most important loadings are: First, the dead load of the shell; and, second, the pipe filled with a liquid, so that the free level just reaches the top of the shell.

Case 1.—Dead Load Stresses.—Designating the weight of the pipe shell per unit area by w, Fig. 3 gives the following values for the load components: $Z = w \cos u$; $Y = w \sin u$; and $X = 0$. Substituting Z in Equation (1), the ring stress component becomes,

$$T_2 = -r\,w\cos u \quad \text{.....................} (4)$$

Substituting the partial derivative, $\frac{\partial T_2}{\partial u} = r\,w\sin u$, and the value of Y in Equation (2):

$$s = -2\,w\,x'\sin u \quad \text{.........................} (5)$$

The partial derivative of s, $\frac{\partial s}{\partial u} = -2\,w\,x'\cos u$, is then substituted in Equation (3). By integration, $T_1 = \frac{w\,(x')^2}{r}\cos u + f_2(u)$. Since $T_1 = 0$, when $x' = \frac{L}{2}$, $f_2(u) = -\frac{w\,L^2}{4\,r}\cos u$. Therefore,

$$T_1 = \frac{w}{r}\left[(x')^2 - \frac{L^2}{4}\right]\cos u \quad \text{.................} (6)$$

The unit stresses are obtained by dividing the expressions for the stress components by the shell thickness, t.

Equation (4) shows that the ring stress is independent of the span. The maximum values occur at the top (compression) and at the bottom (tension). The stress at the horizontal diameter is zero.

The shearing stresses, Equation (5), reach their maximum values at the end disks and are distributed over the cross-section as in a hollow, cylindrical beam, subject to bending. Equation (6) shows that the longitudinal shell stresses are also identical with those obtained by the ordinary theory of flexure, because cos u defines a straight-line stress distribution. Considering the shell as a simply supported beam, then, with the load assumptions previously given, the maximum moment is, $M_{\text{max.}} = \frac{2\,\pi\,r\,w\,L^2}{8}$.

The section modulus of a thin circular ring is, $S = \pi\ t\ r^2$, therefore, the maximum beam stress,

$$f_{\text{max.}} = \frac{M_{\text{max.}}}{S} = \frac{w\ L^2}{4\,r\,t} \qquad (7)$$

By comparing Equation (7) with Equation (6), it may be noted that the maximum stresses are identical.

The direct longitudinal stresses, therefore, are the same as those in a hollow, cylindrical beam, but the addition of the ring stress, T_2, changes the principal stress system.

Case 2.—Stresses for Pipe Precisely Full.—Assuming that a liquid of the unit weight, q, precisely fills the pipe to the top, with the free level at $u = 0$, the load components are given by Fig. 3, as, $Z = -\ q\ r\ (1 - \cos u)$; $Y = 0$; and $X = 0$.

From Equation (1),

$$T_2 = q\ r^2\ (1 - \cos u) \qquad (8)$$

Proceeding as shown for Case 1, from Equation (2),

$$s = q\ r\ x'\ \sin u \qquad (9)$$

Equation (3) becomes,

$$T_1 = -\ \frac{q}{8}\left[L^2 - 4\ (x')^2\right]\cos u \qquad (10)$$

Equation (8) shows that the ring stress is tension, and again is independent of the span. It increases from zero at the top to a maximum value at the bottom.

The shearing stress and the longitudinal stress are also identical with those obtained by the ordinary beam theory. It is interesting to note that the longitudinal stress due to liquid load is independent of the diameter.

Case 3.—Pipe Half Full.—A detailed analysis of the direct and secondary bending stresses in the pipe shell for this case of loading is given in a paper by A. F. Samsioe,[4] which came to the writer's attention after the present paper was submitted. The example given by Samsioe indicates that the maximum combined shell stresses for a pipe half full are of the same order as those obtained by the present method, when the direct stresses of Case 2 are combined with the rim bending stresses, as shown subsequently. For practical purposes, a design based on Case 2, including the rim stresses, will, therefore, also be safe for a pipe half full.

---

[4] "Die Spannungen in einem auf mehreren Stützen in gleicher gegenseitiger Entfernung aufgelegten und zur Hälfte mit Wasser gefüllten Rohr," by A. Frey Samsioe, pub. by Svenska Bokhandelscentralen, Stockholm, 1926.

Case 4.—Combined Direct Stresses.—Combining the two cases of loading and designating the maximum unit ring stress by f'_r, then from Equations (4) and (8), with $D = 2r$,

$$f'_r = \frac{D}{2t}(w + qD) \qquad (11)$$

This stress occurs at the bottom of the shell, where the tension due to the dead load is increased because of the weight of the liquid.

If the pipe is under pressure, corresponding to a head, h, above the bottom of the pipe, then the maximum combined ring stress, designated by f_r, becomes,

$$f_r = \frac{D}{2t}(w + qh) \qquad (12)$$

The combined maximum longitudinal stress (f_L) is obtained from Equations (6) and (10); with $x' = 0$, and $u = 0$, or $u = \pi$,

$$f_L = \mp \frac{L^2}{4t}\left(\frac{2w}{D} + \frac{q}{2}\right) \qquad (13)$$

It can be shown that, in case of continuous pipe lines, the direct longitudinal stresses can also be derived from the theory of continuous beams.

If the pipe is prevented from expansion and contraction due to temperature changes, the longitudinal stresses due to this cause must be superimposed to the stresses, f_L. However, by providing expansion joints and bearings of low frictional resistance the temperature stresses can practically be eliminated.

Ring buckling of the pipe shell must be investigated only in case of possible outside pressure, for instance, that due to partial vacuum. It will generally be more economical to avoid vacuum pressure by the installation of stand-pipes and relief valves. Buckling due to longitudinal compressive stresses in thin, hollow cylinders has been analyzed by Timoshenko.[5] It may be expected that no reduction of the usual design stresses will be required until the ratio, $\frac{r}{t} > 500$, which is a remote possibility in practical cases.

Longitudinal and circumferential joints of riveted and welded construction must be designed to transmit the full shell stress.

RIM STRESSES

Assume that the pipe section shown in Fig. 1 is under uniform inside pressure. Due to the elasticity of the shell the pipe diameter will increase by a small amount in direct proportion to the ring stress. The shell rims, on account of their rigid connection with the end disks, cannot widen in the same manner as the more distant shell portions, so that bending deformations occur in the restrained rim zone.

---

[5] "Einige Stabilitätsprobleme der Elastizitätstheorie," by Timoshenko, *Zeitschrift für Mathematik und Physik*, 1910, p. 337.

In practical cases the pipe is built as a continuous structure over more than two supports. In order to provide an unrestricted flow area the full disks of Fig. 1 are replaced by ring disks members. Fig. 4 (*a*) shows the state of deformation of a pipe shell, which is under a uniform inside pressure, p, and is rigidly connected to a circular ring of constant cross-sectional area, A_r. The radius of the unrestricted shell portions has increased by the elastic amount, r'_p, and the radius of the ring disk, by the amount, r'_d. Fig. 4 (*b*) shows one-half the pipe shell cut at its connection with the ring. The original deformation of the free rim is restored by applying a uniformly distributed radial thrust, H, acting inward, and a uniformly distributed radial moment, M, which has the tendency to turn the rim outward. H and M are measured per unit length of circumference.

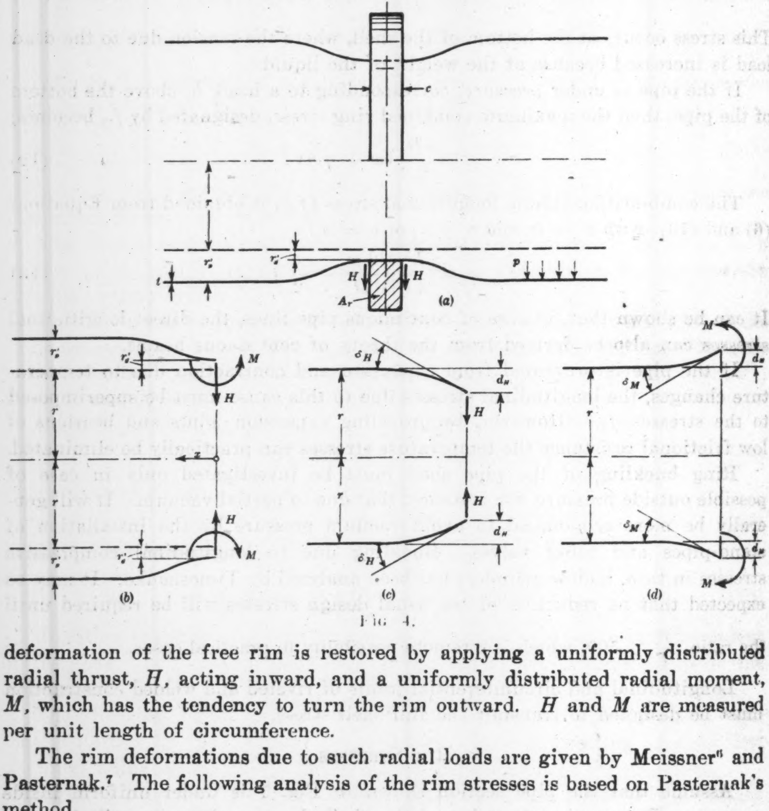

FIG. 4.

The rim deformations due to such radial loads are given by Meissner[6] and Pasternak.[7] The following analysis of the rim stresses is based on Pasternak's method.

If the free cylinder rim is loaded by the radial thrust, H, alone, as shown in Fig. 4 (*c*), the rim deformation is expressed by the radial deflection,

---

[6] "Zur Festigkeitsberechnung von Hochdruck-Kesseltrommeln," by E. Meissner, *Schweizerische Bauzeitung*, Vol. 86, July 4, 1925, p. 1.

[7] "Die praktische Berechnung biegefester Kugelschalen, kreisrunder Fundamentplatten auf elastischer Bettung und kreiszylindrischer Wandungen in gegenseitiger monolither Verbindung," by P. Pasternak, *Zeitschrift für angewandte Mathematik und Mechanik,* Vol. 6, 1926, p. 1.

d_H, and the angular change of the generatrix, designated by δ_H. If the free rim is loaded by the radial moment, M, alone, as shown in Fig. 4 (d), the corresponding deformations are designated by d_M and δ_M, respectively.

Pasternak has derived the following expressions for the deformations of the rim, due to the radial loads, H and M:

$$d_H = \frac{2\, r^2\, H}{t\, z\, E} \quad \text{(14)}$$

$$\delta_H = \frac{2\, r^2\, H}{t\, z^2\, E} \quad \text{(15)}$$

$$d_M = \frac{2\, r^2\, M}{t\, z^2\, E} \quad \text{(16)}$$

and,

$$\delta_M = \frac{4\, r^2\, M}{t\, z^3\, E} \quad \text{(17)}$$

in which z is a constant for the shell, equal to $\dfrac{\sqrt{r\, t}}{\sqrt[4]{3\,(1 - m^2)}}$.

Due to the inside pressure, p, per unit area, the radius of the unrestricted shell portions increases by the amount,

$$r'_p = \frac{p\, r^2}{t\, E} \quad \text{(18)}$$

The disk ring is loaded by the direct pressure, p, acting over the width, c, and the radial thrust, H, transmitted from both shell rims. Designating by N_t the total tension in the ring caused by the combined loads, then,

$$N_t = (p\, c + 2\, H)\, r \quad \text{(19)}$$

Furthermore, if A_r designates the cross-sectional area of the ring,

$$r'_a = (p\, c + 2\, H)\, \frac{r^2}{A_r\, E} \quad \text{(20)}$$

With reference to Fig. 4 (b), the following relation can next be written,

$$r'_p - d_H + d_M = r'_a \quad \text{(21)}$$

Since the connection between the ring and the shell is assumed as fixed,

$$\delta_H = \delta_M \quad \text{(21a)}$$

Substituting the corresponding values for the deformations, Equations (14), (15) (16), (17), (18), and (20), in Equations (21) and (21a), respectively,

$$H = p\, z\, \frac{(A_r - c\, t)}{(A_r + 2\, t\, z)} \quad \text{(22)}$$

and,

$$M = \frac{p\, z^2}{2}\, \frac{(A_r - c\, t)}{(A_r + 2\, t\, z)} \quad \text{(23)}$$

For steel, with $m^2 = 0.10$, the shell constant equals,

$$z = \frac{\sqrt{r\, t}}{\sqrt[4]{3\,(1 - m^2)}} = 0.78\, \sqrt{r\, t} \quad \text{(24)}$$

Therefore, Equation (22) becomes,

$$H = 0.78\, p \sqrt{r\, t}\, \frac{(A_r - c\, t)}{(A_r + 1.56\, t \sqrt{r\, t})} \quad \ldots\ldots\ldots\ldots (25)$$

and Equation (23),

$$M = 0.304\, p\, r\, t\, \frac{(A_r - c\, t)}{(A_r + 1.56\, t \sqrt{r\, t})} \quad \ldots\ldots\ldots\ldots (26)$$

The section modulus, S', of the shell plate, per unit width of circumference, is $\frac{t^2}{6}$. Designating by f_{bo} the maximum rim bending stress of the shell, from Equation (26),

$$f_{bo} = \frac{M}{S'} = 1.82\, \frac{(A_r - c\, t)}{(A_r + 1.56\, t \sqrt{r\, t})} \times \frac{p\, r}{t} \quad \ldots\ldots\ldots\ldots (27)$$

In Equation (27), the factor, $\frac{p\, r}{t}$, is identical with the ring stress in the unrestricted shell, also called the cylinder stress. The rim bending stress is, therefore, a function of the cylinder stress in the more distant shell portions. If A_r becomes very large, comparable to an absolutely unyielding disk, the rim bending stress approaches an absolute maximum value, designated by f_{bm}, for which Equation (27) gives,

$$f_{bm} = 1.82\, \frac{p\, r}{t} \quad \ldots\ldots\ldots\ldots (28)$$

In this extreme case the rim bending stress exceeds the cylinder stress by fully 82 per cent. The smaller the area of the ring disk, the smaller the rim bending stress will be. The bending stresses in the rim zone cannot be neglected in the design, because in continuously supported pipe lines the longitudinal stresses due to beam action are combined with the longitudinal rim bending stresses.

Equation (27) also shows the influence of the width, c, on the magnitude of the rim bending stress. The wider the ring disk, the smaller will be the bending stress for a constant area, A_r.

In all thin shells of revolution, subject to symmetrical rim loads, the bending stresses decrease rapidly with increasing distances from the rim in the shape of a damped wave, as shown by Geckeler.[8] Designating by f_{bx} the rim bending stress at the distance, x, from the rim,

$$f_{bx} = f_{bo} \sqrt{2}\; e^{\frac{-x}{z}} \cos\left(\frac{x}{z} + \frac{\pi}{4}\right) \quad \ldots\ldots\ldots\ldots (29)$$

Equation (29) shows that the thinner the shell compared to its diameter, the narrower the rim zone of secondary bending stresses will be.

The total tension, N_t, in the supporting ring can now be determined by substituting H, from Equation (25), in Equation (19), which gives,

$$N_t = p\, r \left[c + 1.56 \sqrt{r\, t}\, \frac{(A_r - c\, t)}{(A_r + 1.56\, t \sqrt{r\, t})} \right] \quad \ldots\ldots\ldots\ldots (30)$$

---

[8] "Ueber die Festigkeit achsensymmetrischer Schalen," by J. Geckeler, *Forschungsarbeiten* auf dem Gebiete des Ingenieurwesens, Heft 276, VDI-Verlag, Berlin, 1926.

This determination of the rim stresses applies only to symmetrical rim loads. Dischinger[9] has shown that in case of unsymmetrical loads the maximum rim bending stress is obtained with good approximation by substituting the maximum ring stress in place of the cylinder stress, $\frac{p\,r}{t}$, in Equation (27). In the present case, the maximum ring stress is given by Equation (12).

STRESSES IN SUPPORTING RING

Fig. 5 shows a circular ring of uniform cross-section, loaded and held in equilibrium by the external forces, *P*. For the purpose of analysis the ring is cut at the top and the right half is fixed at *C′*. The left half is provided with a rigidly connected lever arm, *C O*, in which, *O* represents the elastic center of the ring (identical in this case with the geometric center). At *O*, the unknown forces, X_1, Y_1, and the unknown moment, M_z, are applied so that the ring deformations at *C*, with respect to *C′*, disappear.

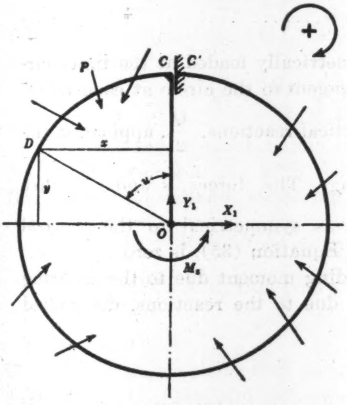

FIG. 5.

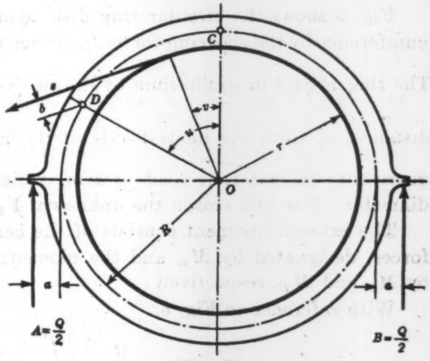

FIG. 6.

If *dl* designates the length of a small ring element and M_e defines the moment of the external forces between *C* and *D* with respect to *D*, then the unknowns are found from the following equations, as given by Mueller-Breslau:[10]

$$X_1 = \frac{\int M_e\, y\, dl}{\int y^2\, dl} \qquad \text{(31)}$$

$$Y_1 = \frac{\int M_e\, x\, dl}{\int x_1^{\,2}\, dl} \qquad \text{(32)}$$

and,

$$M_z = \frac{\int M_e\, dl}{\int dl} \qquad \text{(33)}$$

---

[9] Handbuch für Eisenbetonbau, Vol. 6, Fourth Edition, p. 247.

[10] "Die neueren Methoden der Festigkeitslehre," by H. Mueller-Breslau, pp. 125, 134, pub. by Alfred Kroener, Leipzig, 1913.

The forces, X_1 and Y_1, are assumed positive when acting in the direction shown in Fig. 5, and all moments are taken as positive when acting clockwise.

Substituting $dl = R\,du$; $x = R \sin u$; and $y = R \cos u$; and integrating between the limits, $u = 0$ and $u = 2\pi$, Equations (31), (32), and (33) become,

$$X_1 = \frac{1}{\pi R} \int_0^{2\pi} M_e \cos u \, du \dots\dots\dots\dots\dots (34)$$

$$Y_1 = \frac{1}{\pi R} \int_0^{2\pi} M_e \sin u \, du \dots\dots\dots\dots\dots (35)$$

and,

$$M_z = \frac{-1}{2\pi} \int_0^{2\pi} M_e \, du \dots\dots\dots\dots\dots (36)$$

Designating by Q the total load of the pipe shell, transmitted by shear to one ring disk, the distribution of the shear, s, per unit width of circumference is given by Equations (5) or (9); therefore, with reference to Fig. 6,

$$s = \frac{Q}{\pi r} \sin v \dots\dots\dots\dots\dots (37)$$

Fig. 6 shows the circular ring disk, symmetrically loaded at the inner circumference by the shearing forces, s, acting tangent to the circle at each point. The ring is held in equilibrium by the two vertical reactions, $\frac{Q}{2}$, applied at the distance, a, from the neutral axis of the ring. The forces, s and $\frac{Q}{2}$, then represent the external load system, which is symmetrical to the vertical diameter. For this reason the unknown, Y_1, Equation (35), is zero.

The external moment consists of the bending moment due to the shearing forces, designated by M_s, and the moments due to the reactions, designated by M_A and M_B, respectively.

With reference to Fig. 6,

$$M_s = \int_0^u b \, s \, r \, dv \dots\dots\dots\dots\dots (38)$$

From analytic geometry,

$$b = R\left(\sin u \sin v + \cos u \cos v - \frac{r}{R}\right) \dots\dots\dots\dots\dots (39)$$

and, therefore, with s from Equation (37),

$$M_s = \frac{Q\,R}{\pi} \int_0^u \sin v \left(\sin u \sin v + \cos u \cos v - \frac{r}{R}\right) dv \dots\dots (40)$$

By integration,

$$M = \frac{Q\,R}{\pi}\left[\frac{u}{2} \sin u - \frac{r}{R}\,(1 - \cos u)\right] \dots\dots\dots\dots\dots (41)$$

The left reaction causes a moment between $u = \frac{\pi}{2}$ and $u = 2\,\pi$, equal to,

$$M_A = \frac{Q\,R}{2}\left(\frac{a}{R} - \sin u + 1\right) \dots\dots\dots\dots\dots (42)$$

and the right reaction between $u = \frac{3\pi}{2}$ and $u = 2\pi$, causes a moment,

$$M_B = -\frac{Q\,R}{2}\left(\frac{a}{R} + \sin u + 1\right) \ldots\ldots\ldots\ldots\ldots (43)$$

Equation (34) then becomes,

$$X_1 = \frac{1}{\pi\,R}\left[\int_0^{2\pi} M_s \cos u\, du + \int_{\frac{\pi}{2}}^{2\pi} M_A \cos u\, du + \int_{\frac{3\pi}{2}}^{2\pi} M_B \cos u\, du\right]. (44)$$

Substituting Equations (41), (42), and (43) in Equation (44), and integrating between the given limits,

$$X_1 = \frac{Q}{\pi}\left(\frac{r}{R} - \frac{a}{R} - \frac{3}{4}\right) \ldots\ldots\ldots\ldots\ldots (45)$$

For the moment, M_z, Equation (36) gives,

$$M_z = -\frac{1}{2\pi}\left[\int_0^{2\pi} M_s\, du + \int_{\frac{\pi}{2}}^{2\pi} M_A\, du + \int_{\frac{3\pi}{2}}^{2\pi} M_B\, du\right] \ldots (46)$$

Substituting Equations (41), (42), and (43), and integrating between the limits shown,

$$M_z = \frac{Q\,R}{\pi}\left[\frac{r}{R} - \frac{\pi}{4}\left(1 + \frac{a}{R}\right)\right] \ldots\ldots\ldots\ldots\ldots (47)$$

The resulting moment at any point of the ring is obtained by combining the external moment, M_e, with the moment, M_z, and the moment due to X_1. Designating the moment at the top of the ring, $u = 0$, by M_0;

$$M_0 = M_z - R\,X_1 = \frac{Q\,R}{\pi}\left[\frac{3}{4} - \frac{\pi}{4} + \frac{a}{R}\left(1 - \frac{\pi}{4}\right)\right] \ldots\ldots (48)$$

The normal force at this point, designated by N_0, is equal to X_1,

$$N_0 = \frac{Q}{\pi}\left(\frac{r}{R} - \frac{a}{R} - \frac{3}{4}\right) \ldots\ldots\ldots\ldots\ldots (49)$$

Designating the resulting ring moment in the first quadrant by M_1, then, from Equations (41), (48), and (49),

$$M_1 = M_0 + N_0\,R\,(1 - \cos u) + M_s \ldots\ldots\ldots\ldots\ldots (50)$$

or,

$$M_1 = \frac{Q\,R}{2\pi}\left[u \sin u + \frac{3}{2}\cos u - \frac{\pi}{2} + \frac{2\,a}{R}\left(\cos u - \frac{\pi}{4}\right)\right] \ldots (51)$$

Designating the resulting ring moment in the second quadrant by M_2, then

$$M_2 = M_0 + N_0\,R\,(1 - \cos u) + M_s + M_A \ldots\ldots\ldots\ldots (52)$$

and, with reference to Equation (42),

$$M_2 = -\frac{Q\,R}{2\pi}\left[(\pi - u)\sin u - \frac{3}{2}\cos u - \frac{\pi}{2} - \frac{2\,a}{R}\left(\cos u + \frac{\pi}{4}\right)\right]. (53)$$

A comparison of Equations (51) and (53) shows that the absolute moment values in both quadrants are the same. Except for the opposite sign, the moment curves are symmetrical about the horizontal diameter. On account of symmetry in loading the moments in the third and fourth quadrant are identical with those in the second and first quadrant.

In order to determine the maximum moments it will be sufficient, therefore, to consider the first quadrant only. Extreme values occur at $u = 0$, at $u = \frac{\pi}{2}$, and at some intermediate angle, which is found by differentiating Equation (51) with respect to u, thus,

$$u \cot u = \frac{1}{2} + \frac{2\,a}{R} \ldots\ldots\ldots\ldots\ldots\ldots (54)$$

The maximum intermediate moment, designated by M_i, is obtained by substituting in Equation (51) the value of u given by Equation (54). Designating the moment for $u = \frac{\pi}{2}$ by M_a, Equation (51) gives,

$$M_a = -\frac{Q\,R}{4} \times \frac{a}{R} \ldots\ldots\ldots\ldots\ldots\ldots (55)$$

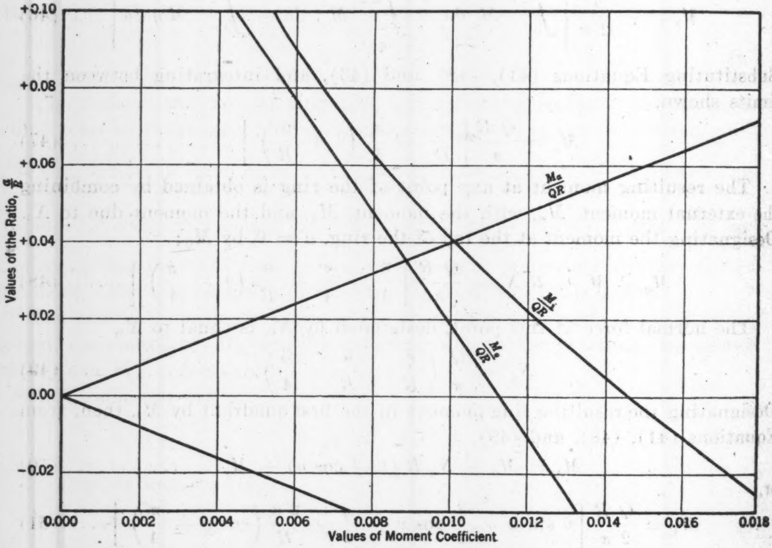

FIG. 7.—BENDING MOMENTS IN SUPPORTING RING.

Fig. 7 shows the absolute values of M_o, M_i, and M_a plotted in the function of the ratio, $\frac{a}{R}$. The eccentricity, a, is taken as positive when the reactions are applied outside the neutral axis of the supporting ring. The minimum possible ring moment is obtained for $\frac{a}{R} = +\,0.04$, in which case,

$$M_i = M_a = 0.010\;Q\,R \ldots\ldots\ldots\ldots\ldots\ldots (56)$$

Fig. 8 illustrates the moment distribution for this case.

Karlsson,[11] by a different method, has derived the maximum ring moment for the special case, $a = 0$. He also quotes the absolute minimum moment derived by Hoeckerberg.[12] Fig. 7 checks both these values.

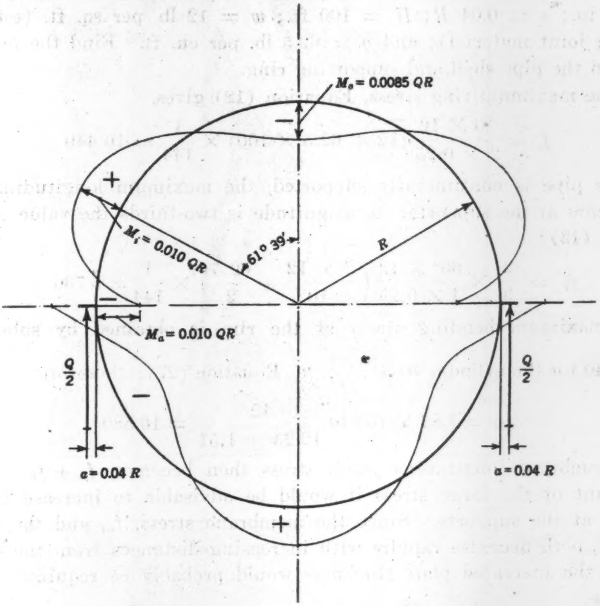

FIG. 8.—BENDING MOMENTS IN SUPPORTING RING FOR $\frac{a}{R} = 0.04$.

The maximum normal ring force, due to the shearing forces, s, occurs at $u = \frac{\pi}{2}$ and is designated by N_a, expressed by the relation,

$$N_a = \frac{Q}{4} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (57)$$

This force exerts compression just above, and tension just below, the horizontal diameter. Since, for $\frac{a}{R} \geqq +0.04$, the maximum bending stress is also found at this point, a somewhat smaller combined stress will be obtained with $+0.04 > \frac{a}{R} > 0.00$.

In addition to the normal force, N_a, the ring is stressed by the tensile force, N_t, Equation (30), which is independent of $\frac{a}{R}$, but can assume large values for higher heads in combination with thicker shells.

EXAMPLE AND APPLICATIONS

Assume a pipe line, continuously supported by circular rings, and having the following characteristics: $D = 10$ ft.; $t = \frac{1}{4}$ in.; $L = 60$ ft.; $A_r = 1$ in. by 12.25 in.; $a = 0.04\ R$; $H = 100$ ft.; $w = 12$ lb. per sq. ft. (estimated, including joint material); and $q = 62.5$ lb. per cu. ft. Find the maximum stresses in the pipe shell and supporting ring.

For the maximum ring stress, Equation (12) gives,

$$f_r = \frac{10 \times 12}{2 \times 0.25}(12 + 62.5 \times 100) \times \frac{1}{144} = 10\ 440$$

Since the pipe is continuously supported, the maximum longitudinal beam stress occurs at the supports; its magnitude is two-thirds the value given by Equation (13):

$$f_L = \frac{2}{3} \times \frac{60^2 \times 12}{4 \times 0.25}\left(\frac{2 \times 12}{10} + \frac{62.5}{2}\right) \times \frac{1}{144} = 6\ 730$$

The maximum bending stress at the rim is obtained by substituting $f_r = 10\ 440$ for the cylinder stress, $\frac{p\ r}{t}$, in Equation (27); therefore,

$$f_{bo} = 1.82 \times 10\ 440\ \frac{12}{12.25 + 1.51} = 16\ 580$$

The combined longitudinal shell stress then becomes, $f_L + f_{bo} = 23\ 310$. On account of the large stress it would be advisable to increase the shell thickness at the supports. Since the membrane stress, f_L, and the bending stress, f_{bo}, both decrease rapidly with increasing distances from the supporting disk, the increased plate thickness would probably be required for only one course.

The total reaction, in pounds, transmitted to one supporting ring is, $Q = 60\ (\pi \times 10 \times 12 + \pi \times 5^2 \times 62.5) = 317\ 000$. Fig. 7, with $\frac{a}{R} = 0.04$, gives for the maximum ring moment, in inch-pounds, $M = 0.010 \times 317\ 000 \times 66.25 = 210\ 000$. The maximum bending stress in the supporting ring then is, $f_1 = \frac{210\ 000 \times 6}{12^2} = 8\ 750$.

From Equation (57) the maximum normal ring stress due to the shearing forces, s, equals $f_2 = \frac{317\ 000}{4 \times 12} = 6\ 610$. The normal ring stress due to radial forces, from Equation (30), equals $f_3 = \frac{43.4 \times 60}{16}\left(1 + 6.04 \times \frac{12}{12.25 + 1.51}\right) = 1\ 020$. Since all these stresses occur combined at the horizontal diameter, the maximum fiber stress, (tension), in the supporting ring becomes, $f = f_1 + f_2 + f_3 = 16\ 380$.

Although principally developed for large pipe lines, the preceding analysis, with due modifications, may also be used for the design of horizontal storage tanks, tank cars, flumes, and under-water tubes supported on piers, etc.

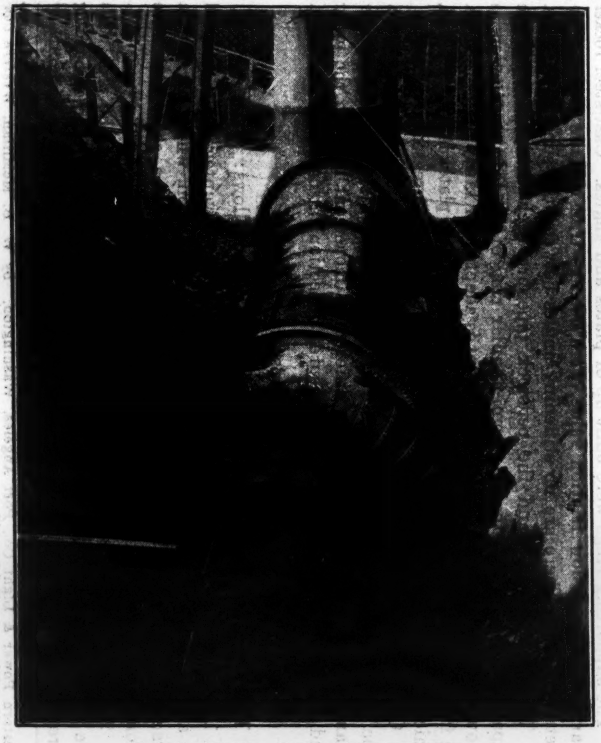

FIG. 9.—GLINES CANYON PRESSURE PIPE.

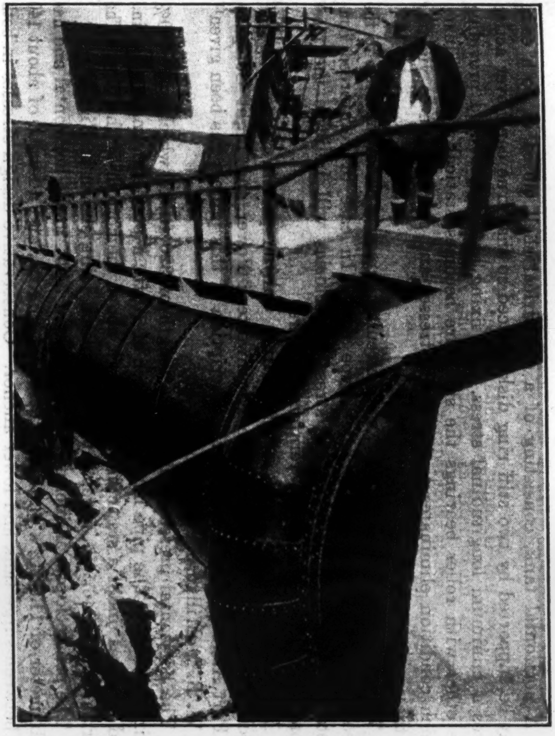

FIG. 10.—GLINES CANYON PENSTOCK PIPE.

A horizontal tank, consisting of a cylindrical shell closed at both ends, may be supported by two stiff ring disks spaced so that true cantilever action gives a minimum longitudinal stress. By fixing one support and providing the other with roller bearings the structure becomes statically determinate, which condition eliminates temperature stresses and stresses due to yielding of the supports.

The design of self-supporting, semi-circular flumes is closely related to the theory of the Zeiss-Dywidag barrel-type roof. In case of reinforced concrete construction, the principal stress trajectories will indicate the most economical direction of the reinforcing bars.

Figs. 9 and 10 are views of the Glines Canyon pressure pipe and penstock, designed and built for the Northwestern Power and Light Company at Port Angeles, Wash. A general description of this project has been given[13] by W. B. McMillan, M. Am. Soc. C. E.

The horizontal pressure pipe has a length of 320 ft., of which about 70% is in a tunnel. The pipe has a diameter of 10 ft., a plate thickness of $\frac{7}{16}$ in., and operates under a static head of 120 ft. above the bottom of the pipe. The normal span is 46.5 ft., except at the expansion joint, shown in Fig. 9.

The penstock pipe is inclined at an angle of 34.5° to the horizontal and has a diameter of 11.5 ft., a plate thickness of $\frac{1}{2}$ to $\frac{3}{4}$ in., and a length of about 140 ft. between surge tank and lower anchor. Conservative design stresses in both pipes were adopted on account of water-hammer action.

The supporting rings were built up of plates and angles. Cast-steel rocker bearings, giving a low friction value, were used to transmit the load to concrete footings. There are no stiffening angles between the supporting rings.

The pressure pipe and the penstock pipe are each equipped with one expansion joint, consisting of a semi-annular ring of riveted construction, as shown in Figs. 9 and 10. This type of joint is adapted for fairly high pressures. In future installations, electric butt-welding of the joint plates is contemplated, which will give a more economical joint combined with increased flexibility.

Observations made on the empty pipe by M. Juul Hvorslev, Assoc. M. Am. Soc. C. E., show that the temperature variation at the top is considerably larger than at the bottom, which causes a differential movement between the upper and lower part, as confirmed by the measured deflections at the expansion joint.

CONCLUSIONS

The writer has reached six major conclusions as follows:

1.—Cylindrical shells, subject to water loads, are advantageously designed in accordance with the theory of thin shells of revolution, which permits an exact knowledge of the stress distribution and leads to a safer and more economical design than the customary empirical methods.

2.—If the pipe is supported by stiff, disk-shaped members, the pipe walls are mainly subject to direct stresses, except for a very narrow zone of bending stresses at the supports. For this reason the shell is entirely stable without any

intermediate stiffening rings, thus permitting the use of large spans in combination with thin plates.

3.—On account of the reduced number of supports the use of bearings with small friction values becomes feasible. In connection with expansion joints it is possible practically to eliminate temperature stresses.

4.—The larger spans permit easy access for painting, and, in many cases, the cost of excavation can be considerably reduced.

5.—Due to the small deformations under all conditions of loading the joints remain tight.

6.—Pipe lines thus designed present a pleasant appearance, because the finished structure expresses the typical properties of a thin shell.

DISCUSSION

L. J. MENSCH,[14] M. AM. SOC. C. E. (by letter).—This interesting paper is too abbreviated for American practice. It is based on a number of German articles on the strength of membranes, the authors of which claim to have obtained simple working formulas by making simplifying assumptions in the treatment of the subject as found in Professor Love's "Treatise of the Mathematical Theory of Elasticity." The author accepts their differential equations on trust and then calls his product an exact theory. This latter expression is constantly found in all prominent works on elasticity from Professor St. Venant on, but the writer considers it very misleading and unjustified by tests and experience. Geometry is considered an exact science for the purpose of the engineer (but not for that of the astronomer as Riemann and Einstein have showed), but the new sciences of mechanics and strength of materials are not advanced far enough to treat of exact theories in these branches. Engineers have no exact column theory, nor an exact beam theory, but simply a belief that their hypotheses lead to formulas with a more or less approximation of the truth.

Equations (2) and (3) were obtained by omitting a great many factors from what Professor Love calls the equations of equilibrium of an infinitesimal part of the surface of a membrane. It seems that for the case of a full-circle pipe, simply supported around its periphery, these equations lead, as the author shows, to useful results which agree with the common theory; it should be noted, however, that his assumption of stresses for a continuous pipe on many supports cannot be derived from Equations (2) and (3), but are based on the common theory of bending only. Dischinger used these equations for the design of elliptically shaped roofs, but in such cases the writer found that his stresses deviate as much as 50% from those obtained by the common theory, and although the firm with which he is connected, made large-sized tests to prove to the public the safety of its concepts, the writer finds that the test objects were largely over-designed, although to the ordinary engineer they appear extremely bold and novel. Let it be stated that similar roofs were constructed in the United States ten to twenty years before they were tried in Germany.

The practicing engineer will not have the time nor the opportunity to look up all the authorities cited by the author and this might lead him to disregard, or look with suspicion upon this valuable paper. The writer is pleased to state that more than twenty years ago he obtained the same results as the author by a much simpler method, and can attest the correctness of Equation (28). He knows that Equation (29) was obtained by a difficult chain of reasonings, with many approximations; it may be correct. He can give, however, some data on the condition of restraint which will simplify the understanding and work of the designer. The rim stresses of $1.82\,\frac{pr}{t}$

---

[14] Gen. Contr., Chicago, Ill.

become zero at the distance, $x = 0.588\sqrt{rt}$. A reversed maximum moment occurs at nearly twice this distance from the rim, namely, $1.15\sqrt{rt}$, and these reversed stresses amount to $0.4\frac{pr}{t}$. In the author's example, $r = 60$ in. and $t = \frac{1}{4}$ in.; hence, the two critical distances are 2.75 in. and 4.40 in., respectively. This shows that there are great changes of stress in a very short distance, involving considerable shear, and this part of the pipe should be carefully designed, with low stresses, which practice was recommended to his students by Professor Grashof more than fifty years ago. In the design of the circular ring disk the consideration of the Lamé stresses might be advisable in most cases.

W. P. ROOP,[15] M. AM. SOC. C. E. (by letter).—This interesting and important paper gives a theoretical analysis of a novel type of support for horizontally disposed, thin-walled tubes. In the section headed, "Direct Stresses in Pipe Shell," solutions are offered for the stresses due to weight of tube and contents, carried by the tube itself, considered as a girder, and also as modified by the tensile stresses in the shell (rim stresses) due to hydrostatic pressure. In a second section these rim stresses receive more detailed study, especially as affected by the supports, consisting of very rigid peripheral stiffeners. The stresses in these rings themselves are considered in a third section, and the paper closes with examples showing the practical advantages of this type of construction.

The mathematical procedure is somewhat formal, but the details could doubtless be readily reconstructed by one who wished to follow the analysis through closely. The summary is excellent. The present comment is confined to references to related work not quoted, and to emphasizing some features which may possibly not otherwise come to the notice of the casual reader.

A structure of circular form draws enormous benefit with respect to its rigidity from its symmetry, and the application studied by Mr. Schorer, while extending to various cases mentioned under "Example and Applications," by no means exhausts the usefulness of such a symmetrical form. As examples, the writer wishes to cite the cantilevers upon which he reported in 1929[16] and the tubes under external pressure discussed by Messrs. H. E. Saunders and D. F. Windenburg in a paper[17] entitled "Strength of Thin Cylindrical Shells Under External Pressure."

It is necessary, of course, that the circular form be adequately maintained, and the peripheral stiffener has been found to be an effective means of doing this. In the cases thus far mentioned, the interior of the shell is left open and the stiffeners are rings, inside or outside. In other cases, however, it is possible to use diaphragms extending entirely across the section of the cylinder. Such, for example, are the transverse bulkheads in a submarine. Although surface ships depart widely from circular sections, the form is approximately cylindrical on a section partly symmetrical. The typical structure is reproduced naturally in the stem of the bamboo plant.

[16] *Transactions*, Am. Soc. Mech. Engrs., Vol. 51 (1), 1929 (A. P. M.-51-7), p. 69.

[17] *Loc. cit.*, Sept.-Dec., 1931, Applied Mechanics, (A. P. M.-53-17A).

Turning again to Mr. Schorer's paper, it is noted that his numerical example shows stresses of an acceptable intensity in pipe the diameter of which is 480 thicknesses supported only by peripheral stiffeners at intervals of 6 diameters. Contrast such a structure with one of cast pipe, supported by trusses, such as may be seen in many large industrial plants. The writer believes that there is no doubt that savings in weight of the order of one-half or more of that used in continuous structures of traditional type can be made in many cases by close analysis of the requirements of accurately specified loads, and that a structure of continuous character may be built up of plates shockingly thin if due attention is given to their favorable disposition and to their adequate support even at rather widely spaced boundaries. Such a structure will generally be characterized by high rigidity and by relative immunity to complete failure due to moderate local damage. In general, the more specific the load, however, the greater the liability to injury through occurrence of unforeseen loads.

The use of thin plating perhaps has extended further in ship building (and aircraft construction) than in other branches of engineering. Structures of high weight efficiency and, at the same time, high adaptability to undetermined loads have been developed, very largely through empirical and evolutional methods. It has more than once occurred that analysis like that used by Mr. Schorer has led to the conclusion that the type of structure evolved by experience has merits which the analysis reveals clearly without being able to carry them much further. Experience has thus rather blindly found the way in advance of analysis. Such cases, however, are exceptional; analysis can proceed systematically and, at least, greatly accelerate progress toward the structure perfectly designed for its function.

JOHANNES SKYTTE,[18] **ASSOC. M. AM. SOC. C. E.** (by letter).—The author is to be commended for producing this paper. It is the writer's belief that this method can be applied with advantage in many cases to the design of pipe lines and other cylindrical structures.

Primary Stresses in the Pipe Shell.—The stress condition will be general only when it involves the radial shears, S_r and S_l, and the moments, M_r and M_l (see Fig. 11). However, S_l and M_l are very small quantities for any partial filling of pipe and will be herein considered equal to zero.

For the three cases treated in the paper, namely, (1) dead weight of pipe; (2) pipe just full; and (3) pipe under pressure,

$$S = -C \sin u \quad \text{.......................} (58)$$

in which, C is a constant. Consequently, T_1 has a straight-line variation as for ordinary beams, and S_r and M_r become equal to zero.

---

[18] Asst. Hydr. Engr., Hetch Hetchy Project, San Francisco, Calif.

The general formulas, Equations (59), (60), and (61), are derived by projection on the three axes. Equation (62) is derived by taking the moment around the X-axis.

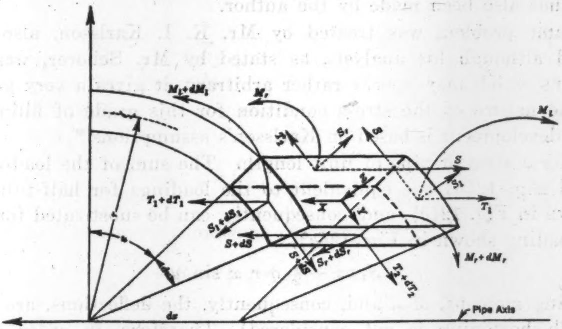

FIG. 11.

Projection on the Z-axis gives:

$$Z\ r\ du\ dx + (T_2 + dT_2)\ dx\ \tfrac{1}{2}\ du + T_2\ dx\ \tfrac{1}{2}\ du + dS_r\ dx = 0$$

or,

$$T_2 = -r\left(Z + \frac{dS_r}{r\ du}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (59)$$

Projection on the Y-axis gives:

$$Y\ r\ du\ dx + (T_2 + dT_2)\ dx - T_2\ dx - 2S_r\frac{du}{2}dx + (S + dS)\ r\ du - S\ r\ du = 0$$

or,

$$dS = -\frac{d\,T_2\ dx}{r\ du} + \frac{S_r}{r}\ dx - Y\ dx$$

and, consequently,

$$S = -\int\frac{d\ T_2}{r\ du}\ dx + \int\frac{S_r}{r}\ dx - \int Y\ dx + C_1 \ \ldots\ldots\ldots (60)$$

Projection on the X-axis gives, in a similar way:

$$T_1 = -\int\frac{dS}{r\ du}\ dx - \int X\ dx + C_2 \ \ldots\ldots\ldots\ldots\ldots (61)$$

Moment around the X-axis gives:

$$dM_r + r\ du\ S_r = 0$$

or,

$$M_r = -r\int S_r\ du + C_3 \ \ldots\ldots\ldots\ldots\ldots\ldots\ldots (62)$$

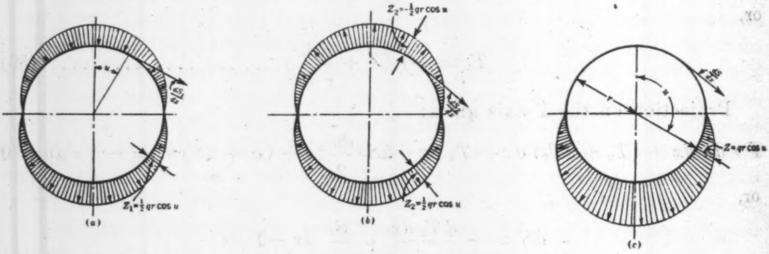
Pipe Partly Filled.—For the case of a pipe partly filled the stress condition becomes very complicated, and, to the writer's knowledge, the general solution for this case has not yet been made. For half-full condition, however, a very thorough and complete analysis has been made[19] by Mr. A. Frey Samsioe, of Stockholm, Sweden, in a volume of about 100 pages, to which reference has also been made by the author.

The same problem was treated by Mr. K. I. Karlsson, also of Stockholm, and although his analysis, as stated by Mr. Schorer, was based on assumptions which may appear rather arbitrary, it gives a very good indication of the nature of the stress condition for this grade of filling, and the following development is based on Karlsson's assumptions.[20]

Consider a slice of pipe of unit length. The sum of the loadings in Fig. 12(*a*) and Fig. 12(*b*) are equivalent to the loadings for half-full condition, or as shown in Fig. 12(*c*), and, consequently, can be substituted for the latter. For the loading shown in Fig. 12(*a*),

$$S_1 = -\tfrac{1}{2}\, q\, r\, x \sin u$$

and the ring moment, M_{r1}, and, consequently, the deflections, are zero at all points (rib-shortening is not considered). Therefore, in order to find the resulting ring moment, M_{r1}, one needs only to consider the loading as in Fig. 12(*b*). In this case the deflection will cause a shortening of the horizontal diameter and a lengthening of the vertical diameter.



u
$\frac{1}{2}\frac{dS_1}{dx}$
$Z_1 = \frac{1}{2} qr \cos u$
(a)
$Z_2 = -\frac{1}{2} qr \cos u$
$\frac{1}{2}\frac{dS_2}{dx}$
$Z_2 = \frac{1}{2} qr \cos u$
(b)
$\frac{dS}{dx}$
r
u
$Z = qr \cos u$
(c)

FIG. 12.

This deformation will be resisted greatly by the rigid ring support and will cause a tangential shear, gradually decreasing from the ring support to the center of the span, where it becomes equal to zero. Since the shear must be symmetrical about the two axes and zero at the ends of the axes it is reasonable to assume that:

$$S_2 = f \times \tfrac{1}{2}\, q\, r\, x \sin 2\, u$$

or,

$$\frac{dS_2}{dx} = f \times \tfrac{1}{2}\, q\, r \sin 2\, u$$

---

[19] "Die Spannungen in einem auf mehreren Stützen in gleicher gegenseitiger Entfernung aufgelegten and zur hälfte mit Wasser gefüllten Rohr," by A. Frey Samsioe, Ingeniörs Vetenskaps Akademiens Handlingar Nr. 50, Stockholm, 1926; pub. by Svenska Bokhandelscentralen, Stockholm, 1926.

[20] "Ueber Schwerkraftspannungen in Rohrleitungen von grossen Durchmessern und deren rationelle Kronstruktion," by Karl I. Karlsson, *Schweizerische Bauzeitung*, Vol. 80, September 2, 1922, p. 105.

Differentiation of Equation (60), with respect to x gives,

$$\frac{dS_2}{dx} = -\frac{dT_2}{r\,du} + \frac{S_r}{r} - Y$$

since $Y = 0$,

$$\frac{dS_2}{dx} = -\frac{dT_2}{r\,du} + \frac{S_r}{r} = f \times \tfrac{1}{2}\, q\, r \sin 2u \ldots\ldots\ldots\ldots\ldots (63)$$

Next, substitute $Z_2 = -\frac{1}{2}\, q\, r \cos u$, in Equation (59), and differentiate with respect to u, thus:

$$\frac{dT_2}{du} = -r\left(\tfrac{1}{2}\, q\, r \sin u + \frac{d^2S_r}{r\,du^2}\right) \ldots\ldots\ldots\ldots\ldots (64)$$

Eliminating T_2 between Equations (63) and (64):

$$\frac{d^2S_r}{du^2} + S_r = \tfrac{1}{2}\, q\, r^2\, (f \sin 2\,u - \sin u)$$

The complete integral is:

$$S_r = \tfrac{1}{2}\, q\, r^2 \left[\frac{u \cos u}{2} - f\,\frac{\sin 2\,u}{3}\right] + C_4\, e^{+u\sqrt{-1}} + C_5\, e^{-u\sqrt{-1}}$$

For $u = 0$ and $u = \frac{\pi}{2}$, $S_r = 0$, or, $C_4 = C_5 = 0$, and, consequently,

$$S_r = \tfrac{1}{2}\, q\, r^2 \left[\frac{u \cos u}{2} - f\,\frac{\sin 2\,u}{3}\right] \ldots\ldots\ldots\ldots\ldots (65)$$

Substituting for S_r in Equation (62) and integrating:

$$M_r = -\tfrac{1}{2}\, q\, r^3 \left(\frac{\cos u}{2} + \frac{u \sin u}{2} + f\,\frac{\cos 2\,u}{6} + C_3\right) \ldots\ldots (66)$$

Since the angle between the tangents at $u = 0$ and $u = \frac{\pi}{2}$ remain unchanged:

$$\int_0^{0.5\pi} M_r\, r\, du = 0$$

or,

$$-\tfrac{1}{2}\, q\, r^3 \left[\frac{\sin u}{2} + \frac{\sin u}{2} - \frac{u \cos u}{2} + f\,\frac{\sin 2\,u}{12} + C_3\, u\right]_0^{0.5\pi} = 0$$

or, $C_3 = \frac{1}{2}\, q\, r^3 \frac{2}{\pi}$, and, consequently Equation (66) becomes:

$$M_r = -\tfrac{1}{2}\, q\, r^3 \left(\frac{\cos u}{2} + \frac{u \sin u}{2} + f\,\frac{\cos 2\,u}{6} - \frac{2}{\pi}\right) \ldots\ldots (67)$$

For a minimum of internal work, f is found equal to 0.85. Substituting this value for f:

$$M_{r0} = -\,0.0050 \times \tfrac{1}{2}\, q\, r^3$$

and,

$$M_{0.5\pi r} = -\,0.0072 \times \tfrac{1}{2}\, q\, r^3$$

For a pipe 12 ft. in diameter:

$$M_{0.5\pi r} = 0.0072 \times \tfrac{1}{2} \times 62.5 \times 6^2 \times 12 = 585 \text{ in-lb.}$$

For a $\frac{5}{16}$-in. shell:

$$f_s = \frac{585 \times 6}{\left(\frac{5}{16}\right)^2 \times 12} = 3\,000 \text{ lb. per sq. in.}$$

The value of T_1 is found next by substituting for $\dfrac{dS}{du}$ in Equation (61):

$$S = S_1 + S_2 = -\tfrac{1}{2}\, q\, r\, x\, [\sin u - 0.85 \sin 2\, u] \;\ldots\ldots\ldots (68)$$

and,

$$\frac{dS}{du} = -\tfrac{1}{2}\, q\, r\, x\, [\cos u - 1.70 \cos 2\, u] \;\ldots\ldots\ldots\ldots (69)$$

Then, by substitution in Equation (61), since $X = 0$,

$$T_1 = -\frac{1}{r}\int -\tfrac{1}{2}\, q\, r\, x\, (\cos u - 1.70 \cos 2\, u)\, dx + C_2$$

$$= \tfrac{1}{2}\, q\, \frac{x^2}{2} (\cos u - 1.70 \cos 2\, u) + C_2 \ldots\ldots\ldots\ldots\ldots (70)$$

For a simply supported pipe, with $x = \dfrac{L}{2}$, $T_1 = 0$, and Equation (70) becomes,

$$T_1 = \tfrac{1}{2}\, q\, (\cos u - 1.70 \cos 2\, u) \left(\frac{x^2}{2} - \frac{L^2}{8}\right) \ldots\ldots\ldots\ldots (71)$$

For $u = \pi$,

$$T_1 = -1.35\, q \left(\frac{x^2}{2} - \frac{L^2}{8}\right)$$

or 1.35 times the value derived for a pipe exactly full.

For continuously supported pipe:

$$T_1 = \tfrac{1}{2}\, q\, (\cos u - 1.70 \cos 2\, u) \left(\frac{x^2}{2} - \frac{L^2}{24}\right) \ldots\ldots\ldots\ldots (72)$$

Mr. Karlsson has also given some measurements for the deformations due to ring stresses for the old Kungfors pipe line in Sweden.[22] If the pipe when empty is considered to have zero deformation, then the maximum deformation for the pipe half full at the center line of the span amounts to $\frac{1}{6}$ in. The pipe is built of $\frac{5}{16}$-in plate with no stiffeners between supporting rings and has a diameter of about 9 ft. and is 38 ft. between the supports. This condition indicates clearly that a direct stress condition exists, practically, for this grade of filling since a possible ring moment of any consequence would cause considerably more deflection.

---

[22] *Schweizerische Bauzeitung*, September 2, 1922.

According to Mr. Samsioe,[22] pipe lines of $\frac{1}{4}$-inch. plate, 12.5 ft. in diameter, and 43 ft. span, and with no stiffeners between the supporting rings, are common practice in Sweden.

***Rim Stresses.*—An approximate value of f_{bm} for unyielding ring support can be found in the following manner. The author's notations are used**

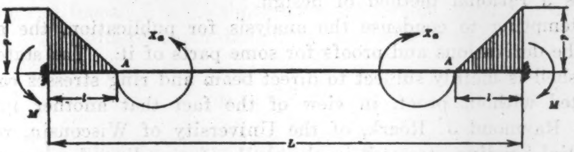


FIG. 13.

and l (Fig. 13) is the distance along the pipe axis from the center line of the ring support to the point, A, where the pipe shell practically has expanded an amount, r'_p, and, consequently, all the load is taken by the ring stresses. It is obvious that the moment at this point, A, must have a value between zero and the value, X_a, which makes the tangent to the elastic line of the pipe shell in A parallel to the pipe axis. It is also evident that the load causing the rim stresses is equal to p at the ring support; and from this point it is decreasing and becomes practically equal to zero at Point A and remains very close to zero between the two points, A.

Assume a straight-line variation of the load between the center line of the ring support and Points A. First, consider the case in which the moment at A is assumed equal to zero. Equating r'_p and the cantilever deflection:

$$\frac{\frac{1}{2}\, p\, l^4}{15\, E\, I} = \frac{p\, r^2}{E\, t}$$

or,

$$l = 1.26 \sqrt{r\, t} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (73)$$

$$M = 0.264\, p\, r\, t \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (74)$$

and,

$$f_{bm} = 1.58\, \frac{p\, r}{t} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (75)$$

In a similar way, for the case in which the moment at A is assumed equal to $X_a = \frac{1}{24}\, p\, l^2$,

$$f_{bm} = \frac{2.58\, p r}{t} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (76)$$

Taking the average of the two values in Equations (75) and (76):

$$f_{bm} = 2.08\, \frac{p\, r}{t} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (77)$$

or 14% more than the value found by the author.

---

[22] **By letter to the writer.**

Donald E. Larson,[23] **Jun. Am. Soc. C. E.** (by letter).—There has been a noticeable scarcity of data for use in the design of large pipe lines. Something can be learned from records of past failures, but such information is not generally available to engineers because failures are not advertised. Mr. Schorer's analysis is a valuable contribution to the subject because it introduces a rational method of design.

In attempting to condense the analysis for publication, the author has omitted the derivations and proofs for some parts of it. The statement that the pipe shell is mainly subject to direct beam and ring stresses can scarcely be accepted without proof, in view of the fact that another investigator, Professor Raymond J. Roark, of the University of Wisconsin, reports circumferential bending stresses[24] in the shells of pipe lines having supports of the same type as those discussed by the author. Furthermore, the results of the two studies should be in agreement because both investigators used the same distribution of longitudinal horizontal shearing stress.

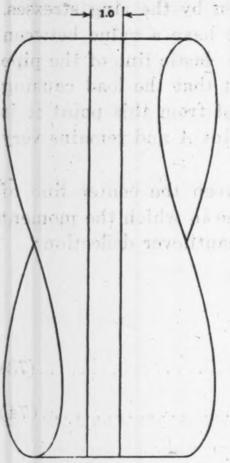

Fig. 14.

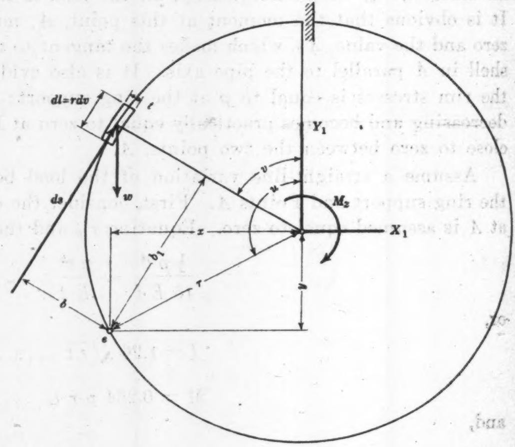

Fig. 15.

The writer has made a study to determine the reason for the disagreement in regard to circumferential bending stresses in the shells of pipes subject to dead load and full water load. An analysis is submitted as proof for the following statements:

(1) There are no circumferential bending stresses in the pipe shell under dead load if the shearing stresses act tangentially as indicated by the author.

(2) There are no circumferential bending stresses in the pipe shell under full water load if the shearing stresses act tangentially.

(3) The shearing stresses do act tangentially as indicated in the author's analysis.

The notation is that introduced by Mr. Schorer, except as otherwise given.

[24] "A Study of Circumferential Bending of Pipes and Cylindrical Containers", *Bulletin No. 69*, Eng. Experiment Station Series, Univ. of Wisconsin, Madison, Wis.

Example (1).—Circumferential Bending Due to Dead Load.—A portion of a pipe having a unit length is shown in Fig. 14. The forces acting on this ring are the shears on the end faces and the weight of the ring itself. The forces tending to produce circumferential bending in the ring are: (1) The weight of the ring; and (2), the difference of the tangential shearing forces on the end faces. Fig. 15 shows these forces acting on a small element of the ring. The difference in tangential shearing forces is given by the following equation:

$$ds = \frac{A\bar{y}\,dQ}{2I} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (78)$$

in which, ds is the tangential shear per unit of circumference, due to change in total shear, dQ. In this case,

$$dQ = 2\pi\, r\, w \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (79)$$

$$A\bar{y} = 2\, r^2\, t \sin v \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (80)$$

and,

$$I = \pi\, r^3\, t \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (81)$$

Substituting,

$$ds = -\, 2\, w \sin v \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (82)$$

Following the Müller-Breslau equations for forces at the neutral point,

$$M_z = \frac{\int M_e\, dl}{\int dl} = \frac{1}{2\,\pi}\int_0^{2\pi} M_e\, du \quad \ldots\ldots\ldots\ldots (83)$$

$$X_1 = \frac{\int M_e\, y\, dl}{\int y^2\, dl} = \frac{1}{\pi\, r}\int_0^{2\pi} M_e \cos u\, du \quad \ldots\ldots\ldots\ldots (84)$$

$$Y_1 = \frac{\int M_e\, x\, dl}{\int x^2\, dl} = \frac{1}{\pi\, r}\int_0^{2\pi} M_e \sin u\, du \quad \ldots\ldots\ldots\ldots (85)$$

in which, M_e is the moment of all forces between the top of the ring and the point, e, about the point, e.

Referring to Fig. 15,

$$M_e = -\int_0^u ds\; b\; r\; dv + \int_0^u w \sin v\; b\; r\; dv - \int_0^u w \cos v\; b_1\; r\; dv \;.. (86)$$

and,

$$b_1 = r \sin (u - v) = r (\sin u \cos v - \cos u \sin v) \quad \ldots\ldots (87)$$

$$b = r\, [1 - \cos (u - v)] = r\, (1 - \cos u \cos v - \sin u \sin v) \quad \ldots (88)$$

Substituting these values of b_1 and b in Equation (86) and performing the indicated integration,

$$M_e = -\, w\, r^2\, (1 - \cos u) \quad \ldots\ldots\ldots\ldots\ldots\ldots (89)$$

Substituting this value of M_e in Equations (83), (84), and (85), and integrating between the limits, 0 and 2π,

$$M_z = -\, w\, r^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (90)$$

$$X_1 = +\, w\, r \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (91)$$

$$Y_1 = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (92)$$

The moment in the ring at any point is,

$$M = -M_z - X_1 r \cos u + M_e \ldots\ldots\ldots\ldots\ldots (93)$$

Substituting the values of M_z, X_1, and M_e from Equations (90), (91), and (89), respectively,

$$M = w r^2 - w r^2 \cos u - w r^2 (1 - \cos u) = 0 \ldots\ldots\ldots (94)$$

This indicates that there is no circumferential bending in the shell of a truly circular pipe due to dead load, providing the shearing forces act tangentially as shown in Fig. 15.

Example (2).—Circumferential Bending Due to Water Load.—Fig. 16 shows the water-load forces tending to produce circumferential bending in the ring. These are: (1) The outward forces due to water pressure; and (2) the difference between tangential shearing forces on the end faces. In this case,

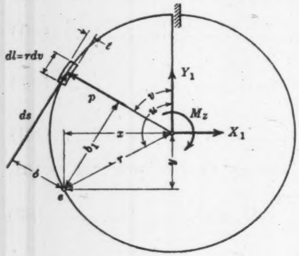

FIG. 16.

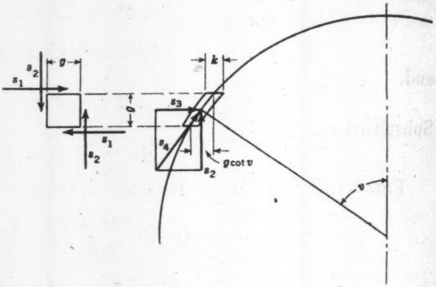

FIG. 17.

$$dQ = q \pi r^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (95)$$

Substituting this value in Equation (78),

$$ds = -q r \sin v \ldots\ldots\ldots\ldots\ldots\ldots\ldots (96)$$

The outward force at any point is given by the relation,

$$p = qr (1 - \cos v) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (97)$$

The moment at the point, *e*, of all the forces between the top of the ring and *e* is,

$$M_e = -\int_0^u ds\ b\ r\ dv + \int_0^u p\ b_1\ r\ dv \ldots\ldots\ldots\ldots (98)$$

Substituting the values of *s*, *b*, *p*, and b_1 from Equations (96), (88), (97), and (87), respectively, and integrating between the limits, 0 and *u*,

$$M_e = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (99)$$

Therefore, $M_z = 0$, $X_1 = 0$, and $Y_1 = 0$, and the moment in the ring at any point is equal to zero. This proves that there is no circumferential bending in the pipe shell due to full water load, providing the shearing stresses act tangentially as shown in Fig. 16.

Example (3).—Tangential Shearing Stresses.—It now remains to demonstrate that the shearing forces do act tangentially. It is in this respect that the author's analysis differs from that of Professor Roark. Fig. 17 shows an element of the pipe shell having a length, g, and a vertical height, g, such that the area of each of the four faces is equal to unity. The shearing stress on the horizontal faces is given by the relation,

$$s_1 = \frac{Q A \bar{y}}{2 I k} \quad \ldots\ldots (100)$$

in which, s_1 is the unit horizontal shearing stress and,

$$k = \frac{t}{\sin v} \quad \ldots\ldots (101)$$

Substituting this value for k and the values of $A\bar{y}$ and I from Equations (80) and (81), Equation (100) becomes,

$$s_1 = \frac{Q \sin^3 v}{\pi r t} \quad \ldots\ldots (102)$$

These shearing stresses on the top and bottom faces form a couple, $s_1\, g$, tending to rotate the element in a vertical plane and a couple, $s_1\, g \cot v$, tending to rotate the element in a horizontal plane. In order to balance these couples, the shearing stresses, s_2 and s_3, must be applied to the end faces. Equating moments,

$$s_2 = \frac{s_1\, g}{g} = s_1 \quad \ldots\ldots (103)$$

$$s_3 = \frac{s_1\, g \cot v}{g} = s_1 \cot v \quad \ldots\ldots (104)$$

The resultant of s_2 and s_3 acts tangentially and has a magnitude,

$$s_4 = \sqrt{s_2^2 + s_3^2} \quad \ldots\ldots (105)$$

in which, s_4 is the tangential unit shear on the end faces.

Substituting the values of s_2 and s_3 given by Equation (103) and Equation (104),

$$s_4 = s_1 \sqrt{1 + \cot^2 v} = \frac{s_1}{\sin v} \quad \ldots\ldots (106)$$

Substituting the value of s_1 given by Equation (102),

$$s_4 = \frac{Q \sin v}{\pi r t} \quad \ldots\ldots (107)$$

This indicates that the shearing forces shown by the author are correct in both magnitude and direction.

The foregoing analysis has been based on the assumption that the horizontal longitudinal shearing stresses in the pipe vary as they would in a cylindrical beam. The author has not given the derivation of the differential equation from which this distribution of shearing stresses was obtained, but it has been shown that such a distribution results in a system of forces which hold each element of the shell in static equilibrium without the application of circumferential bending moments. Such a system of forces does a minimum amount of work and it may be argued from the principle of least not yet

work that the assumed distribution of horizontal longitudinal shearing stresses is the correct one. This being the case, there can be no doubt about the correctness of the author's statement that the pipe shell is mainly subject to direct beam and ring stresses.

Raymond J. Roark,[25] Esq. (by letter).—Because of work the writer had done some time ago on stresses in pipes and cylindrical containers, he is especially interested in Mr. Schorer's valuable paper. The conclusions to which the analysis of such stresses by the theory of elasticity leads, are surprising, and at variance with those reached from cursory consideration. The writer confesses with some chagrin that in his own analysis of these stresses, undertaken some years ago, an error with respect to the shearing stresses led to erroneous expressions for the circumferential bending moments in thin shells of the type here under consideration. The calculations then made indicated the presence of such moments in cylinders either partly or quite filled with liquid, whereas, as Mr. Schorer shows, the uneven pressure in a completely filled pipe can be resisted by a system of shearing and normal stresses which are at every point in the plane of the wall. As a consequence, there is no primary bending under these circumstances, and even a perfectly flexible diaphragm, if rigidly constrained at the ends, will retain its circular form. This fact first came to the writer's attention through an article by Thoma,[26] who shows, in essentially the same manner as Mr. Schorer, that not only in the case of a circular cylinder such as a pipe, but in the case of any developable surface, a distributed pressure can be resisted without primary bending stress.

The demonstration for the full vessel is clear and convincing, but it would appear that for a partly filled vessel some circumferential bending must occur. The writer has had no opportunity to read the paper by Mr. A. F. Samisoe to which Mr. Schorer refers, and Mr. Schorer does not state whether this analysis of the half-filled cylinder indicates the existence of bending or not; but that the pressure in any partly filled vessel cannot be resisted by stresses which are at every point in the plane of the shell would seem to be sufficiently proved by the following.

Let f_u, f_x, and τ denote, respectively, the unit stress in circumferential tension, longitudinal tension, and tangential shear; let u and x, respectively, denote distance measured circumferentially and longitudinally from any chosen origin; let p, t, and r, respectively, denote the unit pressure, thickness of the shell, and radius of the cylinder. Then, if the assumption of plane stress is correct, the following equations must apply:

$$f_u = \frac{p\,r}{t} \qquad (108)$$

$$\frac{\partial f_u}{\partial u} + \frac{\partial \tau}{\partial x} = 0 \qquad (109)$$

---

[25] Associate Prof. of Mechanics, Univ. of Wisconsin, Madison, Wis.

[26] "Die Beanspruchung freitragender gefüllten, Rohre durch das Gewicht der Flussigkeit," *Zeitschrift für das gesamte Turbinenwesen,* February 20, 1920. The discussion is extended by Schwerin in a paper "Uber die Spannungen in freitragender gefüllten Rohren," *Zeitschrift für angewanete Mathematik und Mechanik,* Vol. II, October, 1922.

$$\frac{\partial f_x}{\partial x} + \frac{\partial \tau}{\partial u} = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (110)$$

Equation (108) shows that for any point above the water line, $f_u = 0$; hence, $\frac{\partial f_u}{\partial u} = 0$ in that region, and it follows from Equation (109) that $\frac{\partial \tau}{\partial x} = 0$ and that, since $\tau = 0$ at, say, the middle of a cylinder supported at the ends, it must be zero everywhere above the water-line; but this is obviously inconsistent with the assumption of plane sections and ordinary beam action of the cylinder as a whole.

It seems, therefore, that in the partly filled cylinder there must be some circumferential bending. An analysis of this circumferential bending may be made, as follows:[27]

Let a segment of the pipe of unit length be divided by a vertical diameter; the forces acting on the resulting half-ring are as shown in Fig. 18. They comprise: (1) The unknown couples, C_1 and C_2; (2) the unknown tensions, F_1 and F_2; (3) the water pressure which, at any point at an angular distance, α, from the bottom of the ring, amounts to $p = q\, r\, (\cos \alpha - \cos \theta)$ lb. per in. of arc (q being the specific weight of the contained liquid, in pounds per cubic inch); and (4) the tangential shearing stress which, at any point at an angular distance, α, from the bottom of the ring, amounts to $\tau_s\, t = \lambda\, q\, r \sin \alpha$ lb. per in. of arc (λ being the fractional degree of fullness of the cylinder). It is easy to show that the bending moment due to these forces at any point, A, at an angular distance, α', from the bottom of the ring is, for points below the water level ($\alpha' < \theta$):

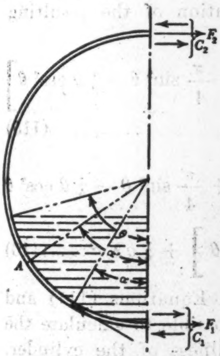

FIG. 18.—FORCES ON FREE RING (WEIGHT NEGLECTED).

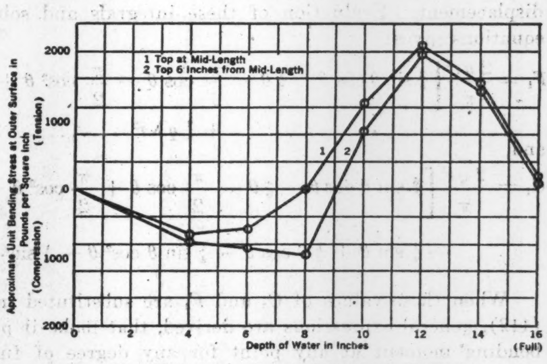

FIG. 19.—MEASURED CIRCUMFERENTIAL BENDING STRESSES ON HORIZONTAL CYLINDER.

$$M = C_1 - F_1 r\, (1 - \cos \alpha') - \lambda\, q\, r^3 \left(\tfrac{1}{2}\, \alpha' \sin \alpha' + \cos \alpha' - 1\right)$$
$$+\, q\, r^3 \left(\tfrac{1}{2}\, \alpha' \sin \alpha' - \cos \theta + \cos \theta \cos \alpha'\right) \ldots\ldots\ldots\ldots (111)$$

---

[27] For complete analysis, see *Bulletin No. 69*, Univ. of Wisconsin, "A Study of Circumferential Bending of Pipes and Cylindrical Containers." Some of the results therein presented are invalidated by the error, corrected in the present discussion, in the expression for the shear stress.

and for points above the water level ($\alpha' > \theta$), the moment is:

$$M = C_1 - F_1 r (1 - \cos \alpha') - \lambda q r^3 (\tfrac{1}{2} \alpha' \sin \alpha' + \cos \alpha' - 1)$$
$$+ q r^3 [\sin \alpha' (\tfrac{1}{2} \theta - \tfrac{1}{2} \sin \theta \cos \theta)$$
$$+ \cos \alpha' (\cos \theta - \cos^2 \theta - \tfrac{1}{2} \sin^2 \theta] \ldots\ldots\ldots\ldots\ldots (112)$$

If the shell is assumed to be perfectly flexible, $C_1 = 0$ and

$$F_1 = q r^2 (1 - \cos \theta)$$

If these values are submitted in Equations (111) and (112), they vanish for $\theta = 180°$; that is, for the case of the completely filled vessel, but do not vanish for any smaller value of θ, showing that for the partly filled vessel some bending must exist.

The existence of the couples, C_1 and C_2, is thus shown to be necessary for equilibrium, and C_1, C_2, F_1, and F_2, all become indeterminate. They may be found from the conditions of statics and the additional relations:

$$\int_0^{2\pi} M r \, d \alpha' = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (113)$$

$$\int_0^{2\pi} M r^2 (1 - \cos \alpha') \, d\alpha = 0 \ldots\ldots\ldots\ldots\ldots\ldots (114)$$

which equations simply express the facts, obvious from symmetry, that as between the bottom and the top of the ring there is neither lateral nor angular displacement. Evaluation of these integrals and solution of the resulting equations gives:

$$F_1 = \frac{2 q r^2}{\pi} \left[\tfrac{3}{8} \sin \theta \cos \theta - \tfrac{1}{8} \theta - \frac{\pi}{2} \cos \theta - \frac{\pi}{2} \cos^2 \theta + \frac{\pi}{4} \sin^2 \theta - \tfrac{1}{4} \theta \cos^2 \theta \right]$$
$$+ \tfrac{3}{4} q \lambda r^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (115)$$

and,

$$C_1 = \frac{2 q r^3}{\pi} \left[\tfrac{5}{8} \sin \theta \cos \theta - \tfrac{3}{8} \theta - \frac{\pi}{2} \cos \theta + \frac{\pi}{2} \cos^2 \theta + \frac{\pi}{4} \sin^2 \theta - \tfrac{1}{4} \theta \cos^2 \theta \right.$$
$$\left. - \tfrac{1}{4} \sin \theta + \tfrac{1}{2} \theta \cos \theta - \tfrac{1}{4} \sin \theta \cos^2 \theta - \tfrac{1}{4} \sin^3 \theta \right] + \tfrac{1}{4} q \lambda r^3 \ldots (116)$$

When these values of C_1 and F_1 are substituted in Equations (111) and (112), general expressions are derived, that make it possible to calculate the bending moment at any point for any degree of fullness of the cylinder. Obviously, such calculations must be made with the greatest precision if the results are to have any value, because the expression for M represents the algebraic sum of a large number of nearly equal terms, and even a small error in these individual terms will produce a large relative error in the result.

In order to secure a verification of the main points of the foregoing discussion, namely, that there is no circumferential bending in the full cylinder, and that there is such bending in the partly filled cylinder, the writer made some tests which, although of a rather "rough and ready" nature, may be of interest. The results are shown in Fig. 19.

A specimen was constructed which consisted essentially of a circular pipe with closed ends; the diameter was 16 in.; the length, 8 ft.; the thickness

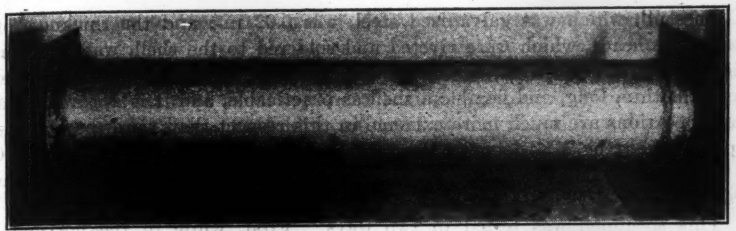

Fig. 20.—Circular Test Pipe, with Square Heads.

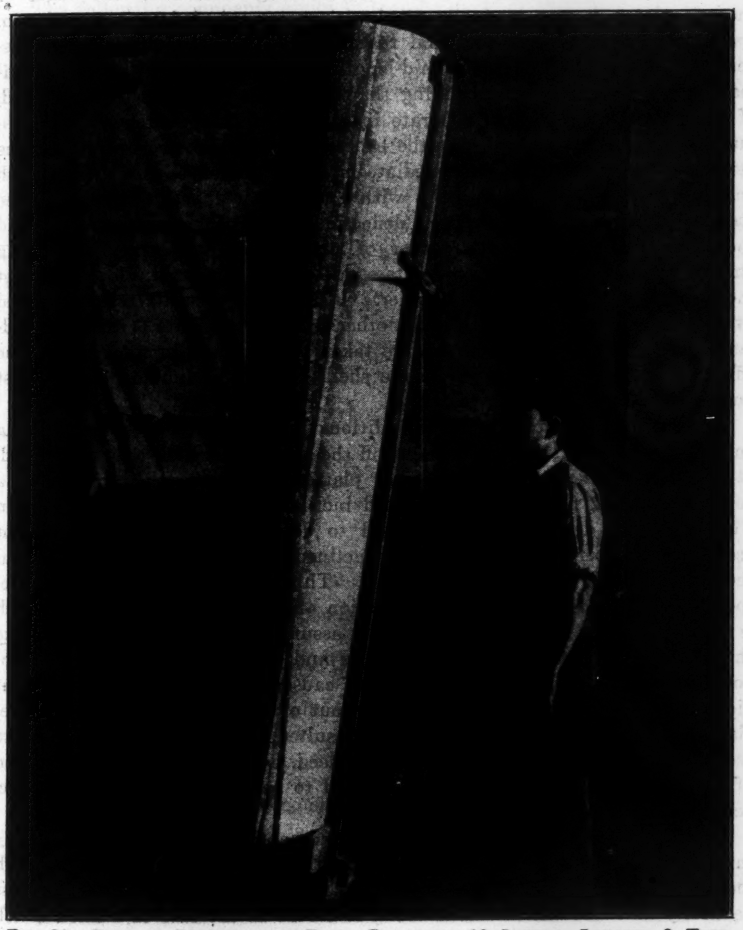

Fig. 21.—Pipe in Position for Test; Diameter, 16 Inches, Length, 8 Feet, Thickness of Shell, 0.02 Inches, and Thickness of Square Heads, 0.125 Inches.

of the shell, which was galvanized steel, was 0.02 in.; and the thickness of the square heads, which were riveted and soldered to the shell, was 0.125 in. Figs. 20 and 21 represent photographs of this specimen. It was intended to secure as thin, long, and flexible a shell as practicable, and it is apparent that the proportions are much more extreme in this respect than were those of the pipe described by Mr. Schorer, the ratio of diameter to thickness being 800 as against 44, and the ratio of unsupported length to diameter being 6 as against 3.7.

This specimen was tested in two ways. First, while in the horizontal position as shown in Fig. 20, the weight being carried by the edges of the end plates, it was gradually filled with water. A deflectometer of 4-in. span, provided with an Ames dial reading to 0.0001 in., was placed transversely on top of the vessel near mid-length, to detect and to measure approximately any circumferential bending that took place. The readings secured, of course, do not afford an accurate indication of the bending stresses produced, but if it is assumed that the bending of the 4-in. arc over which the deflectometer reached, was intermediate in form between that of a beam with end couples and that of a beam with end supports and center load, the stresses corresponding to a given deflection could be easily computed, and should represent roughly the order of magnitude of the actual bending stresses produced. Fig. 19 represents stresses thus computed, plotted against the degree of fullness of the cylinder. One curve represents results secured by measurements at mid-length, the other by measurements 6 in. from mid-length; the two sets of readings were taken to eliminate in some degree the effect of irregularities in form of the shell—flat spots, dimples, etc.—almost unavoidable in such a thin plate.

Second, in order to simulate conditions in a stand-pipe or tank during an earthquake shock, one end was cut off the specimen, which was then bolted, at the other end, to a heavy timber platform. It was then placed in a vertical position, filled with water, and inclined to the vertical as shown in Fig. 21. The deflectometer was used to detect any bending that might occur at the upper end, but even when inclined as steeply as 9° to the vertical the bending was practically negligible. This degree of inclination corresponds roughly to a horizontal acceleration of 5.1 ft. per sec. per sec., which is in excess of the acceleration ordinarily assumed in design when earthquake shock is taken into account. By raising and lowering one end of the supporting platform rapidly, the tank was caused to oscillate with sufficient violence to result in water being thrown out over the top, and yet no appreciable distortion of the cross-section resulted. No effort was made to ascertain accurately the acceleration produced, but from a rough observation of the amplitude and period it was judged to be at least 4 or 5 ft. per sec. per sec.

Although these tests were manifestly crude and the results unquestionably influenced by geometrical irregularities in the specimen and the very rough method used for measuring the stresses, they seem to show none the less definitely that circumferential bending is absent in the case of a filled vessel, and is present, but ordinarily negligible, in the case of a partly filled vessel. It is quite possible, however, that circumstances might occur in which the stresses in this latter case were large enough to be serious in the event of frequent reversal, as in the case of a paper digester or other rotating vessel. For pipes and tanks of usual proportions, however, these stresses would almost certainly be well below the endurance limit of the materials ordinarily used.

F. W. Hanna,[28] **M. Am. Soc. C. E.** (by letter).—The author has presented a useful technical analysis of the design of large pipe lines. The writer has checked this analysis with much interest, and agrees in general with the methods and results obtained.

The following comments apply to specific parts of the paper:

(1) In Equations (38) and (40) the moment, M_s, is negative rather than positive, as given by the author, because he has elsewhere assumed counter-clockwise moments to be negative and because the signs of moments are not determinable from the signs of either the arms or the forces involved.

(2) Equation (39) seems to be incorrectly stated and Equation (37) seems to be incorrectly used in the derivation of Equation (41). The writer suggests the following development.

Using the author's diagrams and nomenclature, the load on the pipe carried to one disk due to the pipe's weight and the water's weight for the condition when the pipe is filled just to the top,

$$Q = [\pi (r + t)^2 - \pi r^2] \frac{w L}{2} + q \pi r^2 \frac{L}{2} \text{ .... } (117)$$

or,

$$Q = \frac{\pi L}{2} [(2 r t + t^2) (w + q r^2)] \text{ .... } (118)$$

Since t^2 is small compared with $2 r t$, it may be dropped without serious error; then, multiplying by $\frac{\sin v}{\pi r}$,

$$\frac{Q \sin v}{\pi r} = \frac{L}{2} (2 t w + q r) \sin v \text{ .... } (119)$$

Applying the author's Equations (5) and (9) to Fig. 6 for the angle, v,

$$s = \frac{L}{2} (2 t w + q r) \sin v \text{ .... } (120)$$

Equating the values of the right members of Equations (119) and (120),

$$s = \frac{Q}{\pi r} \sin v \text{ .... } (121)$$

Since counter-clockwise moments are assumed to be negative, the moment, M_s, of the shearing force, s, is,

$$M_s = - \int_0^u b s r \, dv \text{ .... } (122)$$

---

[28] Chf. Engr. and Gen. Mgr., East Bay Municipal Utility Dist., Oakland, Calif.

Also, from Fig. 6, it is clear that,

$$\cos (u - v) = \frac{r - b}{R} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (123)$$

Transposing, solving for b, and expanding $\cos (u - v)$ in Equation (123),

$$b = r - R (\sin u \sin v + \cos u \cos v) \ldots\ldots\ \ldots\ldots (124)$$

Substituting the value of b from Equation (124) and the value of s from Equation (121) in Equation (122), and re-arranging,

$$M_s = \frac{Q\,R}{\pi} \int_0^u (\sin u \sin^2 v + \cos u \cos v \sin v - \frac{r}{R} \sin v)\, dv \ldots (125)$$

Intergrating Equation (125) between the limits of u and 0, the following final value of M_s is obtained,

$$M_s = \frac{Q\,R}{\pi} \left[\frac{u \sin u}{2} - \frac{r}{R} (1 - \cos u) \right] \ldots\ldots\ldots\ldots (126)$$

Thus, it is apparent that the error in the author's value for b in Equation (39) and his omission of the minus sign before the right-hand member of Equation (38) have cancelled one another and given the correct value of M_s in his Equation (41). The remaining results based on Equation (41) are apparently correct.

The author has developed equations for finding the total normal and bending stresses in the circular supporting disk to moment only. There are stresses due also to thrust and shear, and while those due to shear are generally very small, those due to thrust may be quite considerable. The total normal bending and shearing stresses involving the effect of rib-shortening, moment, and shear, may be found by the writer's method of arch dam analysis.[29]

In short, this method involves the principle of deflections through the application of a rigid bracket between the free end of the cut section and the elastic center. Redundant forces at this point replace the released forces, and also the dummy unit loads at the elastic center. The deflection formula when complete contains terms that provide: (1) For deflection due to rib-shortening; (2) for that due to bending moment; (3) for that due to shear; and (4) for that due to volume changes. For the problem under discussion the third and fourth terms of the formula may be omitted, but the first two terms should be used for accuracy. The author has used only the second term, that providing for deflection due to bending moments.

Paul Bauman,[30] M. Am. Soc. C. E. (by letter).—The ring support of large pipe lines, as outlined by the author, is a decided advance from a standpoint of statical clearness, as compared to the conventional saddle support. The reactions are concentrated and their points of application exactly defined. As the actions too are well established, the actual stress due to moments and shear in the continuous system necessarily must tally closely with the theoretical ones.

---

[29] "The Design of Dams," by Messrs. Hanna and Kennedy, p. 227.

[30] Chf. Designer, Quinton, Code & Hill-Leeds & Barnard, Engrs. Consolidated, Los Angeles, Calif.

The maximum stresses in the pipe shell are likely to be higher with the ring supports than with the saddle supports of equal spacing, as in the latter case the distortion at the supports is less accentuated. The stress distribution in the latter case is too complex for an exact solution, however, and the types compare statically somewhat as a beam-and-girder slab and a flat-slab system of buildings.

Longitudinal shear is a maximum at the support where it combines with the longitudinal stress and the ring stress of the shell to a diagonal or principal stress. Referring to the author's numerical example, the shear, in pounds, on one side of the supporting ring is, $\frac{Q}{2} = \frac{317\,000}{2} = 158\,500$.

The maximum unit shear stress, s, due to $\frac{Q}{2}$, occurs in the plane of the neutral axis,

$$s = \frac{\frac{Q}{2} M_{sT}}{2\,t\,I} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(127)$$

in which, M_{sT} is the statical moment of the upper half of the shell about the horizontal axis of symmetry, and I, the moment of inertia of the shell about the horizontal axis of symmetry; but $M_{sT} = \pi\, r^2\, t \frac{\sin u}{u} = 2\, r^2\, t$; and $I = \pi\, t\, r^3$. Substituting in Equation (21), the maximum unit shear stress, in pounds per square inch, is, $s = \frac{Q\, r^2\, t}{2 t^2 \pi r^3} = \frac{Q}{2\, r\, \pi\, t} = 3\,365$. This value is checked by the author's Equations (5) and (9).

The maximum rim stress for $x \neq 0$, and a rigid ring is given by Equation (29) for,

$$\frac{d(f_{bx})}{dx} = 0 = f_{bo} \sqrt{2} \left[-\frac{e^{-\frac{x}{z}}}{z} \cos\left(\frac{x}{z} + \frac{\pi}{4}\right) - \frac{e^{-\frac{x}{z}}}{z} \sin\left(\frac{x}{z} + \frac{\pi}{4}\right) \right]$$

or,

$$\sin\left(\frac{x}{z} + \frac{\pi}{2}\right) = 0 \ldots\ldots\ldots\ldots\ldots\ldots(128)$$

which is the case for $\frac{x}{z} = \frac{\pi}{2}$; $\frac{3\pi}{2}$; .. etc.; and, since, $z = 0.78 \sqrt{r\,t} = 3.025$, x for $f_{bx} \Big]_{\text{min.}}^{\text{max.}} = 4\tfrac{3}{4}$ in.; $14\tfrac{1}{4}$ in.; etc. For $x = 4\tfrac{3}{4}$ in.,

$$f_{bx} \text{ min.} = 1.82 \frac{pr}{} \sqrt{2} \left[\frac{1}{4.81} \times \frac{-\sqrt{2}}{2} = -0.379 \frac{pr}{t} \right] \ldots.(129)$$

and for $x = 14\tfrac{1}{4}$ in.,

$$f_{bx} \text{ max.} = \frac{4.81}{112} \times 0.379 \frac{pr}{t} = +0.0163 \frac{pr}{t} \ldots\ldots\ldots\ldots(130)$$

Introducing numerical values, namely, $p = 100 \frac{62.50}{144} = 43.30$ lb. per sq. in.; $r = 60$ in.; and $t = \frac{1}{4}$ in.; f_{bx} min. $= -3\,950$ lb. per sq. in.; and f_{bx} max. $= +170$ lb. per sq. in.

Neglecting the weight of the pipe, the ring stress at $x = 4\frac{3}{4}$ in. is not due to the full pressure, p, because that is partly carried longitudinally by beam action. To determine this beam load:

$$M_x = Ke^{-\frac{x}{z}} \cos\left(\frac{x}{z} + \frac{\pi}{4}\right) \ldots\ldots\ldots\ldots\ldots\ldots (131)$$

in which, $K = f_{bm} \frac{t^2}{6} \sqrt{2}$. Then,

$$\frac{dM_x}{dx} = Q_x = -\frac{Ke^{-\frac{x}{z}}}{z}\left[\sqrt{2} \sin\left(\frac{x}{z} + \frac{\pi}{2}\right)\right] = -\frac{Ke^{-\frac{x}{z}}}{z} \sqrt{2} \cos\frac{x}{z} \, .(132)$$

and,

$$\frac{d^2M_x}{dx^2} = q_x = -\frac{K\sqrt{2}}{z}\left[-\frac{e^{-\frac{x}{z}}}{z} \sin\frac{x}{z} - \frac{e^{-\frac{x}{z}}}{z} \cos\frac{x}{z}\right]$$

$$= +\frac{2K}{z^2} e^{-\frac{x}{z}} \sin\left(\frac{x}{z} + \frac{\pi}{4}\right) \ldots\ldots\ldots\ldots\ldots\ldots (133)$$

for $x = 0$, $q_x = p$, which checks; and for $x = 4\frac{3}{4}$ in.,

$$q_x = \frac{2 \times 1.82 \frac{pr}{t} \times \frac{t^2}{6} \sqrt{2}}{0.607\, r\, t} \left[\frac{1}{4.81} \frac{+\sqrt{2}}{2}\right] \ldots\ldots (134)$$

or, $q_x = 0.208\ p$. This gives a ring stress, $f_r = \frac{rp\,(1 - 0.208)}{t} = +8\,250$ lb. per sq. in. The unit shear stress, s, at $x = 4\frac{3}{4}$ in., based on $s = 0$ for $x = \frac{L}{2}$, is $s = \frac{12 \times 30 - 4.75}{360} \times 3\,365 = 3\,320$ lb. per sq. in.

In the plane of the neutral axis the longitudinal stress, $f_L = 0$. At $x = 4\frac{3}{4}$ in., therefore, $s = \pm 3\,320$ lb. per sq. in. $= \tau$; $f_{bx} = -3\,950$ lb. per sq. in. $= \sigma_x$; and $f_r = +8\,250$ lb. per sq. in. $= \sigma_y$.

The principal stresses are: $\sigma_{\text{max.}} = \frac{-3\,950 + 8\,250}{2} + \frac{1}{2}\sqrt{4\,(3\,320)^2 + 12\,200^2}$ $= +2\,150 + 6\,940 = +9\,090$ lb. per sq. in.; $\sigma_{\text{min.}} = -4\,790$ lb. per sq. in.; and $\tau_{\text{max.}} = \pm 6\,940$ lb. per sq. in.

If the unit shear stress, s ($= \pm 3\,365$ lb. per sq. in.), is combined with the maximum rim bending stress, f_{bo} ($= \pm 16\,580$ lb. per sq. in.), and if $\sigma_y = 0$: $\sigma_{\text{max.}} = 8\,290 + \frac{1}{2}\sqrt{4\,(3\,365)^2 + 16\,580^2} = +17\,240$ lb. per sq. in., which is still only 74% of $f_L + f_{bo}$, which occurs on top of the shell at the supports. The latter is the critical tensile stress which is economically met by thickening the pipe locally as suggested by the author.

Equation (29), properly modified, permits determining the elastic line of the shell, for example,

$$\frac{EI}{1-m^2}\frac{d^2y}{dx^2}=M=Ke^{-\frac{x}{z}}\cos\left(\frac{x}{z}+\frac{\pi}{4}\right)=K'\left[e^{-\frac{x}{z}}\cos\frac{x}{z}-e^{-\frac{x}{z}}\sin\frac{x}{z}\right]. \quad (135)$$

in which, $K'=1.82\,\frac{prt}{6}$. Furthermore,

$$\frac{EI}{1-m^2}\frac{dy}{dx}=K'\left[\int e^{-\frac{x}{z}}\cos\frac{x}{z}dx-\int e^{-\frac{x}{z}}\sin\frac{x}{z}dx\right]+C_1\ \ldots(136)$$

or,

$$\frac{EI}{1-m^2}\frac{dy}{dx}=K'z\left[e^{-\frac{x}{z}}\sin\frac{x}{z}\right]+C_1\ldots\ldots\ldots\ldots\ldots(137)$$

for $x=0$; $\frac{dy}{dx}=0$; and $C_1=0$. Also,

$$\frac{EI}{1-m^2}y=-\frac{K'z^2}{2}\left[e^{-\frac{x}{z}}\left(\sin\frac{x}{z}+\cos\frac{x}{z}\right)\right]+C_2$$

$$=-\frac{K'z^2}{2}\left[e^{-\frac{x}{z}}\sqrt{2}\sin\left(\frac{x}{2}+\frac{\pi}{4}\right)\right]+C_2\ldots\ldots\ldots\ldots\ldots(138)$$

for $x=0$; $y=0$; and $C_2=+\frac{K'z^2}{2}$. Thus,

$$\frac{EI}{1-m^2}y=\frac{K'z^2}{2}\left[1-\sqrt{2}\,e^{-\frac{x}{z}}\sin\left(\frac{x}{z}+\frac{\pi}{4}\right)\right]\ldots\ldots\ldots(139)$$

in which, $\frac{K'z^2}{2}=\frac{1.11\,pr^2t^3}{12}$; and $I=\frac{t^3}{12}$.

Making the proper substitutions in Equation (139),

$$Ey=\frac{pr}{t}\left[1-\sqrt{2}\,e^{-\frac{x}{z}}\sin\left(\frac{x}{z}+\frac{\pi}{4}\right)\right]\ldots\ldots\ldots\ldots(140)$$

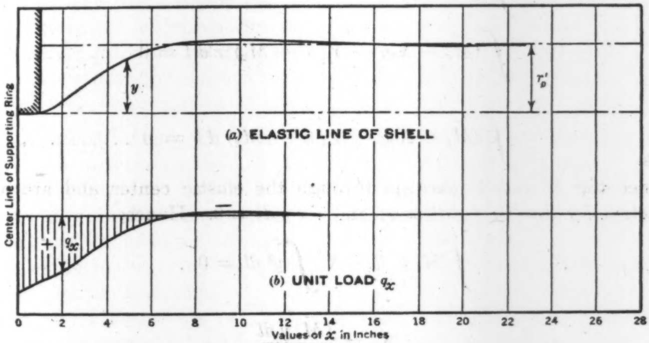

FIG. 22.

In using the numerical values as given in the author's example, a line as shown in Fig. 22, results. As x continues to grow, the term with $e^{-\frac{x}{z}}$ approaches zero and $E\,y$ approaches the ring distortion, r'_p. The loading, q_x, per unit area is shown in Fig. 22(b).

The line of pressure of the statically indeterminate supporting ring could readily be found graphically or analytically by means of the ellipse of elasticity, as previously shown by the writer.[31]

The problem is particularly simple, because the ellipse of elasticity in this case is a circle. Due to symmetry, it is sufficient to consider one-half only, either left or right. As a boundary condition, Reaction *A* or Reaction *B* must be tangent to the line of pressure.

A Check of Equations (31), (32), and (33).—The work of deformation is expressed by,

$$A = \int \frac{M^2}{2\,EI}\,dl \quad\text{.....................}(141)$$

and the condition of least work is,

$$\frac{\partial A}{\partial X_1} = \int \frac{M\left(\dfrac{\partial M}{\partial X_1}\right)}{EI}\,d\,l = 0\text{..............}(142a)$$

$$\frac{\partial A}{\partial Y_1} = \int \frac{M\left(\dfrac{\partial M}{\partial Y_1}\right)}{EI}\,d\,l = 0\text{..............}(142b)$$

and,

$$\frac{\partial A}{\partial M_z} = \int \frac{M\left(\dfrac{\partial M}{\partial M_z}\right)}{EI}\,d\,l = 0\text{..............}(142c)$$

Since $\dfrac{\partial M}{\partial X_1} = -\,y$; $\dfrac{\partial M}{\partial Y_1} = -\,x$; and $\dfrac{\partial M}{\partial M_z} = -\,1$:

$$\int (M_e - X_1 y - Y_1\,x - M_z)\,y\,d\,l = 0 \quad\text{............}(143a)$$

$$\int (M_e - X_1 y - Y_1\,x - M_z)\,x\,d\,l = 0 \quad\text{...........}(143b)$$

and,

$$\int (M_e - X_1 y - Y_1\,x - M_z)\,d\,l = 0 \quad\text{............}(143c)$$

Since the *X* and *Y* axes go through the elastic center and are axes of symmetry, $\int y\,dl = 0$; $\int x\,dl = 0$; and $\int x\,y\,dl = 0$. Hence,

$$\int M_e\,y\,dl - X_1 \int y^2\,dl = 0 \quad\text{...................}(144)$$

or,

$$X_1 = \frac{\int M_e\,y\,dl}{\int y^2\,dl} \quad\text{........................}(145a)$$

$$Y_1 = \frac{\int M_e x\,dl}{\int x^2\,dl} = 0\text{....................}(145b)$$

---

[31] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), pp. 1672–1674.

and,

$$M_s = \frac{\int M_s\, dl}{\int dl} = 0 \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots (145c)$$

which check Equations (31), (32), and (33).

The total tension in the supporting ring is given by Equation (30), or, in general terms, by Equation (19). This is only approximately correct as the ratio between the outside and inside diameters of these rings may vary quite considerably from unity. The tension is then no longer uniformly distributed over the cross-section, but has a maximum intensity on the inside, and a minimum on the outside, of the ring.

If r_i is the inside radius; r_o, the outside radius; and $p' = pc + 2\,H$; then,

$$f_i = p'\,\frac{r_o^2 + r_i^2}{r_o^2 - r_i^2} = p'\,\frac{r_o^2 + r_i^2}{(r_o + r_i)A_r} \;\ldots\ldots\ldots\ldots\ldots (146)$$

instead of, $f_s = \frac{p'\,r_1}{A_r} = 1\,020$ lb. per sq. in.

Let $pc + 2H = p' = \frac{A_r\,f_s}{r} = 204$ lb. per sq. in.; $r_i = 60$ in.; and $r_o = 72$ in. Then, the maximum tensile stress, using the same numerical values as before, is, $f_s = 204\,\frac{5\,200 + 3\,600}{1\,600} = 1\,125$ lb. per sq. in., or an increase of 10 per cent.

The author's formulas are also applicable to flanged pipes of small shell thickness.

For penstocks on steep inclines the weight component in the direction of the axis must be introduced. It produces a tensile stress if the pipe is anchored on top of the incline, which is a desirable arrangement. The expansion joint is then located either at the bottom of each run or immediately below the anchor point, depending on its type.

The elimination of uncertainties in the outer or inner stability of structures should be made an outstanding task by all designing engineers.

The author has again contributed to the clarification of statical systems and deserves the appreciation of his colleagues.

L. J. LARSON,[82] ASSOC. M. AM. SOC. C. E. (by letter).—This interesting paper gives a concise analysis of the action of a thin-walled large pipe supported by ring girders. It also indicates, to a striking degree, the advantage that may be gained by supporting a structure so as to carry the loads by direct, instead of bending, stresses. The dead-load stresses in a thin pipe improperly supported, may be greater than those due to the pressure for which the pipe is designed.

Referring to Equations (4), (5), and (6), it is interesting to note that all the unit stresses obtained by dividing each by the shell thickness, t, are independent of the thickness, since $\frac{hw}{t}$ is the weight per unit volume of the material in the pipe.

---

[82] Research Engr., A. O. Smith Corporation, Milwaukee, Wis.

Taking the weight of steel as 0.283 lb. per cu. in., the maximum values for the unit stresses are: $\frac{T_2}{t} = 0.283\,r$; $\frac{S}{t} = 0.283\,L$; and $\frac{T_1}{t} = \frac{0.283}{r} \times \frac{L^2}{4}$.

The unit ring stress obtained from Equation (4) is particularly striking when it is compared to the bending stresses in a similar pipe without ring girders, supported continuously along the bottom. Using the values assumed by the author under "Example and Applications," the ring stress due to dead load is equal to: $\frac{T_2}{t} = 0.283 \times 60 = 16.98$ lb. per sq. in. If a pipe of the same dimensions were supported on a horizontal plane the maximum bending stress would be, approximately, $2.5\,\frac{r^2}{t}$, or 36 000 lb. per sq. in. While it is true that this bending stress can be reduced materially by supporting the pipe on a larger area, or along two lines at the ends of the horizontal diameter, still the stress will be proportional to $\frac{r^2}{t}$, and large, thin pipes will be subject to high stresses and considerable deformation.

In the derivation of stresses in the pipe and the supporting ring, the author assumes that the shearing stresses in the pipe are applied to the ring. It would be of interest to know to what extent the results are affected if the ring is attached to the pipe only at intervals and, also, if the ring is not attached but fits the pipe snugly. The amount of slip or relative movement between the pipe and the ring, necessary to relieve all the shearing stresses may be very small, and if such movement occurs the ring will act as if it were unattached. The action of a loose ring may not be serious unless it changes the entire state of stress in the pipe and invalidates the equations developed. If the author has made any analysis based on a loose ring support, the results will be helpful.

In the application of the author's equations to tanks it would also be of interest to know to what extent the usual type of convex, "dished" heads act as ring girders. Such heads are not as stiff as flat plates in the radial direction, but they will withstand a considerable radial load without collapsing. As far as the head itself is concerned it could probably be used as a disk or ring girder in supporting a tank, but, it is a question whether the small movements or deformations permitted in the shell by such a support are sufficient to change the action of the entire shell in resisting the dead and live loads. If the author can show that the theory holds for tanks with various types of heads, his analysis will find many additional applications.

C. M. ORR,[33] ESQ. (by letter).—Reference has frequently been made to the bending stresses in the rim zone of a pipe line due to restraint of the pipe at the support. It has been customary to say that these stresses "shall be considered in the design," or "cannot be neglected in the design," although cases of similar restraint may be pointed out in which the effects of the restraint are neglected. While the existence of these stresses, approaching 1.82 times the $\frac{pr}{t}$ cylinder stresses, is not questioned, it may be argued that they may be neglected as logically or safely in the case of a pipe shell as in the case of the following:

---

[33] Asst. Research Engr., Chicago Bridge & Iron Works, Chicago, Ill.

(1) In the shells of vertical, flat-bottom storage tanks, near the connection to the bottom, the bending stresses approach the theoretical 1.82 $\frac{pr}{t}$ value; yet it is in accordance with standard specifications to consider only the $\frac{pr}{t}$ tension stresses in the design.

(2) In the shells of elevated, suspended bottom tanks, near the connection to the bottom, bending stresses are introduced, due to the restraint of a horizontal circular girder. This girder is necessary to resist the inward thrust from inclined tower posts, but its effect on shell stresses is commonly neglected, it being usual to consider only $\frac{pr}{t}$ tension stresses in the shell design.

(3) In the case of every pressure container composed of a cylindrical shell with closed ends, the shell is restrained to some extent by the ends, yet the design is based on stresses due to pressure.

While it is recognized that, in some respects, the foregoing examples are not identical with the pipe line, they are presented with the idea of suggesting that bending stresses due to restraint are not necessarily of prime importance in pipe-line design.

The combination of rim bending stresses with longitudinal stresses due to beam moments would affect only a small section of the pipe. The effect of overstressing the pipe by this combination would be some local change of shape affecting a small area, rather than failure of the pipe as a whole. If this change of shape were sufficient to cause a permanent distortion over this small area, it would be of such small extent and relatively small magnitude as to be negligible. Common precice permits not only the use of material previously stressed beyond its yield point, but it also permits working stresses in this material comparable with stresses in material which has not been previously distorted.

Complete elimination of all bending stresses in the rim zone due to restraint may be imagined. If it were practical to make the diameter of the ring equal to that of the pipe when expanded by full pressure, and then to stretch the shell plate at the ring to this increased diameter, leaving the remainder of the shell unchanged, no rim bending would occur under full load.

If it were possible to support the shell at the ring by radial members projecting from the shell through holes in the ring, in such a manner that expansion of the pipe under pressure were permitted, no rim bending stresses would occur.

Either of these suggestions would probably be impractical, but the writer mentions them with the idea of emphasizing the thought that they are also unnecessary. Because similar restraint stresses are safely ignored in other structures, and because of the limited area of pipe affected by such stresses, and the small possibility of serious distortion over this area, may not these stresses be neglected in large pipe lines?

Edward J. Bednarski,[34] Assoc. M. Am. Soc. C. E. (by letter).—The author has presented an interesting study of the reaction exerted by a thin-walled pipe ($\frac{r}{t}$ = 200 and more) on a support in the form of a rigid ring or a diaphragm when the pipe is horizontal and precisely full. In Conclusion 2 he states that,

> "If the pipe is supported by stiff, disk-shaped members * * *, the shell is entirely stable without any intermediate stiffening rings, thus permitting the use of large spans in combination with thin plates."

The "Complete Report on Construction of the Los Angeles Aqueduct" contains the statement that $\frac{1}{4}$ in. is the minimum thickness of steel plate that can be used for pipes as large as 10 ft. in diameter, and still maintain a satisfactory rigidity. This limit, it is claimed, gives satisfactory tensile strengths to sustain a head of as much as 144 ft.

Before it was filled, the Nine-Mile Siphon (designed diameter, 9.5 ft.), of the Los Angeles Aqueduct[35] measured 9 ft. vertically and 9.81 ft. horizontally. Under a pressure of 50 lb. per sq. in., these inside dimensions changed to 9.54 ft. and 9.58 ft., respectively.

The pipe was placed on concrete piers, 2 ft. wide, spaced 24 ft., center to center, and cast to fit the pipe. When two adjacent piers on a side hill, settled away from the pipe, the span was 72 ft. This pipe when filled remained suspended without injury until the defective supports could be replaced.

In another instance[36] a break occurred in a section of the aqueduct composed of a 10-ft. pipe, with $\frac{1}{4}$-in. and $\frac{5}{16}$-in. shells, crossing the Antelope Valley in the Mojave Desert region. The water escaped rapidly, under a head of 200 ft., and the pipe collapsed like an emptied fire hose for a distance of nearly 2 miles. At some points the top of the pipe was forced down to within a few inches of the bottom. After the break was mended the water was turned on and the pipe restored to its original form by pressure.

In the example given by the author the pipe has all the characteristics of the Los Angeles Aqueduct line, with a pressure of almost 50 lb. per sq. in. Therefore, it might possibly stand up for some time on similar piers, with a span of 60 ft.

The property of this kind of a pipe, when empty, to change its shape to another cross-section when under pressure, proved to be an asset. The thin-walled pipe cannot stand the bending stresses any more than the cables of a suspension bridge. It seems that under a liquid load of comparatively light specific gravity a thin-walled circular pipe with a comparatively high modulus of elasticity, just full, cannot assume any shape except that of a circle (regardless of the method by which the dead weight of the pipe and the liquid is supported), because a circle is a contour containing a maximum possible area for a given perimeter or a contour of a maximum expansion. As any other shape contains less area, a pipe in order to take this other shape would have to expel a part of the liquid it contains. If it is assumed that the water cannot escape from the pipe, the pipe may change the form of its cross-section to another form containing the same area only by elongation of its perimeter. For a very small elongation a distortion consequently should be insignificant. In the case of a thin-walled rubber pipe filled with mercury the shape of the pipe will change quite considerably with every particular method of support. It is probable, that for the ring-like support at the ends, the rubber pipe will retain a circular cross-section throughout its length.

---

[34] La Verne, Calif.

[35] "Complete Report on Construction of the Los Angeles Aqueduct," Dept. of Public Service, Los Angeles, Calif., 1916, p. 195.

[36] *Loc. cit.*, p. 29.

Due to the flexibility of the pipe walls the bending stresses should be insignificant. Any additional internal pressure will add to the stability of the circular shape of the pipe and make it more nearly a perfect circle. In the case of a 10-ft. pipe, a head of 100 ft. makes a difference of only 10% between the pressures at the top and at the bottom, or 4.33 lb. per sq. in., as compared with the total of 43.3 lb. per sq. in. This is not enough to produce any considerable distortion. In the foregoing case the distortion is $\frac{1}{2}$ in. for 50-lb. pressure on a pipe 9 ft. 6 in. in diameter. It should be noted that the pipe in this case was supported by concrete piers "2 ft. wide, and only 3 or 4 ft. of circumference of the pipe was bearing on the pier."[37]

The supports of the Los Angeles Aqueduct type seem to have the following advantages:

1.—They do not require special reinforcement for the pipe at the pier due to the difference between the rigidity of the pipe and the supporting ring, causing the additional bending stresses near the ring.[38] Thus, the pipe may be made of plates with uniform thicknesses for its entire horizontal length.

2.—The location of the piers may be changed if necessary in the field without causing any inconvenience.

3.—Uniform thickness of the pipe wall insures the pipe from being damaged beyond recovery in case a sudden vacuum occurs in the line and the relief valves fail to act promptly and efficiently.

The disadvantage of the Los Angeles Aqueduct type of pier seems to be the necessity of using shorter spans of 24 ft., as against 60 ft. for the ring-girder supports. It would be interesting to know what would happen to the Antelope Pipe Line in the Mojave Desert region if it were supported by ring girders and piers.

H. C. Boardman,[39] **M. Am. Soc. C. E.** (by letter).—As used by Mr. Schorer, the terms "exact theory," "exact stress condition," and "exact knowledge," are repugnant to the writer. "Exact theory" teases the mind for definition; "exact knowledge" of "exact stress conditions" is a goal constantly striven for, but seldom attained.

The author states that the governing design stresses in the shell of a pipe line are "derived," but his derivation consists essentially of a statement of the Bauersfeld differential Equations (1), (2), and (3), which are unfamiliar to American engineers, and their application to a simple beam with cylindrical section. The resulting equations for transverse shear and direct longitudinal stresses are shown to agree with those obtained by the ordinary theory of flexure applied to a simple, hollow, cylindrical beam. Is this, in the mind of the average reader, an indication of the validity of the Bauersfeld equations, or of the validity of the beam formulas? The transition to the case of multiple supports is made by the statement, "It can be shown that, in case of continuous pipe lines, the direct longitudinal stresses can also be derived from the theory of continuous beams." The implication is that the longitudinal stresses in continuous pipe lines have been derived by the use of the Bauersfeld equations alone, without the use of the theory of continuous beams. The writer is unable to make this derivation. Partial liquid loadings, to which the Bauersfeld equations are presumably not applicable, because the surface loads are discontinuous, are treated by a rather cursory reference to a paper[40] written by Mr. A. Frey Samsioe covering half-full liquid loading.

The writer feels that the author would have accomplished his purpose more directly, and to the greater satisfaction of American engineers, if he had omitted Equations (2) and (3) and simply stated, as in effect he has, that:

(*a*) The shell of a cylindrical pipe line full of liquid, and kept essentially round at two or more supports, acts as a memorane free from bending stresses, except for a narrow zone near the supports.

(*b*) Under the conditions of Statement (*a*), the shearing stresses on a transverse section of the shell are necessarily tangential, and are distributed in accordance with the ordinary theory of flexure as applied to a hollow, cylindrical beam.

(*c*) Under the conditions of Statement (*a*), the longitudinal shell stresses may be obtained by an application of the ordinary beam formulas.

With Statement (*a*) granted, Equations (1), (4), (8), (11), and (12) follow directly from the equations of statics expressing the equilibrium of inward and outward radial forces on a differential element of the shell.

Still more convincing, in the writer's opinion, would have been an application of the well-known Mueller-Breslau Equations (31), (32), and (33), to an analysis of the dead load and the full liquid load stresses in a ring cut out of the pipe some distance from the supports by two transverse planes, 1 in. apart—the ring being held in equilibrium by tangential shearing forces distributed as in a hollow, cylindrical beam, by vertical dead weight forces, and by radial pressure forces. Such an analysis leads very simply to Equations (4) and (8), and to zero bending stresses.

---

[39] Research Engr., Chicago Bridge & Iron Works, Chicago, Ill.

[40] "Die Spannungen in Einem auf Mehreren Stützen in gleicher, gegeseitiger Entfernung Aufgelegten und zur Hälfte mit Wasser Gefüllten Rohr," by A. Frey Samsioe, Stockholm, 1926.

Mr. Schorer has done a great service in calling attention to the fact that the shearing stresses on a ring between two transverse planes are tangential. Other investigators, the writer among them, have fallen into the error of considering only the vertical components of the shearing forces on the edges of the ring. A little consideration will disclose the fact that the shearing forces must be tangential to satisfy the laws of statics as applied to a differential arc of the ring.

It is unfortunate that the author treats so lightly the conditions of partial liquid loading. It is feared that many engineers who, like the writer, do not read German, will fail to obtain a translation of Mr. Samsioe's paper, and, as a result, will harbor a suspicion that the full liquid loading emphasized by the author is not critical. For this reason the following analysis of ring stresses in a pipe half full of liquid is offered in the hope that, in combination with a test to be discussed later, it will help others, as it has helped the writer, to gain a clearer idea of the true stress conditions. The notation is essentially that of the author; departures therefrom are self-explanatory.

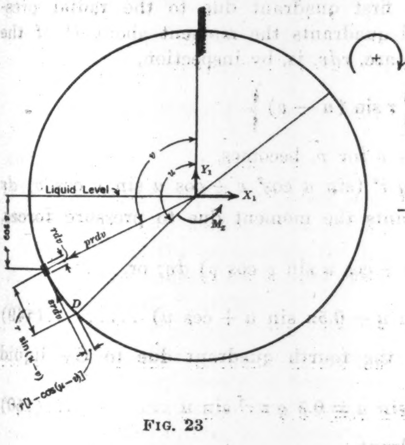

FIG. 23

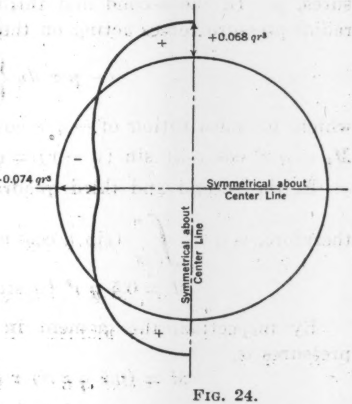

FIG. 24.

The ring chosen is 1 in. wide longitudinally, and the transverse plane of one edge is midway between two pipe supports. The shearing stresses are first assumed to be distributed in accordance with the ordinary theory of flexure as applied to hollow, cylindrical beams, their intensities being one-half those for full liquid loading. Later, it is shown that a different shear distribution would result in practically zero moments throughout the ring, a condition which seems to correspond with the observed behavior of an experimental pipe section subsequently described.

In Fig. 23, $p = 0$ above the liquid, and below the liquid surface, $p = -q\,r \cos v$. Furthermore, $s = 0.5\,q\,r \sin v$, which is one-half the value of s for full liquid load. The forces, s and p, represent the external load system, which is symmetrical about the vertical diameter. For this reason, Y_1 is zero. The moment at the point, D, caused by the tangential shearing force on the arc, rdv, is, by inspection of Fig. 23:

$$M_D = s\,r\,dv\left\{r\,[1-\cos(u-v)]\right\}$$

which, by substitution of $0.5\,q\,r\sin v$ for s, becomes,

$$M_D = 0.5\,q\,r^2\sin v\,dv\left\{r\,[1-\cos(u-v)]\right\}$$

or,

$$M_D = 0.5\,q\,r^3\,(\sin v - \cos u\sin v\cos v - \sin u\sin^2 v)\,dv$$

In all quadrants the moment due to shearing forces, therefore, is,

$$M = 0.5\,q\,r^3\int_0^u(\sin v - \cos u\sin v\cos v - \sin u\sin^2 v)\,dv \text{ . (147)}$$

which by integration becomes,

$$M = 0.5\,q\,r^3\,(1-\cos u - \tfrac{1}{2}\,u\sin u)\ldots\ldots\ldots\ldots(148)$$

There are no moments in the first quadrant due to the radial pressures, p. In the second and third quadrants the moment about D of the radial pressure forces acting on the arc, rdv, is, by inspection,

$$-\,p\,r\,dv\left\{r\sin(u-v)\right\}$$

which, by substitution of $-\,q\,r\cos v$ for p, becomes,

$$M_D = q\,r^2\cos v\,dv\sin(u-v) = q\,r^3\,(\sin u\cos^2 v - \cos u\sin v\cos v)\,dv$$

In the second and third quadrants the moment due to pressure forces, therefore, is $q\,r^3\int_{0.5\pi}^{u}(\sin u\cos^2 v - \cos u\sin v\cos v)\,dv$; or,

$$M = 0.5\,q\,r^3\,(u\sin u - 0.5\pi\sin u + \cos u)\ldots\ldots\ldots(149)$$

By inspection, the moment in the fourth quadrant due to the liquid pressures is,

$$M = (0.5\,q\,\pi\,r^2)\,r\sin u = 0.5\,q\,\pi\,r^3\sin u\ldots\ldots\ldots\ldots(150)$$

Summarizing: In the first quadrant,

$$M_{e1} = 0.5\,q\,r^3\,(1-\cos u - 0.5\,u\sin u)\ldots\ldots\ldots\ldots(151)$$

in the second and third quadrants,

$$M_{e23} = 0.5\,q\,r^3\,(1-\cos u - 0.5\,u\sin u)$$
$$+\,0.5\,q\,r^3\,(u\sin u - 0.5\,\pi\sin u + \cos u)\ldots\ldots\ldots\ldots(152)$$

and, in the fourth quadrant,

$$M_{e4} = 0.5\,q\,r^3\,(1-\cos u - 0.5\,u\sin u) + 0.5\,q\,r^3\,(\pi\sin u)\ldots(153)$$

Equation (34) then becomes,

$$X_1 = \frac{1}{\pi\, r}\left[\int_0^{\frac{\pi}{2}} M_{e1} \cos u\, du + \int_{\frac{\pi}{2}}^{\frac{3\pi}{2}} M_{e23} \cos u\, du \right.$$

$$\left. + \int_{\frac{3\pi}{2}}^{2\pi} M_{e4} \cos u\, du \right] \ldots\ldots\ldots\ldots\ldots\ldots (154)$$

from which,

$$X_1 = -\tfrac{1}{4}\, q\, r^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (154)$$

Equation (36) becomes,

$$M_Z = -\frac{1}{2\pi}\left[\int_0^{\frac{\pi}{2}} M_{e1}\, du + \int_{\frac{\pi}{2}}^{\frac{3\pi}{2}} M_{e23}\, du + \int_{\frac{3\pi}{2}}^{2\pi} M_{e4}\, du\right] \ldots (155)$$

from which,

$$M_Z = q\, r^3 \left(\frac{1}{\pi} - \frac{1}{2}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (156)$$

By combining M_z and the moments due to X_1, with the M_e moments expressed by Equations (151), (152), and (153), the following ring moments are obtained,

$$M_1 = q\, r^3 \left(\frac{1}{\pi} - \frac{1}{4} \cos u - \frac{1}{4}\, u \sin u\right) \ldots\ldots\ldots\ldots (157)$$

$$M_2 = M_3 = q\, r^3 \left(\frac{1}{\pi} + \frac{1}{4} \cos u - \frac{\pi}{4} \sin u + \frac{1}{4}\, u \sin u\right) \ldots (158)$$

and,

$$M_4 = q\, r^3 \left(\frac{1}{\pi} - \frac{1}{4} \cos u + \frac{\pi}{2} \sin u - \frac{1}{4}\, u \sin u\right) \ldots\ldots (159)$$

A study of the expressions for Equations (157), (158), and (159) will show that the moment curves are symmetrical about both the horizontal and vertical axes (see Fig. 24).

Attention is called to the fact that the moments in Fig. 24 are those which would exist if the transverse shears were distributed in accordance with the ordinary theory of flexure as applied to hollow, cylindrical beams. They are of considerable magnitude; for example, if applied to the pipe line chosen by the author to illustrate the application of his formulas, the moment of 0.074 $q\, r^3$ for a half-full water load would result in a calculated bending stress of $\dfrac{0.074 \times 0.362 \times 60^3}{\frac{1}{6} \times \left(\frac{1}{4}\right)^2}$ = 55 000 lb. per sq. in., indicating large deformations and over-stress while the pipe is being filled.

The writer believes no such over-stress or deformation would actually occur. He has recently directed the testing of a copper cylinder, 22½ in. in diameter and 68 in. long, made of No. 24 gauge material. A wooden disk was closely fitted into each end and the cylinder was supported on four vertical wooden legs, two nailed to each disk, as shown in Fig. 25.

The cylinder was slowly filled with water, and measurements were made at the mid-section to determine the changes in shape. The recorded variations were very small, and not perceptible to the eye, although the calculated

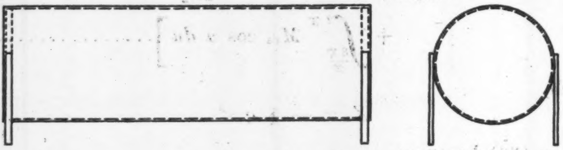

FIG. 25.

bending stress due to a moment of $0.074\ q\ r^3$ is $\frac{0.074 \times 0.0362 \times 12.25^3}{\frac{1}{6} \times (\frac{1}{40})^2}$ = 36 000 lb. per sq. in., probably more than the ultimate strength of the copper. As a check the filling and measuring were done three times, always with essentially the same result. The ratio of diameter to thickness was 900. The shells of large oil-storage tanks show a similar remarkable resistance to deformation under wind loads, if they are kept round at the top by suitable circular girders.

Only one explanation seems possible. The transverse shears must be distributed so as to result in practically no moments in rings cut out by transverse sections. A clue to the approximate magnitude and direction of the shearing forces which must be applied to a ring acted upon by shearing stresses distributed in accordance with the ordinary theory of flexure, in order to result in zero moments, may be gained by an inspection of Fig. 24. The moment graph is the general shape the ring would take if the indicated moments actually existed. It is apparent that four tangential forces acting as shown in Fig. 26 would tend to pull the ring into its original circular shape.

Assuming each of these forces to be unity, the resulting moments through the ring can be found as follows, using the Mueller-Breslau equations. Since the load system is symmetrical about the vertical diameter, Y_1 is zero. The moment of the force at A about any point, P, if $u > \frac{\pi}{4}$, is, by inspection, $-\left[r\left\{1-\cos\left(u-\frac{\pi}{4}\right)\right\}\right]$, or,

$$M = r\,(-1 + 0.707 \cos u + 0.707 \sin u) \ldots\ldots\ldots (160)$$

Similarly, the moment of the force at B about any point P, if $u > \frac{3\pi}{4}$, is,

$$M = r\,(1 + 0.707 \cos u - 0.707 \sin u) \ldots\ldots\ldots (161)$$

the moment of the force at C about any point, P, if $u > \frac{5\pi}{4}$, is,

$$M = r\,(-1 - 0.707 \cos u - 0.707 \sin u) \ldots\ldots\ldots (162)$$

and the moment of the force at D about any point, P, if $u > \frac{7\pi}{4}$, is,

$$M = r\,(1 - 0.707 \cos u + 0.707 \sin u) \qquad (163)$$

Combining: For values of u (Fig. 26), between 0° and 45° and 315° and 360°,

$$M_e = 0 \qquad (164)$$

for values of u between 45° and 135°,

$$M_{ea} = r\,(-1 + 0.707 \cos u + 0.707 \sin u) \qquad (165)$$

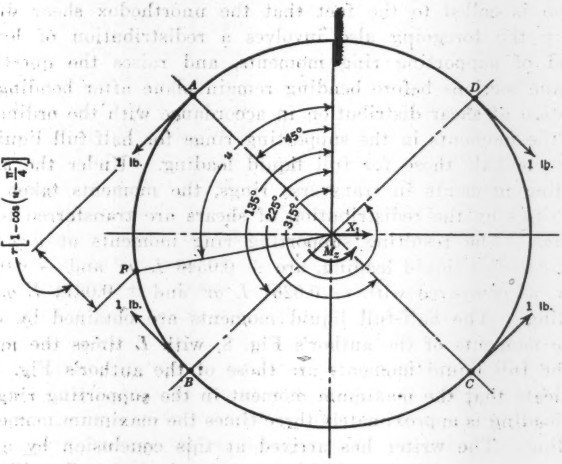

FIG. 26.

for values of u between 135° and 225°,

$$M_{eb} = r\,(1.414 \cos u) \qquad (166)$$

and, for values of u between 225° and 315°,

$$M_{ec} = r\,(-1 + 0.707 \cos u - 0.707 \sin u) \qquad (167)$$

By inspection, $X_1 = 0.707$ and Equation (36) becomes,

$$M_Z = -\frac{1}{2\pi}\left[\int_{\frac{\pi}{4}}^{\frac{3\pi}{4}} M_{ea}\,du + \int_{\frac{3\pi}{4}}^{\frac{5\pi}{4}} M_{eb}\,du + \int_{\frac{5\pi}{4}}^{\frac{7\pi}{4}} M_{ec}\,du\right] \qquad (168)$$

from which, $M_Z = 0.5\,r$.

By combining M_z in Equation (168), and the moments due to X_1 with the moments given by Equations (165), (166), and (167), ring moments of $+ 0.207\,r$, $+ 0.207\,r$, $- 0.207\,r$, and $+ 0.207\,r$, are obtained for points, $u = 0°$, $u = 90°$, $u = 180°$, and $u = 270°$, respectively. The corresponding moments of Fig. 24 are, $+ 0.068\,qr^3$, $- 0.074\,qr^3$, $+ 0.068\,qr^3$, and $- 0.074\,qr^3$, respectively, for which the arithmetical mean is $0.071\,qr^3$. It follows that a

shearing force at A, B, C, and D, of $\frac{0.071}{0.207} qr^2$, or 0.343 qr^2, in addition to the shearing forces of Fig. 23, will result in practically zero moments throughout the ring.

It is not claimed that concentrated shearing forces of 0.343 qr^2 exist at the points, A, B, C, and D of Fig. 26. The actual forces are doubtless distributed over the entire circle according to a law for which the writer has not obtained a mathematical expression. However, the foregoing crude demonstration serves to reveal the nature of the shear distribution necessary to result in practically zero ring moments under half-full liquid loading.

Attention is called to the fact that the unorthodox shear distribution suggested in the foregoing also involves a redistribution of longitudinal stresses and of supporting ring moments, and raises the question as to whether plane sections before bending remain plane after bending. Under the assumption of shear distribution in accordance with the ordinary theory of flexure, the moments in the supporting rings for half-full liquid loading are exactly one-half those for full liquid loading. Under the assumption of no bending moments in transverse rings, the moments taken from the transverse rings by the redistribution of shears are transferred to the supporting rings. The resulting supporting ring moments at $u = 0°$ and $u = 90°$, for half-full liquid loading, are $+ 0.0546\ L\ qr^3$ and $- 0.0897\ L\ qr^3$, respectively, as compared with $- 0.0267\ L\ qr^3$ and $\pm\ 0.0314\ L\ qr^3$, for full liquid loading. The half-full liquid moments are obtained by combining 50% of the moments of the author's Fig. 8, with L times the moments of Fig. 24; the full liquid moments are those of the author's Fig. 8. These results indicate that the maximum moment in the supporting ring for half-full liquid loading is approximately three times the maximum moment for full liquid loading. The writer has arrived at this conclusion by a combination of observation and logic. If his reasoning is faulty, he will appreciate correction.

Mr. Schorer is to be congratulated on his effort to rationalize pipe design. His paper is instructive and stimulating. However, he has thrown himself open to the charge of concentrating on the condition of loading for which the stress analysis is simplest, namely, full liquid loading. For this reason his paper should be supplemented by further investigation, both analytical and experimental, to establish, conclusively, the stress conditions in supporting rings and cylinder for all partial liquid loadings.

R. L. TEMPLIN,[41] M. AM. SOC. C. E., AND R. G. STURM,[42] ASSOC. M. AM. SOC. C. E. (by letter).—The author is to be commended for bringing before the Engineering Profession so vital a subject. His paper presents one method of supporting a thin-walled cylinder so that the stresses set up in the shell are not serious even when spans greater than those in common practice are used. This, however, should not be construed as the only method of supporting a pipe to obtain small distortions and low stresses.

---

[41] Chf. Engr. of Tests, Aluminum Co. of America, New Kensington, Pa.

[42] Research Structural Engr., Aluminum Research Laboratories, Aluminum Co. of America, New Kensington, Pa.

The writers agree with the fundamental principles and basic assumptions set forth, but feel that several questions which have a direct bearing on the usefulness of the theory might well be clarified. The first question is in regard to the eccentricity, *a*, of the reaction which is the first term defined in the "Notation." Referring to Fig. 6 and the subsequent analysis, it seems that the distance, *a*, should be defined as measured from the neutral axis of the ring. The location of the neutral axis of the ring and shell requires some knowledge or assumptions as to how much of the shell acts with the stiffener, because the pipe shell itself will tend to act integrally with the ring to a certain degree. In the illustrative example given by the author, the variation in the location of the neutral axis may be more than 100% of the computed eccentricity of reaction. As no measured values are given of stresses that actually exist in a pipe so stiffened and so supported, deviations of the theoretical stresses from the actual stresses are not known.

It is interesting to note that the two radii, r and R, both occur in the first set-up of the equations, but the final formulas contain only R, thereby eliminating the effect of the relative size of stiffener and pipe. The writers believe that neglecting this effect is a justifiable approximation in the practical cases, although it does not give an exact theory.

Another question which may be raised is: "How does the example of a pipe, supported as in the case of the Glines Canyon pipe, prove or disprove the theory when it does not appear to comply with the assumptions made in the analysis?" In the first place, the supports of the Glines Canyon pipe are riveted securely to the stiffener ring over a considerable distance extending from the horizontal diameter to a point well below it. Therefore, the point of support is not definitely at the ends of the horizontal diameter nor at any fixed point with reference to the center line of the girder; nor is it supported on knife-edges as assumed in the analysis of the paper. The writers would like to ask, therefore, "Does the fact that this pipe stands without appreciable distortion or without developing serious stresses, necessarily indicate the validity of the analysis presented in the paper?" Apparently, it does show that a pipe reinforced by stiffeners and supported on strut supports has appreciable advantages over pipe supported by other means.

Early in 1928, one of the writers was called upon to make extensive field tests of the Santeetlah Pipe Line which was part of one of the hydro-electric power developments of the Tallassee Power Company in Western North Carolina. This line, including tunnels, is about 5 miles long, and was fabricated from steel plates varying in thickness from $\frac{3}{8}$ in. to $\frac{1}{2}$ in. so as to form a circular conduit having an inside diameter of 11 ft. The pipe is supported on saddles at intervals of about 30 ft. These saddles were fabricated from steel plates and angles so as to extend over an arc of 90° of the pipe shell, and, in turn, are supported on concrete piers or steel trestle bents, depending on the topography. The pipe was stiffened at the supports with 4 by 6 by $\frac{3}{8}$-in. angles riveted to the shell circumferentially, with the longer leg outstanding. The saddles were spaced so as to be adjacent to or framed into one of the stiffening rings.

Tests were made to determine the change in the stresses at critical points in the pipe shell when it was subjected to various water loads up to the maximum load. The places at which the stresses were measured included various points on the stiffening rings, stresses in different directions in the pipe shell around the ends of the saddles and adjacent to the stiffeners, and at various points around the entire circumference of the pipe at mid-span and near the supports. The deformation of the shell from the initial circular section was also determined.

The results of these first field tests showed that when the pipe was almost full of water high stresses occurred in both the saddles and the stiffening rings at certain critical points, namely, in the shell near the ends of the saddles, in the saddle stiffener rings at the top of the vertical diameter, and at both ends of the horizontal diameter. The amount of stiffening ring steel was increased, therefore, by arc welding additional angles to those already on the pipe so as to form a Z-section. These added angles were 4 by 4 in. by $\frac{3}{8}$ in., and were attached to the others so that the final depth of the stiffening ring was about 7 in.

After the completion of this reinforcing work, the pipe was again tested with more extensive measurements than previously. These later tests showed that the high stresses found in the first tests, were decreased substantially to acceptable safe working values. Strengthening the stiffener rings automatically relieved the high stresses in the saddles and in the pipe shell.

Although this pipe line had been designed according to a theory that gave satisfactory results on smaller sizes yet deficiencies in the design theory became apparent when it was applied to lines of the size of that just described. Accordingly, an extensive research was carried out on the design of pipe lines and their supports. This research included tests of models, together with a development of a theory of design which differs from that given by Mr. Schorer.

The models were built to approximately one-tenth the scale of the Santeetlah Pipe Line, and were made of aluminum alloy sheet, so as to magnify the strains and distortions. The models were supported on saddle supports which were in contact with the pipe shell over distances of 66°, 90°, and 180° of arc. These saddles were arranged so as to give a series of spans varying from 3 to 15 diameters, the total length of the model pipe being 15 diameters.

Since models of such size preclude any extensive measurement of localized strains it was decided to depend for the most part on the deformation or distortion of the pipe shell as an index of such strains and hence stresses resulting from various water loads. Strains were actually determined, however, with $\frac{1}{2}$-in. "tensometers," at some points in the models.

Fig. 27 shows a sketch of one of the models in position for test with supports at intervals of 3 diameters. Fig. 28 shows typical distortion curves for an unstiffened pipe on three kinds of saddles. The maximum distortion was found to occur when the pipe was just full of water, but under no pressure.

It was found that the effects of the saddles were quite independent of the length of span and that the effects of the span were nearly independent of the type of saddle.

In view of these results more models were built and tested, using different types of stiffeners. One type was a series of bands of heavier gauge than the material in the shell, varying in width from one-fourth to three-fourths the diameter of the pipe. The main shell was cut for the space occupied by the bands, except for the metal required to make the lap-joints. The bands were bolted to the pipe with small machine screws (No. 2), spaced approximately 1 in. on centers.

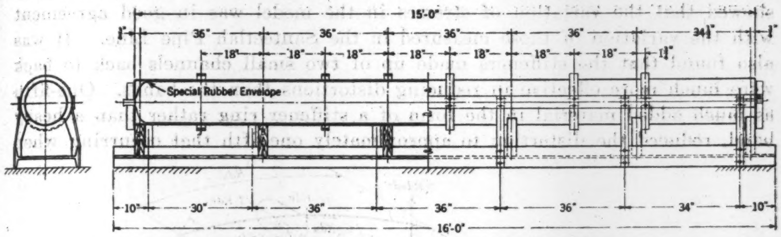

FIG. 27.—GENERAL ARRANGEMENT OF MODEL PIPE LINE AND SUPPORTS.

Another type of stiffener was made up of two channels, which were placed back to back at the joints of the pipe. The pipe was arranged so that the saddles came adjacent to one side of the stiffener rings thus formed. The types of saddles and spans were the same as before. Stresses were measured with "tensometers" attached to the stiffeners as shown subsequently in Fig. 33.

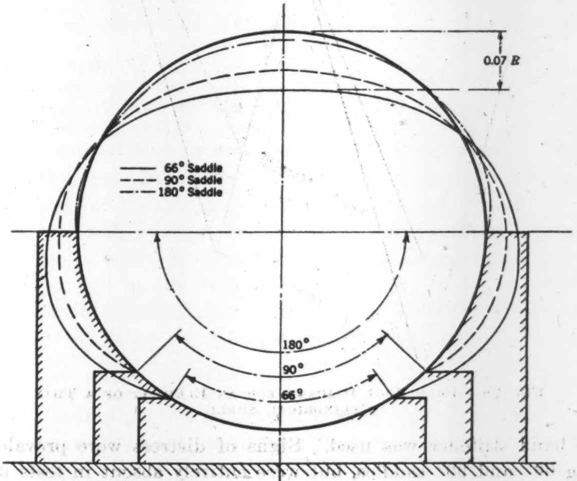

FIG. 28.—DISTORTION OF UNSTIFFENED PIPE SHELLS USING SADDLE TYPE SUPPORTS AND A SPAN OF THREE DIAMETERS.

It was found that the distortion of the pipes, stiffened with the bands at the supports, was very little less than the distortion of the unstiffened pipe, and was found to vary over wide limits because of the indefinite connection between the bands and the shell by means of the bolts used. However, in cases where the bolts apparently held, the distortion varied inversely with the moment of inertia of the combined shell and band. The points of distress and points of contraflexure were found to be the same as in the prototype, and the points of distress as determined by stress measurements on the stiffeners showed that the variation of stresses in the model was in good agreement with the variation of those measured in the Santeetlah Pipe Line. It was also found that the stiffeners made up of two small channels back to back were much more effective in reducing distortions than the bands. One-fifth as much added material in the form of a stiffener ring rather than a heavy band, reduced the distortion to approximately one-fifth that occurring when

FIG. 29.—FREE BODY DIAGRAM FOR AN ELEMENT OF A THIN CYLINDRICAL SHELL

that wide band stiffener was used. Signs of distress were prevalent in the tests using 66° and 90° saddles, but were entirely absent in tests using 180° saddles. The general conclusions might be drawn that the use of 180° saddles would be entirely safe, although prohibitively expensive for general use.

With these data as a background, it was possible to develop a theory of the action of a horizontal pipe line, just filled with liquid, supported on saddles which would give reliable indications of stresses and distortions of stiffened or unstiffened pipe shells supported on various types of saddles. The general differential equation expressing the equilibrium of any elemental section of the pipe shell was derived from a consideration of a free body diagram of such a small portion. Fig. 29 is a sketch of a small element of a pipe shell showing all the forces acting on that small part. From a consideration of equilibrium of such a small particle, a general differential equation involving the forces acting on such an element is obtained. Then, assuming that, since the shell is thin, ordinary flexural formulas hold, the equations of continuity may be combined with the differential equation of equilibrium so as to give a general differential equation in terms of the distortion, ρ, of the shell. This equation was found to be:

$$\frac{EI}{R^4\,(1-m^2)}\left[\frac{\partial^4 \rho}{\partial u^4} + R^2\,\frac{\partial^2 \rho}{\partial u^2} + 2\,R^2\,\frac{\partial^4 \rho}{\partial u^2\,\partial\,(x')^2} + m\,R^4\,\frac{\partial^2 \rho}{\partial\,(x')^2} + R^4\,\frac{\partial^4 \rho}{\partial\,(x')^4}\right]$$

$$= -N' - \frac{T_2}{R_2}\left(R - \frac{\partial^2 \rho}{\partial u^2}\right) - T_1\,\frac{\partial^2 \rho}{\partial\,(x')^2}\;\ldots\ldots\ldots\ldots(169)$$

in which,

x' = distance along the pipe from the center line to the point considered;
ρ = change in radius at any point;
R = mean radius of the pipe shell;
N' = intensity of the hydrostatic pressure at any point;
E = modulus of elasticity of the material in the shell;
$I = \frac{t^3}{12}$ = moment of inertia of a cross-section of the shell of unit length;
t = thickness of the shell;
m = Poisson's ratio for the material in the shell;
T_2 = tangential pull, in pounds per linear inch, circumferentially;
T_1 = tangential pull, in pounds per linear inch, longitudinally.

In connection with Fig. 29 it should be noted also that ρ is positive outward; x' is positive toward the reader; u is positive clockwise; and, M is positive when it tends to cause tension in the outer surface.

The general solution of Equation (169) involves work very similar to that carried through in laborious detail by Mr. A. Frey Samsioe.[43] In view of the experimental data, certain simplifying assumptions were made with the result that the following equation was derived:

$$S = -\,qRx'\sin u\ldots\ldots\ldots\ldots\ldots\ldots(170)$$

in which, q = weight per cubic foot of the liquid in the pipe and u = angular position at any point. The meaning of the other terms are as defined for Equation (169).

Equation (170) has been derived by a different line of reasoning by D. Thoma.[44] In passing, it would be well to point out that in the mathematical work involved in deriving Equation (170) it was found that, of all the possible types of solutions for the general differential equation, a series of the form, $\rho = A_0 + A_2 \cos 2\theta + A_4 \cos 4\theta$ * * *, fulfills the conditions if A_0, A_2, and A_4 are considered as functions of x'. Considering only the first two terms of the series, one would conclude that the general shape of the distorted pipe with the ends fixed would tend to be that of a cosine curve. This would mean that the distortions of a shell with perfectly fixed ends would be of the same general shape as the measured distortions of the shell tested (see Fig. 28).

[43] "Die Spannungen in einem auf mehreren Stützen in gleicher gegenseitiger Entfernung aufgelegten und zur Hälfte mit Wasser gefüllten Rohr," by A. Frey Samsioe, Ingeniörs Vetenskaps Akademien, Handlingar Nr. 50, 1926.

[44] *Zeitschrift* für das Gesamte Turbinenwesen, February 20, 1920.

In the models and in the practical case of the Santeetlah Pipe Line the distortions at the support are very large compared with those of a "fixed ended" shell. Hence, the distortions at the supports were considered as the controlling factor. Using Equation (170) as the distribution of shearing forces on the cross-section of the shell, it seems reasonable that at the point of support a stiffening ring or some other rigid member should be attached to the pipe shell to transmit these forces to the support. The actual conditions may be quite closely approximated by considering that these forces are transmitted to a stiffening ring by the shell at the junction between the ring and the shell.

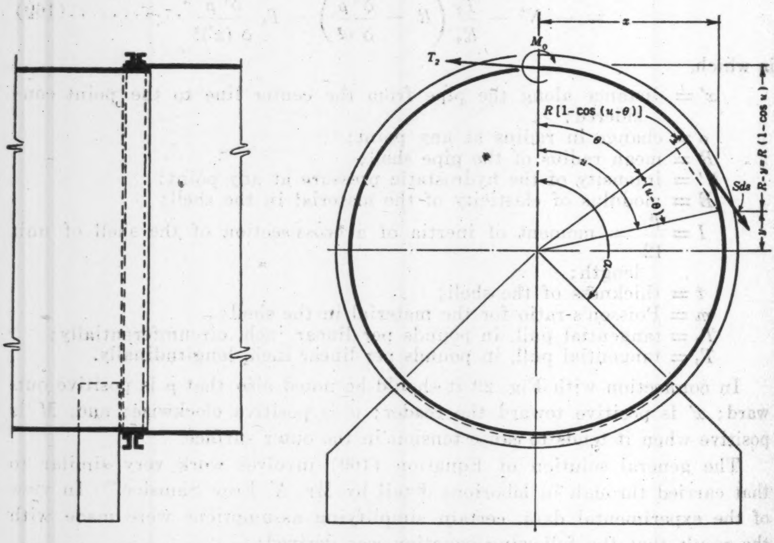

FIG. 30.—SCHEMATIC SKETCH OF PIPE AT SUPPORT, SHOWING FORCES ACTING ON IT.

Fig. 30 is a schematic sketch of a portion of the shell near the support showing the forces acting on it. Treating this part of the structure as an isolated continuous ring with these forces acting on it, equations for the bending moments in the ring resulting from water load are found to be as follows:

For the 66° saddle:

$$M_u = qR^3L\left[0.6327 - 0.5046 \cos u - \frac{u}{2} \sin u\right] \ldots\ldots (171)$$

For the 90° saddle:

$$M_u = qR^3L\left[0.6791 - 0.5847 \cos u - \frac{u}{2} \sin u\right] \ldots\ldots\ldots (172)$$

For the 180° saddle:

$$M_u = qR^3L\left[0.8411 - 0.8211 \cos u - \frac{u}{2} \sin u\right] \ldots\ldots\ldots (173)$$

From the theory of elasticity of curved members involving the relationship,

$$M_u = \frac{EI}{R^2}\left(\frac{\partial^2 \rho}{\partial u^2} + \rho\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (174)$$

the radial distortions may be found to be:

For the 66° saddle ($\alpha = 147°$):

$$\rho = \frac{q R^5 L}{EI}\left[0.6327 - 0.6976 \cos u - 0.3773\, u \sin u + 0.125\, u^2 \cos u\right] . (175)$$

For the 90° saddle ($\alpha = 135°$):

$$\rho = \frac{q R^5 L}{EI}\left[0.6791 - 0.7173 \cos u - 0.4173\, u \sin u + 0.125\, u^2 \cos u\right] \,.. (176)$$

For the 180° saddle ($\alpha = 90°$):

$$\rho = \frac{q R^5 L}{EI}\left[0.8411 - 0.8441 \cos u - 0.5355\, u \sin u + 0.125\, u^2 \cos u\right] \,.. (177)$$

A comparison between the theoretical distortions and the distortions measured on the model involves a consideration of several important factors: First, since the stiffeners were bolted to the pipe shells there is a possibility of as much as 10% variation in the combined moment of inertia of the stiffener and that part of the plate acting with it. A difference between the measured stresses at the same water levels in the prototype during filling and emptying indicates that there was a tendency for re-adjustment to take place there as well as in the models. By checking the bolts very carefully and keeping them tight, it was possible to hold this variation well within 10 per cent. In connection with the combined moment of inertia of the stiffener and plate, supplementary tests were run to determine what proportion of the plate would act monolithically with the stiffener. From tests made on a flat sheet stiffened with two channels back to back, bolted together and to the plate, it was found that on an average about eight times the thickness of the plate outside of each row of bolts could be considered as acting monolithically with the stiffener so as to give computed load-deflection and load-stress values that agreed with experimental results. This value was used in the computations mentioned herein.

A second factor which enters into a comparison between the theoretical and measured deflections or stresses is that the model pipes did not fit the saddles exactly and thereby permitted the pipe to deform until this discrepancy was rectified before the type of action theoretically assumed would begin. The maximum discrepancies were in the order of 0.01 or 0.02 in., which would not seriously affect the distortion of the shell with 66° and 90° saddles; but it would make a decided difference for the 180° saddles since it was assumed that the horizontal diameter of the 180° saddles would not change, which would be the case for the pipe shell if rigidly attached to the saddle or a perfect fit was obtained.

Another factor which entered into the measurements was that the pipe was tested in a room of ordinary temperature, but was filled with water at a considerably lower temperature. The temperature difference between the water and room was occasionally as great as 15° cent. Such variations made stress determination rather difficult because of the large correction necessary for temperature variation. In spite of these factors the curves given in Fig. 31 show that the agreement between the actual measured and computed distortions is quite close.

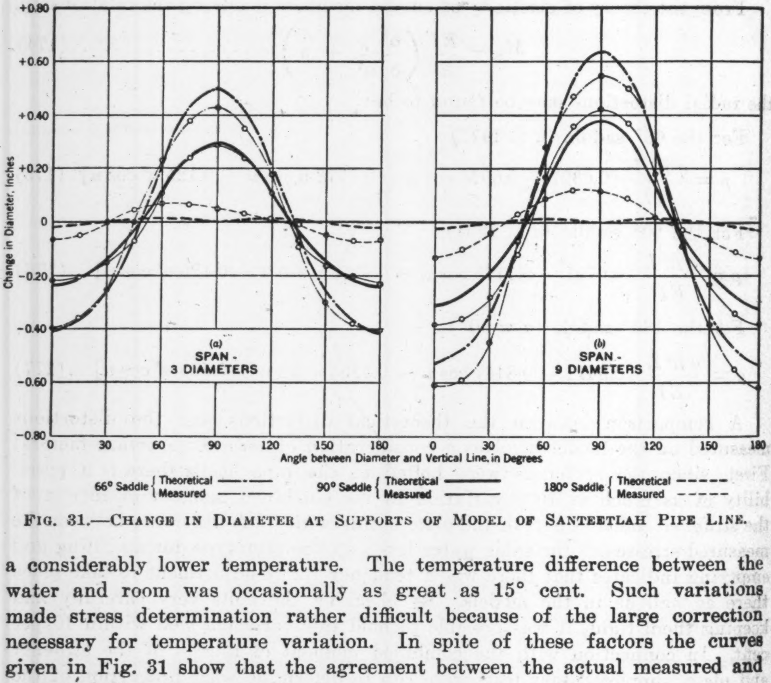

FIG. 31.—CHANGE IN DIAMETER AT SUPPORTS OF MODEL OF SANTEETLAH PIPE LINE.

Table 1 gives the measured and computed stresses in the stiffeners for two span lengths on the three types of saddles. In Item 4, Columns (4) and (6), a highly localized yielding was noted beside the gauge line. This caused the stiffener to pull away from the pipe shell so as to deflect noticeably past the edge of the support, thereby relieving the stress in the stiffener. The 180° saddles showed a clearance of 0.01 to 0.02 in. at the sides. This would tend to make the stresses at the top and sides of the pipe with the 180° saddles greater than the computed stress.

A consideration of the bending moments in the shell of the pipe, supported by saddles, reveals the fact that relatively high stresses must always occur at the ends of the saddles. This phenomenon was also quite apparent in the prototype and in the models. The nature of the theoretical distortion curve shows that if the edge of the saddle were free to move and, at the same time, the center portion of the saddle were also relieved, the change in curvature would be greatly reduced. This observation suggested that the pipe line may be supported by struts attached to stiffener rings at some point below the horizontal diameter and in so doing minimize the moments throughout the ring.

TABLE 1.—MEASURED AND COMPUTED STRESSES IN A STIFFENED MODEL PIPE LINE 12 INCHES IN DIAMETER

(In kips per square inch.)

Item	Position	Span length, in inches	66° SADDLES		90° SADDLES		180° SADDLES	
			Measured	Computed	Measured	Computed	Measured	Computed

4......		108	18.6	36.0	12.0	26.0	......	5.6

In order to eliminate excessive stresses in the top of the strut caused by the twisting resulting from the distortions of the shell, the horizontal component of the resultant reaction of the strut was chosen so that there would be no rotation of the top of the strut under a full water load. Since the strut would probably be joined to the stiffener by a gusset-plate, a concentration of bending moments at the point of support would be eliminated because of the distribution of the forces through the gusset-plate. For the purposes of analysis, however, the resultant reaction of the strut was considered as acting at a point on the neutral axis of the stiffening ring and pipe shell combined. Again applying the theory of elasticity, involving the consideration that the member is curved, three equations involving the moment at the top, the tangential force at the top, the horizontal component of the strut reaction, and the angular position of the point of application of the strut reaction are obtained.

For various values of the angular position, α, corresponding values for bending moment and tangential force at the top of the pipe and horizontal component of strut reaction were found. By plotting these values against the corresponding values of α it was found that the moment at the top of the shell will pass through zero for some particular α and for the same α the other values would be nearly a minimum. From this it may be concluded that if the resultant reaction of a strut intersects the neutral axis of the combined stiffener and shell at a point 117.3° below the top center, the bending moment at the top will be practically zero and that at the point of support will be nearly a minimum. The reasons involved in choosing this point for the application of the strut reaction may be enumerated, as follows:

1.—Since the point of application of the struts does not rotate (a condition imposed by the choice of the horizontal component of thrust), the slope at this point does not change and, therefore, the distortion must be a maximum.

2.—The distortion of the shell is caused by changes in curvature which, in turn, are caused by bending moments.

3.—The bending moment at the top of the shell is indicative then of the change in curvature of the top and, consequently, to a degree an indication of the distortion.

4.—The magnitude of the distortion at the top is indicative of the magnitude of the distortions throughout the shell.

5.—Consequently, by making M_1 as small as possible, the distortions and stresses are kept small.

Using the value of $\alpha = 117.3°$, equations for the bending moment throughout the ring have been determined. The bending moment at any point in the stiffening ring may be expressed by the following equations:

For values of u between 0 and α,

$$M_u = qR^3L\,[0.825 - 0.825 \cos u - 0.500\, u \sin u] \;\ldots\ldots\ldots (178)$$

and for values of u between α and π,

$$M_u = qR^3L\,[0.564 - 0.452 \cos u + 1.571 \sin u - 0.500\, u \sin u] \;\ldots (179)$$

Again using the fundamental differential equation, (174), the equations for the distortion of the shell are found to be:

For values of u between 0 and α,

$$\rho = \frac{q\,R^5\,L}{E\,I}\,[0.825 - 0.809 \cos u - 0.537\, u \sin u + 0.125\, u^2 \cos u]\,.(180)$$

and for values of u between α and π,

$$\rho = \frac{q\,R^5\,L}{EI}\,[- 0.568 + 0.641 \cos u + 1.103 \sin u - 0.785\, u \cos u$$
$$- 0.351\, u \sin u + 0.125\, u^2 \cos u] \;\ldots\ldots\ldots\ldots (181)$$

Because the distortions of the pipe on this type of support are so small it would be desirable to make corrections in the computed distortions for the temperature change. A very close approximation to the actual distortion caused by temperature change may be expressed by the equation,

$$\rho = \Delta\,(4.29 - 3.37 \cos u - 3.37\, u \sin u] \;\ldots\ldots\ldots (182)$$

in which, Δ equals the change in diameter caused by the temperature change.

In order to check the validity of this theoretical investigation, another model was made using the same scale as for the previous models. The stiffeners were again bolted to the shell and the struts joined to the stiffeners by gusset-plates. Fig. 32 shows an end view of the model built to check the

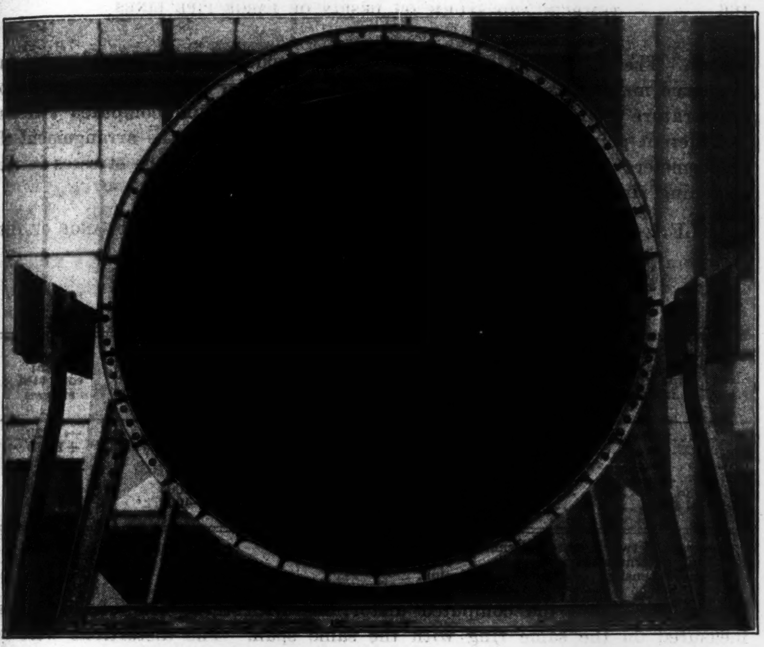

FIG. 32.—END VIEW OF PIPE SUPPORTED BY SPECIAL STRUTS.

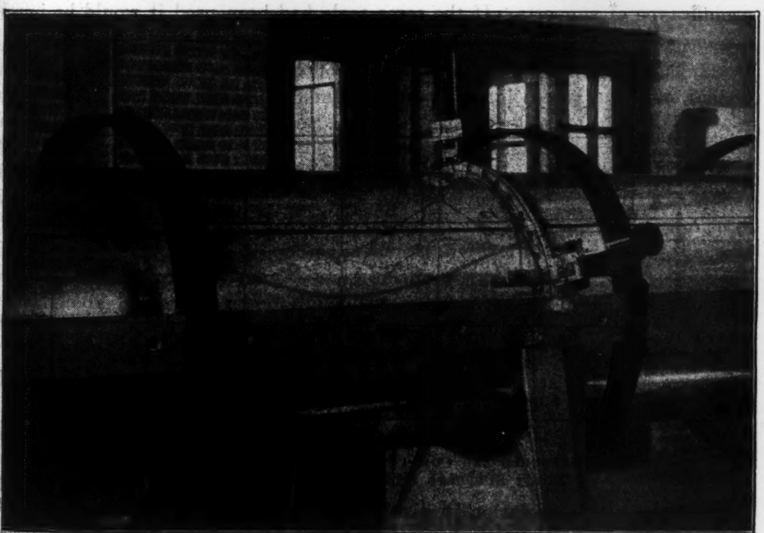

FIG. 33.—ARRANGEMENT OF TENSOMETERS FOR MEASURING STRESSES IN THE STIFFENING RINGS ON A MODEL PIPE LINE.

theory. The distortions and stresses of the model were measured again in the same manner as in former tests, with particular consideration given to temperature changes. Table 2 shows the measured and computed stresses at different points around the pipe shell. Fig. 33 shows the arrangement of "tensometers" previously mentioned herein, for measuring the stresses in the stiffening rings on a model pipe line.

TABLE 2.—MEASURED AND COMPUTED STRESSES IN THE OUTER FLANGE OF THE STIFFENERS OF THE MODEL PIPE LINE ON STRUT SUPPORTS WITH 108-INCH SPAN

Fig. 34 shows the computed distortions with three sets of distortions measured on the same ring with the same span. The distortions were so small that the scale necessary to show them is ten times that used for the saddle type of supports. If the same scale had been used it would be impossible to detect the variation in distortion resulting from this type of support because they would all lie so near the zero axis. It was concluded, therefore, that for all practical purposes the distortions are negligible. In view

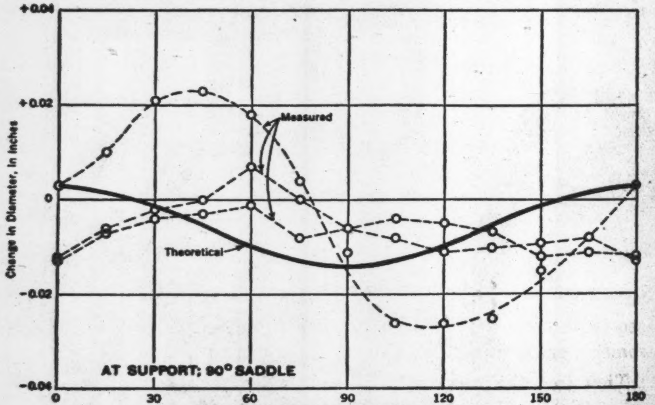

FIG. 34.—MEASURED AND COMPUTED DISTORTIONS OF A MODEL SUPPORTED ON STRUT SUPPORTS SHOWN AS CHANGES IN DIAMETER.

of the agreement between observations on the model and computed values, the writers believe that the theory may be considered a reliable guide in the design of supports and stiffeners for large, thin-shelled cylindrical containers.

From the nature of the moment equation it may be seen that the stresses in the stiffening ring and struts are directly proportional to the span length for any given diameter and that they vary as the cube of the radius of the pipe for spans of equal length. The critical bending moment for design purposes will be that at the bottom of the shell because the moment at the point of support is not only absorbed by the gusset-plate, but also diminished by the distribution of the strut reaction by the gusset-plate. The maximum bending moment at the bottom of the shell reduces to,

$$M_{\pi} = 0.112\ qR^3L \ \ldots\ldots\ldots\ldots\ldots\ldots (183)$$

This equation is on the side of safety because of the stiffening effect of the gusset-plates and the fact that the strut reaction is distributed over a considerable portion of the ring by the gusset-plate. The maximum shear stresses in the side of the shell may be found from the equation,

$$S_{ys} = \frac{qR\,x'\,\sin u}{t} \ldots\ldots\ldots\ldots\ldots\ldots (184)$$

which reduces to,

$$S = \frac{qRL}{2t} \ \ldots\ldots\ldots\ldots\ldots\ldots (185)$$

for the maximum shear stress in the side of the shell.

F. Knapp,[45] Esq. (by letter).—The subject of this interesting paper has been treated[46] previously by Professor Dr. Dieter Thoma, of Munich, Germany, in a paper entitled "Die Beanspruchung freitragender gefüllter Rohre durch das Gewicht der Flüssigkeit." Using the fundamental equations of the theory of elasticity as a basis, Professor Thoma considers the case of a completely filled pipe, either "encastrée" at the ends, or having the end sections connected to rigid rings which may move normally and in the direction of, but not inclined to, the axis. However, he does not consider the design of these rings.

Through the special courtesy of Professor Dr. L. Föppl, of the Technische Hochschule of Munich, the writer was fortunate enough to study, in the original, the work of Dr. R. Abdank, entitled "Die Berechnung freiaufliegender Rohre bei beliebiger Füllhöhe," regarding the stresses in large pipe lines caused by partial filling of the pipe.[47]

Based on the extensive experiments made on a model pipe for the Shannon Development, in Ireland, Dr. Abdank studies the following two cases:

(1) That in which the inclination of the pipe is such that partial filling is possible without the water level cutting the supporting rings. (In this

[46] *Zeitschrift* für das gesamte Turbinenwesen, 1920, p. 49.

[47] Submitted as a thesis in partial fulfillment of requirement for the degree of Doctor of Engineering at the Technische Hochschule, of Münich. An abstract of this thesis was published by Dr. Abdank in *Die Bautechnik*, for June 19, 1931.

case, Professor Thoma's formulas for a completely filled pipe may be applied with safety); and,

(2) That in which the pipe is horizontal. In Case (2) the maximum normal stress in the membrane in the direction of the axis of the pipe and for a freely supported pipe, may be calculated by the approximate formula:

$$f_{(\max.)} = \frac{3}{32} L \times \frac{L}{t} \sqrt{\frac{R}{t}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (186)$$

In the case of a continuous pipe, this stress is reduced to $\frac{2}{3}$ $f_{(\max.)}$, tension at the connection of the ring, and to $\frac{1}{3}$ $f_{(\max.)}$, compression midway between the rings. These stresses are always greater than in the case of a completely filled pipe.

C. P. Vetter,[48] Assoc. M. Am. Soc. C. E. (by letter).—The author has made a valuable contribution to the art of designing large pipe lines subject to low pressures. The manner of support advocated by him is not entirely new, and several attempts have been made by others to produce a satisfactory stress analysis of which at least one is entirely rational, although, unfortunately, far too cumbersome for practical use. This is the analysis by Mr. A. Frey Samsioe mentioned by the author under "Case 3." Mr. Schorer deserves credit, therefore, for the suggestion of applying the membrane theory (developed largely for the design of domes and vaulted roofs) to the problem, and thereby establishing surprisingly simple formulas.

Some time may elapse before designers gain confidence in the author's membrane equations, as has been the case with every innovation in engineering mathematics. Mr. Schorer would undoubtedly help his cause by giving details of some of the tests that have been conducted under his auspices. There is no doubt that his solution is an approximation, good only for thin pipe shells. Its value, however, may best be determined by tests since the exact mathematical solution is so complicated that it is practically unavailable.

Unfortunately, no details are given of the derivation of the primary equations, (1), (2), and (3), and Fig. 2 is of little help because the all-important increments of stress which form the basis for the stress equations, have been omitted. Therefore, an attempt at a rational stress analysis along the lines suggested by the author may be of interest.

Fig. 35 shows a section of pipe shell subjected to a radial load, *p*, in pounds per square inch, and a mass load (weight), *w*, in pounds per cubic inch. The pipe shell is assumed to possess that special quality by which it is capable of sustaining normal forces and shear, but not bending moments. The section is part of a circular cylinder with its axis along the *X*-axis (in the diagram). In so far as its incapacity to resist bending moments is concerned the shell represents, in space, something similar to a string or a cable in a plane. The principal difference is that a string cannot sustain internal shear while the pipe shell can. If it is assumed that the shape of the string under load were known by intuition, and the corresponding internal stresses were found by applying the principles that shear and bending moments must not occur, then the assumed shape is a true one if each and every point of the string is found to be in equilibrium.

---

[48] San Francisco, Calif.

Fig. 36 will illustrate this reasoning: Let A and B be two forces acting on a string of the assumed shape, *c-a-b-d*. Under the assumptions that shear and bending cannot exist, the internal stresses, p and q, are found. If p is equal and opposite to q, then every point of the string is in equilibrium and the assumed shape of the string is stable.

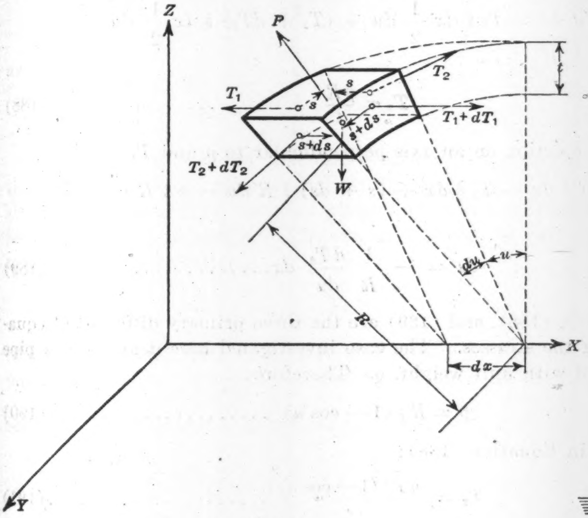

FIG. 35.

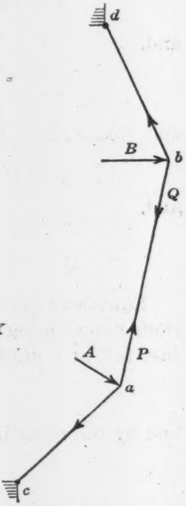

FIG. 36.

Applying this principle to the pipe shell of which a section is shown in Fig. 35, the outside forces are p and w; the assumed shape is a circular cylinder; and the problem is to find the internal stresses under the assumption that bending moments cannot occur. If, after the internal stresses have been determined, it can be proved that every point of the shell is in equilibrium, then the assumed circular cylinder shape is correct and the structure is stable.

The author starts out, as do the originators (Messrs. Kraus and Dischinger) of the membrane formulas, by assuming an outside force with components, X, Y, and Z. If the outside force is to be taken as a surface load this is not possible, because any component in a tangential plane would necessarily produce both radial shearing stresses and bending moments in the shell. Surface loads, therefore, must be confined to radial loads, that is, loads perpendicular to the surface. Mass loads, such as gravity, are not surface loads, and are not affected by this rule. They may have any direction and, in Fig 35, are assumed parallel to the Z-axis (or the Z-axis is assumed vertical).

Returning to Fig. 35, the influence of p only is considered. Assuming $w = 0$ and by projection on the X-axis:

$$(T_1 + dT_1)\ R\ t\ du - T_1\ R\ t\ du + (s + ds)\ t\ dx - s\ t\ dx = 0$$

and,

$$dT_1 = -\frac{1}{R}\frac{ds}{du}\ dx \qquad (187)$$

and by projection on p:

$$p\ R\ du\ dx = T_2\ t\ dx\ \frac{1}{2}\ du + (T_2 + dT_2)\ t\ dx\ \frac{1}{2}\ du$$

and,

$$T_2 = \frac{pR}{t} \qquad (188)$$

and, finally, by projection on an axis perpendicular to p and T_1:

$$(T_2 + dT_2)\ t\ dx - T_2\ t\ dx + (s + ds)\ t\ R\ du - s\ t\ R\ du = 0$$

and,

$$ds = -\frac{1}{R}\ \frac{dT_2}{du}\ dx \qquad (189)$$

Equations (187), (188), and (189) are the three primary differential equations determining the stresses. The case investigated here deals with a pipe just full of a fluid with unit weight, q. Therefore:

$$p = Rq\ (1 - \cos u) \qquad (190)$$

and by inserting in Equation (188):

$$T_2 = \frac{q\ R^2\ (1 - \cos u)}{t} \qquad (191)$$

and by differentiation: $\frac{dT_2}{du} = \frac{qR^2}{t}$ sin u; which inserted in Equation (189) gives,

$$ds = -\ \frac{qR}{t}\ \sin u\ dx \qquad (192)$$

By integration with respect to x: $s = -\frac{qR}{t} x \sin u + f_1\ (u)$ and, again, by differentiation with respect to u: $\frac{ds}{du} = \frac{qR}{t}\ x \cos u + \frac{d\,[f_1(u)]}{du}$.

Inserting in Equation (187):

$$dT_1 = \frac{q}{t}\ x \cos u\ dx - \frac{1}{R}\ \frac{d\,[f_1(u)]}{du}\ dx$$

and by integration with respect to x:

$$T_1 = \frac{1}{2}\ x^2\ \frac{q}{t}\ \cos u - \frac{1}{R}\ x\ \frac{d\,[f_1(u)]}{du} + f_2\ (u) \qquad (193)$$

in which, f_1 (u) and f_2 (u) are the integration constants. They represent functions that may contain the variable, u, but not x, and their determination is not the least part of the problem.

Let it first be assumed that the pipe considered is the overhanging portion of a pipe line, such as would occur at an expansion joint. Then, by choosing the origin of the co-ordinate system at the end of the pipe, it is evident that for $x = 0$, $T_1 = 0$, and $s = 0$. Therefore, $f_1\ (u) = 0$ and $f_2\ (u) = 0$, and, consequently:

$$s = -\frac{qR}{t}\, x \sin u = -\frac{q}{t}\, x\, y \dots\dots\dots\dots\dots\dots (194)$$

and,

$$T_1 = \frac{1}{2}\, \frac{q}{t}\, x^2 \cos u = \frac{1}{2}\, \frac{q}{tR}\, x^2\, z \dots\dots\dots\dots\dots\dots (195)$$

Equation (195) shows that for constant x, the direct stress is proportionate to the Z-co-ordinate, indicating that except for deflections due to shear, the cross-section remains plane under load, assuming proportionality between stress and strain. The stress, T_1, may be expressed, therefore, by the well-known equation:

$$T_1 = \frac{M}{I}\, z \dots\dots\dots\dots\dots\dots\dots\dots\dots (196)$$

which is based on this same assumption only and where M is the bending moment of the exterior forces and I, the moment of inertia of the cross-section. The moment is expressed by $M = \frac{1}{2}\, \pi\, R^2\, x^2\, q$, and,

$$I = 4 \int_0^{\frac{\pi}{2}} R^3\, t \cos^2 u\, du = \pi\, R^3\, t$$

Therefore, $T_1 = \dfrac{\frac{1}{2}\pi R^2 x^2 q}{\pi R^3 t}\, z = \dfrac{1}{2}\, \dfrac{q\, x^2}{tR}\, z$, which is identical to Equation (195). However, the analogy goes still further. If the cross-sections remain plane, the shearing stresses may be expressed by another well-known equation: $s_z = \dfrac{M_z}{I}\, s_v$, in which, s_z is the total horizontal shear per unit length in two radial sections having a distance, z, from the neutral axis; M_z is the static moment with regard to the neutral axis of that part of the cross-section which lies outside the radial sections; and s_v is the total vertical shear. The moment is expressed by:

$$M_z = 2 \int_0^u t\, R^2 \cos u\, du = 2\, t\, R^2 \sin u$$

Furthermore, $s_v = \pi\, R^2\, x\, q$, and, therefore, $s_z = 2\, q\, x\, R \sin u$. The unit shear equals $s = \dfrac{\frac{1}{2} s_z}{t} = \dfrac{qR}{t}\, x \sin u$, which numerically is identical to the value given by Equation (194).

In a pipe supported at either end the origin of the co-ordinate system may be chosen at the section where the total vertical shear, s_v, is zero. For a pipe with uniform load, such as investigated herein, the origin would be in the middle between the supports, as suggested by the author.

From Equation (192) for $x = 0$,

$$s = f_1(u) \qquad (197)$$

and,

$$s_v = 2\int_0^{\pi} s\,R\,t \sin u\,du = 0 \qquad (198)$$

By inserting Equation (197) in Equation (198) and eliminating the constant values:

$$\int_0^{\pi} f'(u) \sin u\,du = 0 \qquad (199)$$

This equation is satisfied by:

$$f'(u) = 0 \qquad (200)$$

and also by numerous other trigonometrical functions. It is evident, however, that these other functions would not agree with the law of continuity, at least not for uniformly distributed load. It must be assumed, therefore, that Equation (200) gives the only possible solution of Equation (199).

Equation (192) then becomes:

$$s = -\frac{qR}{t}\,x \sin u \qquad (201)$$

as for cantilevers, Equation (193) becomes:

$$T_1 = \frac{1}{2}\,x^2\,\frac{q}{t}\cos u + f_2(u) \qquad (202)$$

for $x = \frac{L}{2}$, $T_1 = 0$, in which, L is the length between supports, therefore:

$$f_2(u) = -\frac{1}{8}\,L^2\,\frac{q}{t}\cos u \qquad (203)$$

and,

$$T_1 = -\frac{q}{8t}\,[L^2 - 4x^2]\cos u$$

or,

$$T_1 = -\frac{q}{8tR}\,[L^2 - 4x^2]\,z \qquad (204)$$

By comparing Equation (204) with Equation (195) it is seen that in the case of a pipe supported at either end, the normal stresses are also proportionate to the Z-co-ordinate. It is evident, therefore, that the stresses are the same as those found by the common beam formulas.

This point is of particular interest because in the ordinary beam theory it is necessary to assume that a normal section remains plane under stress in order to establish the usual formulas for the stresses. In the case of thin shells this assumption is not necessary. Neither is it necessary to assume proportionality between stress and strain nor a constant elastic modulus. If, on the other hand, this proportionality exists, the cross-sections will necessarily remain plane.

Thus, it has been shown that the ordinary bending formulas may be applied to this type of cylindrical shells in the case of cantilevers and simple beams. The reasoning may easily be extended to show that they apply also in the case of continuous beams. In addition to the bending stresses, hoop stresses occur, which are determined by Equation (191). They are not affected by the manner in which the pipe is supported.

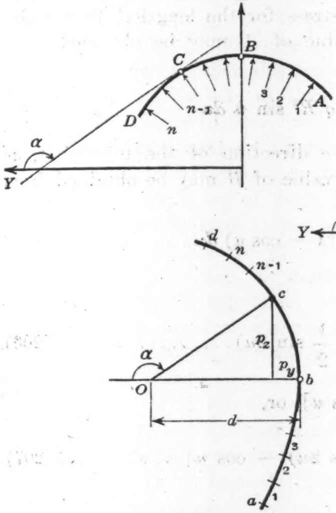

FIG. 37.

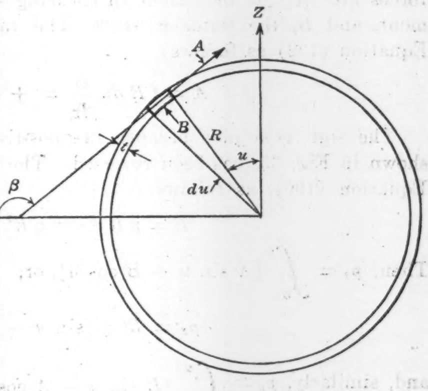

FIG. 38.

It remains to be proved that an arbitrarily chosen element of the shell is in equilibrim when subject to the forces and stresses developed in the preceding equations. A circular ring, cut from the pipe, and of unit length, may be chosen for the proof. It is well known that a circular ring is in equilibrium if the string polygon to all the forces acting upon it is a circle. The equation for the string polygon may be found as follows: Let 1 to *n* (Fig. 37(*a*)) be the external forces, which are infinitely small, infinitely close together, and which form a continuous load. Let *A B C D* be a string polygon to these forces, *B* being the point at which the string polygon is parallel to the *Y*-axis, and *C* being an arbitrary point with co-ordinates (*y*, *z*). The force polygon is shown in Fig. 37(*b*). The points, *a*, *b*, *c*, and *d*, correspond to *A*, *B*, *C*, and *D*, and *O* is the pole. Then, the differential equation for the string polygon may be expressed by $\frac{dz}{dy} = \tan \alpha = -\frac{p_z}{d - p_y}$, in which, *d* is the pole distance. The equation is obviously correct irrespective of the magnitude of d. If $d = 0$, the string polygon becomes the pressure line to the forces, 1 to n, the equation for which becomes:

$$\frac{dz}{dy} = \frac{p_z}{p_y} \quad \text{.........................(205)}$$

in which, p_z and p_y are, respectively, the sum of the Z-components and the sum of the Y-components of all the forces between B and C.

Returning again to the circular element of the pipe (Fig. 38), the external forces are: A, the increment in shearing stress for the length l, of the element, and B, the water pressure. The value of A may be obtained from Equation (192) as follows:

$$A = t\,R\,du\,\frac{ds}{dx} = +\,q\,R^2 \sin u\,du$$

The sign is a plus because the positive direction of the increment, as shown in Fig. 35, has been reversed. The value of B may be obtained from Equation (190), as follows:

$$B = p\,R\,du = q\,R^2\,(1 - \cos u)\,du$$

Then, $p_z = \int_0^u [A \sin u + B \cos u]$, or,

$$p_z = R^2\,q\,(\sin u - \frac{1}{2} \sin 2u) \quad \text{................(206)}$$

and, similarly, $p_y = \int_0^u [B \sin u - A \cos u]$, or,

$$p_y = R^2\,q\,[\frac{1}{2}\,(1 + \cos 2u) - \cos u] \quad \text{...........(207)}$$

and,

$$\frac{p_z}{p_y} = \frac{\sin u - \frac{1}{2} \sin 2\,u}{\frac{1}{2}\,(1 + \cos 2u) - \cos u} = -\tan u = \tan \beta \quad \text{........(208)}$$

and, $\frac{dz}{dy} = \frac{p_z}{p_y} = \tan \beta$.

This is readily seen to be the differential equation for a circle with the center at the origin of the co-ordinate system.

It has thus been proved that the pressure line for the forces acting on a circular ring cut from the pipe is itself a circle. Therefore, the circular shape is stable, and the assumption that no bending moments would occur is correct.

If the same reasoning were applied to the case of dead load without water pressure, it would be found that the author's equations throughout rest on a solid foundation of logic.

L. E. GRINTER,[40] ASSOC. M. AM. SOC. C. E. (by letter).—In spite of its brevity, this paper has real value. If it succeeds in calling the attention of designers to the serious stresses that exist in ring stiffeners and in the shell near the supports, the author will have performed a valuable service. Observation shows that the use of inadequate ring stiffeners has been a common mistake.

---

[40] Prof. of Structural Eng., Agri. and Mech. Coll. of Texas, College Station, Tex.

At the beginning of this paper Mr. Schorer states that the theory developed is applicable to horizontal tanks as well as to pipe lines. He then advocates the use of ring stiffeners at supports only. It is important to realize that horizontal tanks exceeding 12 ft. in diameter are used in industrial plants where the shell may not be exposed to internal pressure. Since the most serious condition exists with the shell full or partly full of liquid, it is clear that the thickness required to resist direct ring stresses is exceedingly small.

Storage tanks of this type might easily be damaged during erection or while in service so that the cross-section would be far from circular. The writer considers the use of thin plates, stiffened at reasonable intervals by intermediate ring stiffeners, to be the proper design in such cases. Wherever resistance to corrosion or internal pressure requires reasonably thick plates, the intermediate stiffeners may be omitted. The important consideration is to produce a structure of such stiffness that any possible change in shape will not produce leakage at the joints.

The safety of a large pipe line or storage tank in which intermediate stiffeners are not used, is dependent largely upon the proper design of ring stiffeners at the supports. The computation of bending stress in the ring is discussed by the author for a special case. The general problem may be solved by any one of several methods, but the "column analogy" method[50] introduced by Hardy Cross, M. Am. Soc. C. E., seems to have the advantage of simplicity. With the aid of Mr. Schorer's equations for shear, which control the load on the stiffener ring, the column analogy may be used to solve directly for the moments irrespective of the type of support.

The writer is fundamentally opposed to the common procedure of analyzing special cases and recording the results as formulas for use in practice. For instance, Mr. Schorer's equations for moments in the ring stiffener are developed for a special type of support, namely, a lug support at each end of the horizontal diameter. On the other hand, the structures which the author lists in his "Synopsis" are quite as likely to be supported by a cradle or by some other special device. The designer would find considerable difficulty in revising these formulas to fit other types of support.

Another criticism inherent with formularization is that the simplified appearance of the final results leads poorly trained engineers to attempt their use. The outcome is likely to be unsatisfactory to all concerned since such a designer may have almost no conception of the important change in stresses which frequently accompanies an apparently slight change in the type of support. The use of a general method of analysis where numerical computations are carried through the entire process tends to eliminate such careless design work. The column analogy method, therefore, may be considered as a tool for extending the usefulness of the author's work.

Many of Mr. Schorer's equations are taken from the mathematical theory of elasticity. Unfortunately, it is not possible to suggest a general method of analysis to take the place of such formulas. Most technical designers do not have the mathematical training which is required to make use of the mathematical theory of elasticity, and, therefore, they must depend upon the results of the work of specialists in this field. The writer believes that a large amount of poor design work is inevitable unless the analysis of all such problems is simplified until it can be understood by the designer.

---

[50] "The Column Analogy," by Hardy Cross, M. Am. Soc. C. E., *Bulletin No. 215*, Univ. of Illinois Eng. Experiment Station, Urbana, Ill.

Mr. Schorer's equations for stresses in the shell near stiffener rings are of great importance. Such flexural stresses would be overlooked by many designers, although they could scarcely miss the stresses caused by longitudinal beam action. The author's numerical example is well chosen since it points out the importance of the rim stress by showing it to be of much greater magnitude than the longitudinal beam stress despite the fact that the unsupported length is 60 ft.

Oren Reed,[61] Assoc. M. Am. Soc. C. E. (by letter).—Ring supports for large pipe lines have several advantages over the usual broad concrete saddles. Generally, no attempt is made to determine the stresses in the pipe shell near the supports with the old type saddle. This is not necessary with a pipe having a heavy shell, but a knowledge of the stress distribution and the possibility of distortion of the pipe over the supports are essential, when a pipe of large diameter and thin shell is to be used. Computation of the stresses in the pipe shell over a saddle support is complicated and uncertain, while with ring supports the stress distribution can be computed more readily.

Ring supports probably should not be used on a pipe line where there is a possibility of collapse due to vacuum. In the event of even a partial collapse, joints might be pulled apart in such a way that a reconditioning of the line would be difficult. However, air-valves and vents should always be provided at summits in the line.

In 1923, the writer inspected the Svaelgfos No. 2 penstock, in Norway. This pipe line is about 7 ft. in diameter and has heavy stiffener angles at about 6-ft. intervals. As pointed out by the author, such a pipe line does not have a pleasing appearance due to the use of the stiffeners.

If the pipe sections are to be transported a long distance, especially by boat, or handled several times before they reach the point of installation, it may be necessary to use stiffening angles for the thin plate sections, unless a definite minimum thickness is adopted. Such a minimum thickness is often much heavier than would be required to withstand the static and dynamic pressures at the location in the line.

At most Swedish hydro-electric plants, heads are not great and the fall is concentrated so that an open penstock is seldom used. However, there are two recent examples of the use of ring supports for pipe lines, at Atrafors and at Tanger. The Atrafors pipe has a diameter of 13.1 ft., a plate thickness of $\frac{7}{32}$ to $\frac{9}{32}$ in., and the span between supports is 44.2 ft. The Tanger power plant was completed in 1931. The penstock has a diameter of 9.2 ft. and operates under a static head of 98.5 ft. above the bottom of the pipe. The line is 2 625 ft. long, and the normal span is 40 ft. between supports. The supporting rings are built up of plates and angles, and rocker-bearings transmit the load to small concrete piers on each side of the pipe. The use of such rocker-bearings makes the design of anchors less difficult. The connection point of the bearings makes an angle of about 30° with the horizontal center line. Ring supports were adopted in order to keep the project construction cost as low as possible.

---

[61] St. Paul, Ind.

Ring supports were also used on the Rempen penstock, of the Waggital Project, in Switzerland, which was completed in 1924. The two penstocks have a diameter of 7.2 ft., a plate thickness of $\frac{3}{4}$ in., and the span between supports is 73.5 ft.

The author will have done the Engineering Profession a worthwhile service, if by his design of the Glines Canyon penstock, and the detailed description, a more general use of ring supports for large pipe lines is adopted in America,

Robert E. Glover,[52] Esq. (by letter).—A rigid connection between stiffener ring and pipe shell will enforce equality of displacements along their common surface of contact. Mr. Schorer has shown how the enforcement of equality of radial displacements results in relieving the circumferential stresses in the pipe shell in the vicinity of the stiffener ring at the expense of increased tension in the ring and local bending stresses in the pipe shell.

It is of interest also to consider the results that follow from the enforcement of equality of circumferential displacements. In this case the bending stresses in the ring are relieved at the expense of circumferential stresses induced locally in the pipe shell, and the net effect is much the same as if a certain part of the pipe shell acted as a flange of the stiffener ring.

In order to ascertain approximately how much of the pipe shell might be considered to act with the stiffener ring to resist bending, the writer calculated, by the theory of elasticity,[53] the strains produced in a flat plate of indefinite extent subjected to forces in its plane such that the intensity, measured in units of force per unit of length, varied as the ordinate of a sine curve. These strains were compared with those calculated for a plate of the same thickness and of finite width under the usual assumption of uniform stress distribution, and the following formula was obtained:

$$\beta = \frac{\lambda}{\pi\left[2 - \frac{(1-m)^2}{2}\right]} \qquad \text{(209)}$$

in which, β represents the width of a uniformly stressed plate that is equivalent to the infinite plate in its ability to resist deformation, and λ represents the wave length of the applied forces.

In order to apply this result to the present problem it was necessary to represent the moment diagram shown on the author's Fig. 8 as nearly as possible by a single sinusoidal variation, and a curve was chosen for the purpose such that its ordinates were proportional to cosine $(3u)$. If it is recalled that forces are transmitted from web to flange in a beam by means of shear stresses the intensity of which is proportional to the rate of change of bending moment with respect to length, it may be seen that for the idealized curve the circumferential forces between stiffener ring and pipe shell will be proportional to sine $(3u)$. Under these conditions:

---

[52] Engr., U. S. Bureau of Reclamation, Denver, Colo.

[53] The stress function used for this purpose may be found in Paragraph 238 of "Applied Elasticity," by J. Prescott.

$$\lambda = \frac{2\,\pi\,r}{3} \quad \text{.........................} (210)$$

and,

$$\beta = \frac{2r}{3\left[2 - \dfrac{(1-m)^2}{2}\right]} \quad \text{.....................} (211)$$

If Poisson's ratio, m, is given the value, 0.28, this relation reduces to,

$$\beta = 0.383\,r \quad \text{.........................} (212)$$

The effect of circumferential equalization on the bending stresses in the stiffener ring may be shown by the following computation based on the data of the author's example, thus: $\beta = 0.383\,r = 0.383 \times 60 = 22.98$ in.; the area of the section is $1 \times 12 + 22.98 \times 0.25 = 17.75$ sq. in.; the center of gravity of the section is 4.27 in. from the inner surface of the pipe shell; $R = 64.27$ in.; the moment of inertia is 293.5 in.^4; and the section modulus $= \dfrac{293.5}{12.25 - 4.27}$ $= 36.75$ in.^3

Hence, $M = 0.010\,Q\,R = 0.010 \times 317\,000 \times 64.27 = 203\,700$ lb-in., and the bending stress in the outer fiber of the stiffener ring is, $f_1 = \dfrac{203\,700}{36.75}$ $= 5\,540\ \dfrac{\text{lb.}}{\text{in.}^2}$. A comparison of these figures with those of the author shows a smaller value of R, a smaller moment, and a reduced bending stress as results accruing from the equalization of the circumferential displacements.

Herman Schorer,[54] Assoc. M. Am. Soc. C. E. (by letter).—The discussion has brought out many important points which the writer, admittedly, had not treated with sufficient detail. It will not be possible to answer all the questions raised, because the entire subject deserves further theoretical investigation, although the practically important points are now fairly well established.

Mr. Mensch refers to the fundamental work by Professor Love[55] who established the general theory of shells forty years ago. Few engineers would be in a position to apply Professor Love's complete theory directly for practical purposes. Messrs. Templin and Sturm, in Fig. 29, present a complete picture of the normal and shearing stress components, the bending and torsional moments, and the load components, that act on a small element in the most general case.

Mr. Mensch doubts the justification of simplifying assumptions made by several investigators. Most engineers will welcome a comparatively simple method, giving results within a few per cent. of the elastic theory. The mathematical physicist will necessarily take a different point of view. Engineering progress, to a large extent, depends on the creation of reliable working tools consistent with the accuracy of the other assumptions made in structural design.

[55] "The Mathematical Theory of Elasticity," by A. E. H. Love, Third Edition, Cambridge Univ. Press, 1920.

Regarding the bending stresses in symmetrical shells of rotation, symmetrically loaded, Geckeler[56] has presented a detailed discussion of his simplified method and that derived by Pasternak,[57] as compared with the fundamental solution by Meissner,[58] the latter strictly conforming to the requirements originally stated by Love. For design purposes, the small deviations can be safely neglected.

The reader is also referred to the publications in the English language by Prescott,[59] Greene,[60] and Coates.[61] The bending stresses in unsymmetrically loaded, cylindrical shells have been treated by Miesel[62] for the case of continuous surface load components, which can be expressed by trigonometric series. Miesel also treats the problem of a full pipe line, inclined at any angle.

All the investigations on bending and torsional shell stresses in closed cylindrical shells, for both symmetrical and unsymmetrical loading, bring out the fact that these stresses are limited to a narrow rim zone, provided the surface loads are distributed over the total shell area in such a manner that a direct stress system is possible. This system of so-called membrane stresses is comparable to the condition of a statically determinate structure.

Mr. Bauman's Fig. 22 clearly illustrates the rapid decrease of the bending deformations with increasing distances from the rim. It is mainly due to the recognition of this point, so typical for structures of the shell type, that their analysis and design can be simplified greatly without any appreciable sacrifice in accuracy.

The development of the Zeiss-Dywidag type of roof, as described by Dischinger,[3] represents a very remarkable step in the application of these principles to open shells for the purpose of wide-span construction over large areas, rectangular or polygonal in plan. Mr. Mensch finds that the stresses given by Dischinger deviate as much as 50% from those obtained by the common theory and claims that the test structures built by the originators were largely over-designed. The writer rather suspects that the common theory used by Mr. Mensch may not represent the actual conditions.

The theory of the Zeiss-Dywidag structures has been verified by numerous model tests made by the designers for the purpose of ascertaining the validity of theoretical simplifications and also at the request of the official building departments entrusted with the authority of guarding the interests of the public and the approval of plans. In addition, independent investigations were made by disinterested experts, among them Professor Kleinlogel. The theory of these structures can now be considered as sufficiently advanced for general application, with due consideration of limiting conditions in the case of discontinuous and concentrated surface loadings. Dischinger[63] has further developed the theory of polygonal shells and their relation to inscribed shells of rotation.

[62] "Ueber die Festigkeit von Kreiszylinderschalen mit nichtachsensymmetrischer Belastung," by Kurt Miesel, *Ingenieur-Archiv,* Vol. 1 (1930), p. 22.

Mr. Roop's references to related work give an excellent idea of possible applications of shell design and diaphragm action in other branches of engineering. He mentions, for instance, the bulkheads in a submarine, which correspond to the ring girder of the pipe line. The importance of an accurate knowledge of the stress conditions in this case is evident, not only in order to obtain minimum weights, but also to prevent certain loss of life in case of structural weakness. The same considerations apply to aircraft construction.

Mr. Skytte, Professor Roark, and Mr. Boardman have presented extremely valuable contributions in connection with the condition of stress in a pipe partly filled. As pointed out in the paper,[3] Equations (1), (2), and (3), derived by Bauersfeld, apply only in case the load components can be expressed as continuous trigonometric functions of the angle, u.

When a pipe is partly filled a discontinuous surface load is created, which, in addition to the direct stresses, must also induce bending and torsional stresses in the pipe shell. The fact that equilibrium cannot be established without bending in this case, is clearly brought out by Professor Roark in his Equation (112). Theoretically, it would be necessary to consider all the forces and moments on a small element, as pointed out by Messrs. Templin and Sturm in Fig. 29. Miesel[64] has shown that nineteen differential equations are required for the complete solution of this problem. Their integration, however, presents a mathematical problem of considerable magnitude.

In order to illustrate the general character of the stress condition in a pipe half full, assume the shell to be cut open over its entire length, along the horizontal diameter. Neglecting the dead load, the upper half shell then is free from external loads. With the designations of Fig. 2, the lower half, now comparable to a semi-circular flume, is loaded by the external load components, $X = 0$, $Y = 0$, and $Z = -q\,r\cos(\pi - u)$. The Bauersfeld Equations (1), (2), and (3), applied to the flume section, give the following stress components between the limits, $u = \frac{\pi}{2}$ and $u = \pi$:

$$T_2 = q\,r^2 \cos(\pi - u) \quad \text{.................(213)}$$

$$s = q\,r\,x \sin(\pi - u) \quad \text{.................(214)}$$

and,

$$T_1 = \frac{q}{8}(L^2 - 4x^2)\cos(\pi - u) \quad \text{.................(215)}$$

---

[63] "Die Theorie der Vieleckkuppoln," by Franz Dischinger, Wilhelm Ernst & Sohn, Berlin, 1929.

[64] "Ueber die Festigkeit von Kreiszylinderschalen mit nichtachsensymmetrischer Belastung," by Kurt Miesel, *Ingenieur-Archiv*, Vol. 1 (1930), p. 32.

The shearing stress component, s, for $u = \frac{\pi}{2}$, has a finite value, $s = q\,r\,x$. Since this stress is acting on all four sides of a small edge element, it is necessary to apply an external shearing force of equal magnitude, acting along the edge in the opposite direction, in order to establish equilibrium. This force requires a longitudinal compression member, as shown in Fig. 39(*a*), monolithically connected to the edge of the shell, similar to the tension member in the Zeiss-Dywidag barrel type of roofs. The force in the compression member, designated by P, is equal to the total longitudinal tension in one lower quadrant and is of opposite sign. From Equation (215), by integration between the limits, $u = \frac{\pi}{2}$ and $u = \pi$:

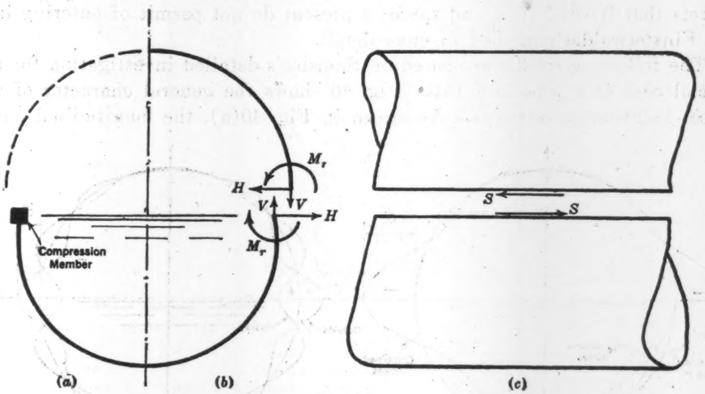

FIG. 39.

$$P = -\frac{qr}{8}\,(L^2 - 4\,x^2) \qquad (216)$$

The semi-circular flume then is subject to direct stresses only, except for the secondary stresses caused by the weight and rigidity of the compression member.

This edge member may now be assumed to be replaced by the full shell. Due to the deformation of the loaded lower half shell, a system of edge forces, H, V, and S, and a radial bending moment, M_r, as shown in Fig. 39(*b*), will be required to close the gap and to restore the continuous curvature of the shell. The deformation of a small element also induces longitudinal bending moments, M_l, and corresponding shears, S_l, as shown in Mr. Skytte's Fig. 11. In addition, there are torsional moments acting in radial and longitudinal planes. The values of M_l and S_l, as pointed out by Mr. Skytte, are very small; the same may be said of the torsional moments. This fact is well supported by the careful tests and analysis of the Zeiss-Dywidag roofs. Samsioe's analysis also indicates comparatively small values of M_l. The longitudinal bending stresses in the narrow rim zone of the supporting ring must be considered as a separate stress system, which is of no importance for the condition of partly filled pipes.

Dr. Finsterwalder[65] has shown that the five stress components, T_1, T_2, S, S_r, and M_r (Fig. 11), can then be derived from a stress function, F, similar to Airy's stress function in case of a plane plate. The resulting differential equation is of the eighth order and the integral consists of two damped waves, originating at the loaded edges. Although mainly developed for the purpose of analyzing the barrel type of roofs, Dr. Finsterwalder's method undoubtedly can be adapted for the analysis of any partial filling of a pipe. The writer regrets that limited time and space at present do not permit of entering into Dr. Finsterwalder's method in more detail.

The following results are based on Samsioe's detailed investigation for the special case of a pipe half full. Fig. 40 shows the general character of the direct longitudinal stresses. As shown in Fig. 40(a), the longitudinal membrane stress (Equation (215)), acts in the lower half of the shell only, and is superimposed by the stress due to the longitudinal force, P (Equation (216)), which is symmetrically distributed about the horizontal diameter in the shape of a damped wave. The relative stress concentration of this force near the horizontal diameter increases with comparatively short spans and thin shells, in which case only a narrow longitudinal zone of the pipe shell acts as a compression member. The combined stress system is shown in Fig. 40(b), indicating that a straight-line stress diagram could not represent the actual conditions.

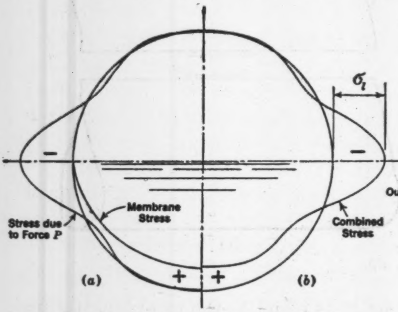

FIG. 40.—PIPE HALF FULL, LONGITUDINAL STRESS.

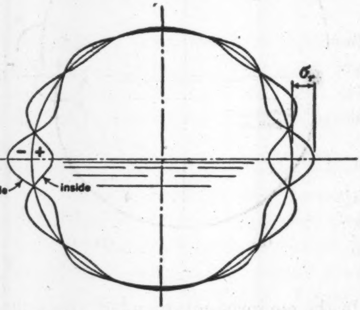

FIG. 41.—PIPE HALF FULL, RADIAL BENDING STRESS.

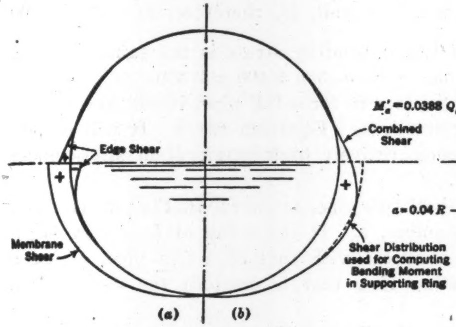
Fig. 41 shows the character of the radial bending stresses, corresponding to the moment, M_r. They are also distributed symmetrically about the horizontal diameter in the form of a damped wave, with a maximum value at the center of the span, decreasing to zero at the rigid supports.

Fig. 42 shows the distribution of the transverse and longitudinal shearing stress, S. This stress (Fig. 42(a)), is composed of the shear in the membrane system (Equation (214)), acting in the lower half of the shell only, and the secondary shear due to the edge conditions. The combined value is shown in Fig. 42(*b*). For comparatively short spans and thin shells the combined shear distribution approaches the membrane condition. For large spans and thick shells the distribution becomes identical with that of a full pipe.

---

[65] "Die Theorie der zylindrischen Schalengewolbe, System Zeiss-Dywidag: Anwendung auf die Grossmarkthalle in Budapest," by Dr. Ing. Ulrich Finsterwalder, International Assoc. for Bridge and Structural Eng., Zurich, 1932.

For design purposes it is convenient to compare the absolute maximum longitudinal stress, σ_l (Fig. 40), and the absolute maximum radial bending stress, σ_r (Fig. 41), with the maximum beam stress f_L, of a simply supported, full pipe (Equation (13); $w = 0$). The corresponding stress ratios, designated by n_l and n_r, can be computed by Samsioe's equations which, after a few transformations, become a function of the pure number, k, defined as follows:



Edge Shear
+
Membrane Shear
Combined Shear
+
Shear Distribution used for Computing Bending Moment in Supporting Ring
(a)
(b)

FIG. 42.—PIPE HALF FULL, TRANSVERSE AND LONGITUDINAL SHEARING STRESS.

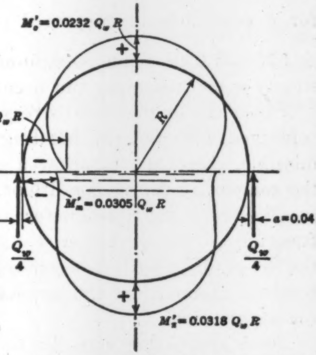


FIG. 43.—BENDING MOMENT IN SUPPORTING RING, PIPE HALF FULL.

$$k = \frac{L}{r}\sqrt{\frac{t}{r}} \quad \text{.........................} (217)$$

In practical cases this characteristic number varies approximately from $k = 0.20$ to $k = 1.20$. A series of values for n_l and n_r has been computed within this range, whereby it was possible to establish the following relations:

$$n_l = \frac{\sigma_l}{f_L} = \frac{1}{\sqrt{k}} \quad \text{....................} (218)$$

and,

$$n_r = \frac{\sigma_r}{f_L} = \frac{0.31}{\sqrt{k}} \quad \text{....................} (219)$$

Equation (218) shows that for values of $k \leqq 1$, the half-full condition will give a larger longitudinal stress than in case of a full pipe. The ratio, n_l, remains the same in case of a continuously supported pipe, because both stresses are reduced in the same proportion. The absolute value of the radial bending stress, σ_r, is independent of the type of support.

A comparison of Equations (218) and (219) shows that the maximum radial bending stress is less than one-third the maximum longitudinal stress at the horizontal diameter. In case $k \leqq 1$, the stress, σ_l, will therefore govern the design, but for values of $k \geqq 1$, it will be sufficient to investigate the maximum beam stress of a full pipe.

Applied to the design example, from Equation (217), $k = \frac{720}{60}\sqrt{\frac{0.25}{60}} = 0.775$. From Equation (218), $n_l = \frac{1}{\sqrt{0.775}} = 1.13$, and $n_r = \frac{0.31}{\sqrt{0.775}} = 0.35$.

The maximum beam stress, in inch-pounds, for a full pipe, simply supported, is: $f_L = \frac{62.5 \times 60^2 \times 12}{8 \times 0.25 \times 144} = 9\,400$. The maximum longitudinal stress for a continuously supported pipe, half full, is, therefore, $\sigma_l = \frac{2}{3} \times 9\,400 \times 1.13 = 7\,050$. The maximum radial bending stress is the same as for a simply supported pipe, and becomes, $\sigma_r = 0.35 \times 9\,400 = 3\,300$.

Since the longitudinal stress, σ_l, is zero for a full pipe, it will never occur combined with the rim bending stress, f_{bo} (Equation (27)). It will be permissible, therefore, to allow a comparatively high longitudinal stress under the temporary filling conditions.

The shear distribution for a half-full pipe, as shown in Fig. 42, is also a function of the characteristic number, k. If the value of k is very large, the shear distribution becomes identical with that of a full pipe, giving a bending moment in the supporting ring that is one-half the value found for a full pipe.

As k approaches zero the shear distribution becomes more and more concentrated in the lower half of the shell, as shown in Fig. 42(*b*), drawn for $k = 0.20$. In the extreme case, $k = 0$, the shear follows the law defined by Equation (214), acting between the limits, $u = \frac{\pi}{2}$ and $u = \pi$. By means of Samsioe's equations it would be possible to find the shear distribution for any given value of k, whereby the corresponding bending moment in the supporting ring could then be evaluated. However, the amount of work is considerable and scarcely justified, because the maximum moment is not greatly affected by a variation of k within the practical range.

For design purposes it will be advisable to assume that $k = 0$. This assumption is on the safe side and can be treated similarly to the method shown in the paper under the heading, "Stresses in Supporting Ring." With the designations of Fig. 6, except for Q, the following equations for the bending moments, M'_1 and M'_2, in the first and second quadrants, respectively, have been obtained:

$$M'_1 = \frac{Q_w R}{2\pi}\left[\frac{2r}{\pi R} - \frac{\pi}{4}\left(1 + \frac{a}{R}\right) + \left(\frac{5}{4} - \frac{r}{R} + \frac{a}{R}\right)\cos u\right] \quad \ldots(220)$$

and,

$$M'_2 = \frac{Q_w r}{2\pi}\left[\frac{2r}{\pi R} + \frac{\pi}{4}\left(1 + \frac{a}{R}\right) + \left(\frac{1}{4} + \frac{r}{R} + \frac{a}{R}\right)\cos u - (\pi - u)\sin u\right] \quad \ldots(221)$$

In Equations (220) and (221), Q_w designates the total water load over one support for a full pipe. The moment coefficients for the half-full condition are, therefore, directly comparable with those obtained by Equations (51)

and (53), when the weight of the pipe is neglected in the latter equations. The dead load moment, as found by Equations (51) and (53), must then be added in both cases.

Fig. 43 shows the moment diagram in the supporting ring, for a pipe half full, with $\frac{r}{R} = 0.90$ and $\frac{a}{R} = +0.04$. Fig. 44 gives the moment coefficients for the maximum moments in the function of $\frac{a}{R}$. It will be noted that, for $\frac{a}{R} = +0.04$, the maximum moment in the supporting ring for the half-full condition is 3.88 times the moment value of a full pipe. In case $\frac{a}{R} = 0$, the corresponding ratio is 2.4.

By observation and logic, Mr. Boardman finally arrives at an approximate ratio of three. A similar value has also been estimated by Karlsson. It is evident that the radial bending moment in the pipe shell, due to partial fillings, is greatly relieved at the expense of the increased bending moment in the supporting ring.

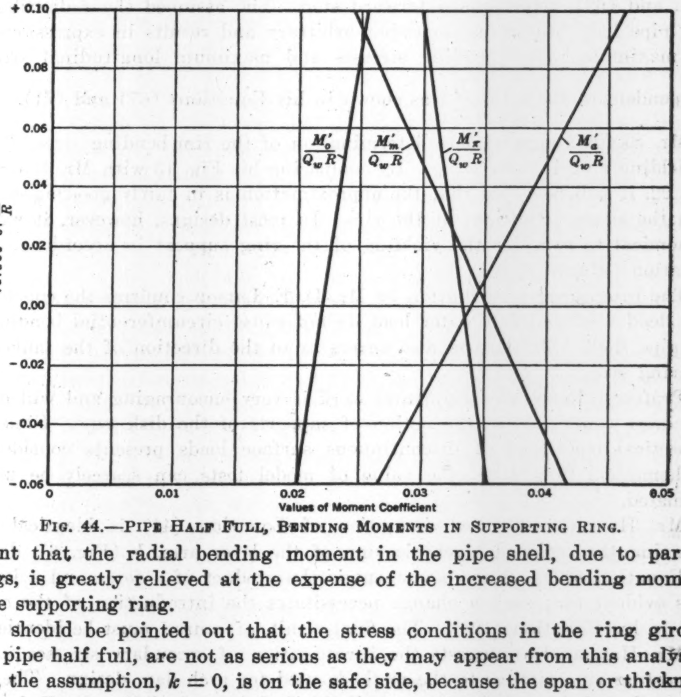

FIG. 44.—PIPE HALF FULL, BENDING MOMENTS IN SUPPORTING RING.

It should be pointed out that the stress conditions in the ring girder, for a pipe half full, are not as serious as they may appear from this analysis: First, the assumption, $k = 0$, is on the safe side, because the span or thickness of the shell never is zero; second, the direct stress in the supporting ring, due to the shearing forces, is only one-half the value given by Equation (57) for a full pipe; third, the direct stress due to the radial pressure (Equation (30)), is practically zero; and fourth, the rigid connection between pipe shell and supporting ring actually increases the effective section modulus of the ring girder; also, the large gusset-plate is placed at the point of maximum

moment. Water-hammer stresses at such a filling are excluded and any inclination of the pipe line will also relieve the bending stresses.

Nevertheless, the stresses in the ring girder for half-full condition should be investigated and compared with the stresses obtained when the pipe is under pressure. In view of the temporary filling conditions and the safe assumptions made in arriving at the moment values, it will be entirely permissible to use stresses close to the elastic limit for this case, although additional resistance to bending can be obtained at small expense. A value, $\frac{a}{R} = 0$, will give more favorable conditions under half-full loading, but higher stresses for full load, than in case $\frac{a}{R} = +0.04$.

In estimating the possible magnitude of the bending stresses in the pipe walls for half-full condition, Mr. Skytte presents Karlsson's reasoning, as illustrated in Fig. 12. His derivation of the general Equations (59), (60), (61), and (62), represents a forward step. The assumed shear distribution of a pipe half full seems somewhat arbitrary and results in expressions for the maximum radial bending stresses and maximum longitudinal stresses independent of the ratio, $\frac{L}{r}$, as shown in his Equations (67) and (71).

Mr. Skytte's approximate determination of the rim bending stress for an unyielding ring is interesting. By comparing his Fig. 13 with Mr. Bauman's Fig. 22, it will be noted that the approximation is in fairly good agreement with the stress conditions at the rim. In most designs, however, it will be economical to consider the yielding of the ring support in accordance with Equation (27).

The interesting contribution by Mr. D. E. Larson confirms the conclusion that dead load and full water load do not cause circumferential bending in the pipe shell. Mr. Larson also agrees as to the direction of the tangential shearing stresses.

Professor Roark's experimental work is very encouraging and will establish more confidence in the action of supports of the disk type. Since the theoretical treatment of discontinuous surface loads presents considerable mathematical difficulties, the value of model tests can scarcely be underestimated.

Mr. Hanna's suggested derivation of Equation (41) is identical with reversing the assumed algebraic sign of the lever arm, b (Fig. 6), defined by Equation (39). Since a moment is the product of a force and a length, it is evident that such a change necessitates the introduction of the minus sign in his Equation (122). The final result, of course, must be identical.

Mr. Hanna also suggests the investigation of secondary stresses in the supporting ring similar to the methods used for arch dam design. The supports of the ring girder are usually designed as flexible columns or are provided with rocker bearings, so as to allow reasonable movement. In addition, it is well known that the secondary stresses in a semi-circular, fixed arch are generally small, except in comparatively thick arches, in which case, the refinements proposed by Mr. Hanna are justified.

The writer is indebted to Mr. Bauman for his able discussion, especially for his presentation of the elastic deformation of the shell and the load distribution at the rim zone, as shown by Fig. 22, which clearly illustrates the damped wave character of the rim conditions.

Mr. Bauman's derivation of Equations (31), (32), and (33) is of convincing simplicity. The more accurate determination of the tensile stresses in the ring also represents a desirable contribution.

Mr. L. J. Larson presents an interesting comparison of a pipe supported on a horizontal plane, in which a direct stress system can not come into play until large deformations have taken place.

Regarding Mr. Larson's question as to the action of a pipe shell attached to the ring at intervals only, it may be stated that such a design is comparable to the action of a riveted connection. Provided the connections are spaced comparatively close and designed to transmit the corresponding forces in a continuous structure, it is reasonable to assume that the general state of stress would not be greatly affected.

The action of a pipe fitted to the ring in a more or less loose manner would change the assumptions decidedly, because the friction forces can not be depended upon to transmit the shearing stresses, except in case of a shrink fit. If the ring fits rather loosely, then the load will be transmitted mostly by direct bearing on the lower half of the ring. In the extreme case the ring would act as a saddle support, which condition is reached more quickly with a comparatively thick shell, than in case of a thin shell. Fig. 28, presented by Messrs. Templin and Sturm, is well adapted to illustrate this point.

Mr. Larson's suggestion as to the use of the dished heads of horizontal tanks as supporting disks is very timely and of great practical importance. The writer has not made any analysis of this possibility, but it is evident that a direct stress system is possible with tangential column supports attached at the center of the dished heads.

As a first approximation, the two end reactions could then be considered as a concentrated force, applied to a point in the direction of a plane of an infinite flat plate, which problem is treated by Prescott.[66] The reaction must be applied over a sufficiently large area, so as to keep the local stresses within safe limits. For this purpose the central area of the dished head may require a gradual increase in thickness. In many cases the flange of a manhole or outlet, located at this point, could be used to transmit the forces.

Mr. Orr finds that the bending stresses in the rim zone can be safely neglected, although he does not question their existence and considerable magnitude. The writer is unable to agree with Mr. Orr on this point, in spite of the fact that standard specifications may not require their consideration. Working stresses close to the elastic limit, especially when accompanied with frequent stress reversal, sooner or later may lead to failures.

Mr. Orr's statement regarding the design of pressure containers, is decidedly in error. The proposed changes in the A. S. M. E. Code for Pressure Vessels, especially the specifications for ellipsoidal heads, are a direct attempt to eliminate or minimize the high stress concentration in the rim zone.

---

[66] "Applied Elasticity," by John Prescott, Longmans Green & Co., Lond., 1924, p. 375.

Mr. Bednarski gives an interesting account of the experience on the pipe line of the Los Angeles Aqueduct, supported on piers of the conventional type. In most practical cases the advantages mentioned by Mr. Bednarski are more than offset by other factors. Although it is quite true that the pipe line, when continuously kept under pressure, would not require any rigid ring supports to maintain its circular shape, it should be pointed out that such ideal operating conditions are seldom realized.

The large deformations at partial filling must invite failure or, at least, cause serious leakage, requiring frequent caulking and replacement of protective paint coatings. A pipe line supported on piers, with comparatively short spans, must necessarily follow the natural contours of the ground very closely, whereas long-span construction permits the choice of a shorter route, which may result in considerable savings in material, together with smaller friction losses.

Mr. Boardman's excellent contribution is of decided value, because it raises important questions in connection with partial filling, already answered in connection with Mr. Skytte's discussion and that of Professor Roark. Mr. Boardman's explanation of the small deformations for discontinuous loadings, as observed on his model, and his reasoning regarding the re-distribution of transverse shearing stresses, closely coincide with the approximation already advanced by Karlsson.[2] Instead of the concentrated shearing forces as indicated by Mr. Boardman in Fig. 26, Karlsson assumed a continuous distribution proportional to sin 2 *u*, also used by Mr. Skytte.

By letter dated June 6, 1932, Mr. Boardman has informed the writer of an interesting test on the tank illustrated in Fig. 45, which is a convincing application of theory to practice. The tank is 12 ft. 0 in. in diameter, 35 ft. 0 in. long, and both shell and heads are made of $\frac{1}{4}$-in. plates butt-welded together, each being stiffened by two horizontal channels, 9 in. by 13.4 lb., welded on the inside. According to Mr. Boardman, this tank, supported entirely on the four vertical angles, two on each head (see Fig. 45), was filled with water and then emptied; no deformations were noticeable to the eye.

Equation (217) gives a characteristic number, $k = 0.343$, for this tank. The maximum longitudinal stress for half-full condition, from Equation (218), is $\sigma_l = 3\,180$ lb. per sq. in., and the maximum bending stress in the pipe walls, from Equation (219), is $\sigma_r = 1\,670$ lb. per sq. in. The magnitude of these stresses sufficiently explains the small deformations observed by Mr. Boardman.

Messrs. Templin and Sturm are to be congratulated for presenting their extremely valuable investigation on the pipe-line problem. All their deductions are based on extensive experimental data, combined with theoretical considerations. It is gratifying to note that, beginning with the tests made on the Santeetlah Pipe Line, Messrs. Templin and Sturm finally arrive at the type of support illustrated in Fig. 32.

Regarding the relative location of the neutral axis of the ring, the writer quite agrees that the integral action of pipe shell, stiffener, and column support requires certain assumptions as to the proper value of *a* (Fig. 6). In

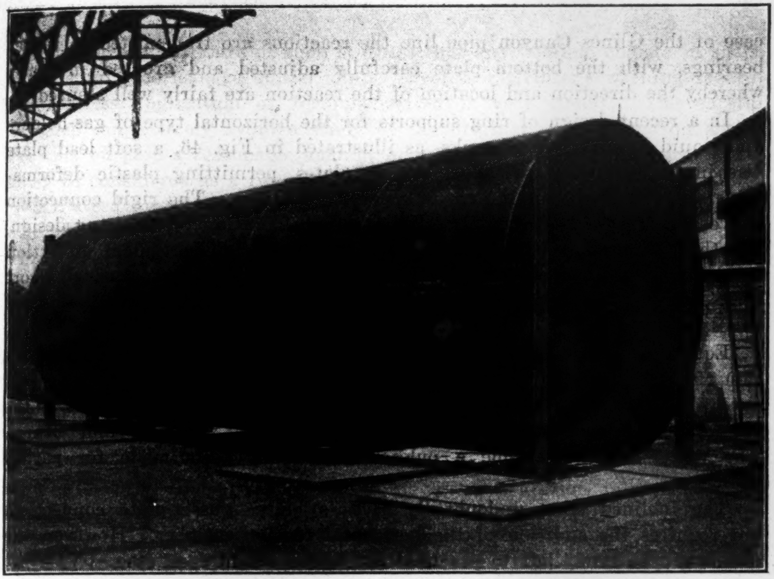

FIG. 45.—TANK FILLED WITH WATER AND EMPTIED WITHOUT CAUSING DEFORMATIONS NOTICEABLE TO THE EYE.

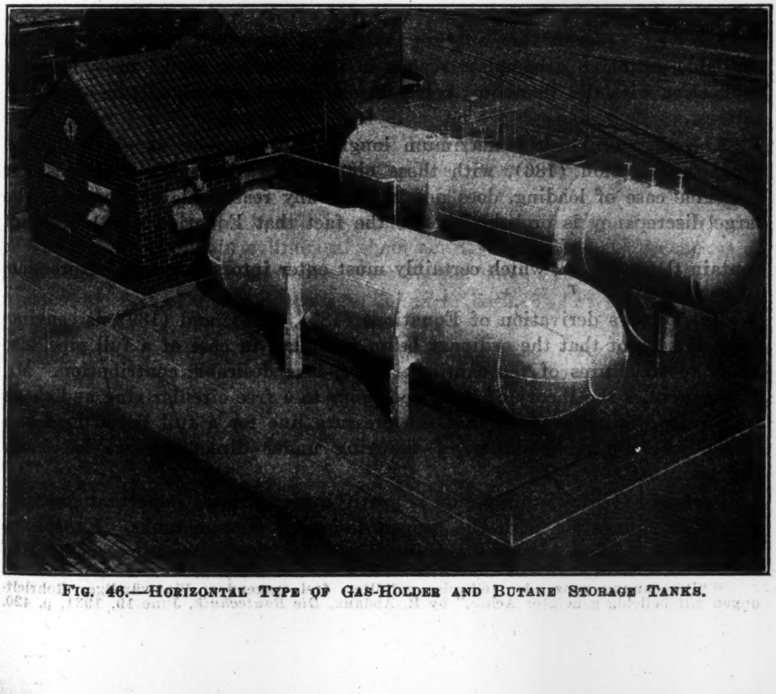

FIG. 46.—HORIZONTAL TYPE OF GAS-HOLDER AND BUTANE STORAGE TANKS.

case of the Glines Canyon pipe line the reactions are transmitted to rocker bearings, with the bottom plate carefully adjusted and grouted in place, whereby the direction and location of the reaction are fairly well assured.

In a recent design of ring supports for the horizontal type of gas-holders and liquid butane storage tanks, as illustrated in Fig. 46, a soft lead plate was inserted between two steel bearing-plates, permitting plastic deformations and re-adjustment in case of eccentric loadings. The rigid connection between ring and shell was not taken into consideration for the ring design, but this assumption is evidently on the safe side. The typical distortion curves of unstiffened pipe shells on saddle supports, with comparatively short spans, as shown in Fig. 28, will serve as an instructive guide for designs of this type.

Equation (170), based on simplifying assumptions, is identical with Equation (9). The same qualifying considerations for partial fillings, as brought out by Mr. Boardman and already answered, also hold for the analysis of the ring supports of the type investigated by Messrs. Templin and Sturm. The writer would welcome a publication of any tests made for partial fillings.

The inclined strut undoubtedly gives a better gusset-plate connection, but requires the addition of the horizontal tension member. However, the choice can be safely left to practical considerations in each case.

Mr. Knapp's reference to the previous paper by Professor Thoma, also referred to by Professor Roark and Messrs. Templin and Sturm, is appreciated.

The writer regrets that only an abstract of the thesis by Dr. Abdank[67] is available, although a complete report on the extensive model tests, made in connection with the Shannon River penstock, would undoubtedly be of general interest.

A comparison of the maximum longitudinal stresses, as given by Mr. Knapp's Equation (186), with those obtained by Samsioe's equations, for the same case of loading, does not indicate any reasonable agreement. The large discrepancy is probably due to the fact that Equation (186) does not contain the ratio, $\frac{L}{r}$, which certainly must enter into any general expression.

Mr. Vetter's derivation of Equations (187), (188), and (189), is convincing. His proof that the ordinary beam formulas, in case of a full pipe, also apply to structures of the cantilever type, is a desirable contribution. Mr. Vetter applies the theory of string polygons to a free circular ring and shows in a very original manner that the pressure line for a full liquid load is a circle, whereby the stability of the ring under direct stresses is clearly demonstrated.

Professor Grinter's discussion is gratifying and raises important practical points in connection with the proper design of storage tanks. Experience will always confirm his excellent statement that the important consideration is to produce a structure of such stiffness that any possible change in shape will not produce leakage at the joints. Professor Grinter's warning regarding careless application of formularization is very timely. The careful designer can scarcely avoid a study of the original publications on shells. For this purpose a reasonable amount of mathematical training must necessarily be considered as a fundamental requirement.

[67] "Berechnung ganz oder teilweise gefüllter, frei tragender, dünnwändiger Rohrleitungen mit beliebig geneigter Achse," by R. Abdank, *Die Bautechnik*, June 19, 1931, p. 420.

Mr. Reed's description of some of the more recent Swedish pipe lines is well adapted to establish further confidence in supports of the ring type, which evidently has become common practice in Sweden for economical reasons.

Mr. Glover's discussion is of decided value, because it raises the question as to what part of the pipe shell can be considered as a flange of the ring girder, when monolithic action is assured. The same problem has also been discussed by Messrs. Templin and Sturm, who suggest that, based on tests of a flat plate, stiffened with two channels back to back, about eight times the thickness of the plate outside each row of bolts can be considered as acting monolithically with the stiffener.

Mr. Glover's analysis is based on the stress condition in an infinitely large flat plate, loaded by forces in its plane along a straight line, the magnitude of these forces varying as the ordinate of a sine curve. Assuming that the closed shell acts in a manner similar to a plate, Mr. Glover then arrives at a total effective width of the shell, $\beta = 0.383\, r$ (Equation (212)), whereas Messrs. Templin and Sturm suggest $\beta = 16\, t$, when both sides of the ring are considered.

The writer is unable to agree with either suggestion. Evidently, the effective width in the case of a shell is a function of both r and t. This fact may be observed roughly by compressing rubber tubes of different dimensions at the two opposite points of a diameter. From the theory of shells it may be concluded that a wave-shaped load around the circumference will not change the effective width greatly, unless the number of waves becomes fairly large.

As an approximation it will be sufficient to compute the effective width of a shrink fit on a thin cylindrical shell, similar to Fig. 4(a). By means of Geckeler's[8] equation for the ring stress in the shell, the width of the corresponding zone of uniform stress is found to be $0.78\sqrt{r\, t}$ on each side of the ring, giving a total effective width, $\beta = 1.56\sqrt{r\, t}$. Applied to the design example, $\beta = 1.56\sqrt{60 \times 0.25} = 6.0$ in., Mr. Glover's formula gives about 23 in. and that of Messrs. Templin and Sturm gives 4 in. for the same case.

As shown by Mr. Glover, the consideration of monolithic action between shell and supporting ring results in reduced bending stresses in the ring girder. In order to take full advantage of the imaginary shell flange, it would be advisable to provide a corresponding flange of equal width and thickness on the outside of the stiffener web, so as to obtain true I-beam action.

HIGHWAY CONSTRUCTION MANAGEMENT[1]

By T. Warren Allen[2], M. Am. Soc. C. E.

With Discussion by Messrs. A. E. Holcomb, and Chester Mueller

Synopsis

The aim of construction management is to conduct operations properly in the least expensive way, whether the task be to construct a bridge, lay a pavement, or move cubic yards of earth.

In its broadest sense such management should begin with the consideration of the economic necessity and priority of procedure. Thus: Should the highway, A-B, be improved? What valid reasons are there for its improvement? What adequate return will there be for the expenditure that may be made? Should this road be improved prior to the improvement of the highway, C-D? What valid reasons are there for its improvement in advance of other highways that should also be improved? To avoid waste, an expenditure of public funds should await suitable answers to these questions. This paper describes how some of these problems have been approached by the Division of Management of the United States Bureau of Public Roads.

The Influence of Administration

Consciously or unconsciously, every administrator having charge of highway improvements, every locator, and every designer is frequently confronted with problems of construction management. During the 1929 construction season the writer encountered two outstanding illustrative cases. One was the construction of a part of a route out of turn. The location of this section was such that it could neither be used to local advantage nor to forward the construction of the remainder of the route. Thus, a sum of several hundred thousands of dollars was tied up, yielding no returns toward paying its interest cost for a period of nearly two years. Furthermore, had an adjoining section been constructed first it would have provided an improved road instead of an unimproved one for transporting the materials used in the first section.

---

[1] Presented at the meeting of the Highway Division, New York, N. Y., January 16, 1930.

[2] Chf., Div. of Management, U. S. Bureau of Public Roads, Washington, D. C.

The other case was that of a highway under contract to be paved. The route covered was mostly new location and several new bridges were required. These bridges were not included in the paving contract; they were let as a separate contract, but not until the paving work was nearly completed. As a result, the paving contractor had to move his plant around each stream, crossing by various detours and often at considerable expense. Incidentally, the paving contract also included the placing of the pavement over these bridges, which could not be done until long after the regular paving had been completed. The loss due to the failure to complete the bridges at an earlier date extends much farther than the mere cost of moving the plant around the detours. For example, while the contractor, in the course of seven days, had to move his equipment to six new locations to dodge unbridged streams, the length of haul from move to move varied as much as 4 miles. Thus, one day it was 3.2 miles; the next it was 7 miles; and the following day, 3 miles. It was impossible to keep a properly balanced hauling equipment on hand, and the rate of production was naturally low even for the actual working time.

These illustrations show the influence of administration on construction management. Another example concerns the mixing time of concrete for the pavement slab. State highway specifications for the time the concrete materials must be held in the drum during mixing vary from 60 to 105 sec. Since modern paving machines require about 15 sec. additional for charging and discharging, it follows that a 60-sec. mixing requirement permits of turning out a maximum of 48 batches per hour, but a 105-sec. specification reduces the maximum possible output to 30 batches per hour. Bearing in mind that the daily operating cost is practically the same in both cases, it is evident that in the latter case the cost of production is increased tremendously over what it would be for the former. The mixing action is not changed by merely moving the paver across State lines. If 60 sec. of mixing produces concrete of the required strength and quality in one State, why is this not also true in a neighboring State? From another viewpoint, if quality is improved by a longer mixing time, is it, for example, improved sufficiently by 45 sec. of additional mixing to pay the cost of 37½% reduction in the rate of production?

HIGHWAY MANAGEMENT RESEARCH

In this connection Table 1 shows typical averages of results of more than three years' work by the Division of Management of the Bureau of Public Roads, which seem conclusive. It gives the average breaking strength of standard cylinders made from samples taken, respectively, from each corner and from the center of the batch as dumped on the sub-grade when the mixing time was varied from 45 to 75 sec. Each entry represents an average of from five to ten cylinders. Cylinders *A* and *B* were taken, respectively, from the left and right-hand corners farthest from the mixer, Cylinders *C* and *D,* from the right and left-hand corners nearest the mixer, and Cylinder *E,* from the center of the batch as dumped on the sub-grade. The locations of the jobs given by numbers are, as follows:

Job No.	Location
1	Mahoning County, Ohio
2	Miami County, Ohio
3	Coshocton County, Ohio
4	Crawford County, Arkansas
5	Gadsden County, Florida
6	Leon County, Florida
7	Harnett County, North Carolina

* This series was mixed in 90 sec.

Fig. 1 also shows graphically the result of more than 3 000 individual tests made on about forty different highway construction projects under a great variety of actual field conditions. These show definitely that the modern road paver in good condition will produce a high quality of concrete in 45 sec. and that certainly nothing of material value is to be gained in strength by extending the mixing time beyond 60 sec.

The field tests also show that with modern equipment and alert management, operation can be maintained on the shorter mixing time at as high a degree of efficiency as on longer mixing times. Furthermore, this additional production can be secured with the employment of little, if any, additional labor except the necessary additional trucks and drivers to deliver the additional batches.

The influence of design on construction management and costs is far-reaching. In the case of a bridge, for example, the design largely controls the methods which can be used in both the fabrication and the erection. In the case of the highway itself the design usually includes many items which vary widely, depending on whether the designer gives real thought to his work and is familiar with the construction problems involved or merely follows the lines of least resistance. The average designer in dealing with the item of grading, for instance, is quite careful to balance his cuts and fills, but he usually fails to give sufficient consideration to the lengths of haul he imposes or how widely or frequently these lengths may fluctuate. Inattention to these details makes it very difficult, if not impossible, for the contractor to adjust the size of his hauling outfit properly so as to fit the work to be done, and increases the cost materially.

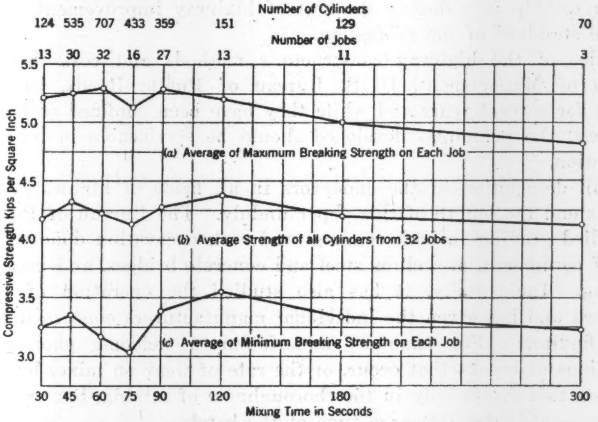

FIG. 1.—EFFECT OF MIXING TIME ON STRENGTH OF CONCRETE.

This may be better appreciated by reference to the actual variations in haul from day to day encountered on a power-shovel grading project. A few consecutive days selected at random from this project show the following average daily haul lengths, in feet; 900, 400, 200, 1 000, 1 000, 550, 800, 1 000, 350, 1 100, and 650.

In this case assume that the shovel was excavating at the rate of 750 cu. yd. of common excavation per 10-hour day. Then, for example, if 1.5-yd. wagons, traveling at a speed of 240 ft. per min., were used for hauling, the number of wagons required for each day would be 9, 5, 4, 10, 10, 6, 9, 10, 5, 11, and 7, respectively.[8] Under such conditions it is practically impossible for the contractor properly to adjust the size of his hauling equipment to the output of the shovel. The condition is really worse than shown, because quite wide variations in hauling lengths also occurred during the progress of each day's work.

---

[8] A full discussion of the method of determining the number of wagons may be found in *Public Roads*, March, 1928, and for the number of trucks in paving work, in *Public*

As a matter of fact in a case like this, the contractor being unable to vary his hauling equipment in such a zigzag fashion, usually decides upon a fixed number of hauling units, say eight, for illustration. He then finds that for the first day's work he is one wagon short, and as the shovel can only dig when there is hauling equipment available the output for the day is 83⅓ cu. yd. short, and at, say, 60 cents per cu. yd., this means a loss of $50 minus $10 (estimated cost of one wagon, including driver), or $40. The following day there is a surplus of hauling equipment of three wagons which at $10 per day means a loss of $30. In like manner, for the succeeding days, losses occur amounting to $40, $70, $20, $40, $70, $30, $92.73, and $10, respectively, or an average loss of about $46.63 per day.

The foregoing discussion is introduced solely to bring to the attention of highway engineers matters which if given due consideration should operate not only to help in reducing the cost of highway improvement, but also to raise the standard of the profession.

Studies of the highway constructor's methods and costs made by the Division of Management, U. S. Bureau of Public Roads, have been in progress for several years and while they have been confined to highways, it is believed the principles developed should be serviceable in other lines of construction.

A full description of the endeavors in all fields of highway contracting would extend the length of this paper unduly. The Bureau of Public Roads has studied grading in both common and rock excavation done with various kinds of equipment, as well as steel and concrete bridges, and many types of surfacing. Incidentally, it has also studied the operation of the equipment used and has given the individual manufacturers concerned the benefit of its findings. For example, manufacturers welcome photographs and descriptions of breaks that occur, or the rate of wear on mixer buckets. The latter is a factor, not only in the thoroughness of mixing, but excessive wear seriously retards the discharge time of the batch.

Analysis of Time Losses

In general, the method used has been to make stop-watch analyses of the various activities on many going projects, covering practically all classes of road work. By this means average performance data have been secured for construction work both by districts and for the entire country. Of course, data showing excellent performance have also been secured. From this experience, and with these averages as a measure, the performance of the individual constructor as determined by stop-watch readings can be analyzed so as to show him not only wherein he fails to attain the fruits of average or excellent management, as the case may be, but also to indicate to him how his future performance can be improved.

The studies invariably disclose time losses. These are divided into major losses (which are of 15 min., or more, in duration), and minor losses (which are of less than 15 min. duration). Major and minor losses are then usually each subdivided into Classes A and B. Class A, in general, includes all those arising from the action of the elements and from contingencies which the exercise of good managerial ability would not have been expected to anticipate and prevent; and Class B includes all time losses which good management, under the conditions of the particular job in question, should have found possible to eliminate. The degree to which a contractor profitably eliminates the Class B losses indicates his grade of management. The results of these studies are recorded on a weekly report known as "Form C. S. 13" (see Table 2). A copy of this form properly filled out is given to the contractor whose job is being studied.

Its purpose is to bring together the data collected in regular production studies into a concise and compact form so as to emphasize as clearly and forcibly as possible the extent or amount of the various classes of time losses which are being incurred, and the effect that these time losses (which seem possible of elimination) are having on the rate of production.

The major time losses consisting of definite stops involving several minutes or hours in duration are, of course, fully apparent and every contractor makes efforts to prevent their occurrence or recurrence. The minor time losses, which are largely repetitive and involve only seconds, are not so apparent to the management; and yet on the average road job, as determined from studies on many hundreds of going projects, the minor time losses consume from 20 to 50% of the total time that the crew is at work. Furthermore, definite stops of from 15 min. each to several days in length consume from 25 to 50% of the otherwise available calendar days. In other words, on the average job about one-half the theoretically available calendar working time is a total loss in so far as any useful production is concerned.

On the basis of studies of nearly a hundred concrete paving jobs with modern equipment, fairly well distributed over the entire United States, the Bureau of Public Roads has found that, on what might be called the average concrete paving job, after the contract is secured and the plant and crew are assembled, the mixer is only used for pouring concrete about 60% of the available calendar working hours. The remainder of the time is lost from the following causes:

MAJOR TIME LOSSES

	Percentage
Rain	9.5
Wet sub-grade	8
Lack of prepared sub-grade	3
Lack of materials	3.5
Moving plant set-up	3.5
Inadequate supply and faulty operation of hauling equipment	3
Mixer trouble	2
Lack of water at mixer	2
Loading plant trouble	1.5
Miscellaneous causes	4
Total	40

TABLE 2.—Summary of Time Losses and Their Effect on Production (Form C. S. 13).

State__________ County__________ F. A. P. No._____ Project No._____

Type of project__________ Dates, including or week ending__________

Total minor delays occurring during time of actual operation, as extended from stop-watch studies *Character*	Class A		Class B		Total all minor delays	
	Hours	Per cent	Hours	Per cent	Hours	%
Totals						
Time major equipment operated at 100% efficiency....................						

Grand total all Class B time losses, hours....................

Possible operating time, all Class B losses eliminated, hrs....................

With all Class B losses eliminated, production would have been....................

Over-all efficiency of major equipment operation, %....................

Notes.—"Major delays" include all stops of 15 min. or more in duration, while "minor delays" include all stops less than 15 min. each in duration as found by stop-watch studies and extended to time of actual operation. Use back of this form for Remarks. Give total extent of stop-watch studies, in hours, for week.

These definite stops, each of 15 min., or more, in duration, do not comprise the entire time loss or time during which the key equipment is idle. Stop-watch studies on these same jobs show that an average of nearly 16% of the total available time, or 26% of the time the crew is at work, is lost in minor stops and interruptions, each less than 15 min. in duration. These are due to the following causes:

MINOR TIME LOSSES

	Percentage
Supply and operation of hauling equipment	7.3
Lack of, or trouble with, water at mixer	1.9
Lack of materials and supplies in place	0.7
Mixer trouble	1.1
Mixer operator	1.3
Finishing	0.4
Sub-grade delays	1.6
Miscellaneous causes	1.3
Total	15.6

In other words, the average concrete road paving contractor is not only out on the road with his crew only about 60% of the available calendar hours, but during this time he is actually operating at only about 74% of the rate at which his key equipment is capable of maintaining. The details from which these averages are derived were assembled in forms, of which samples are illustrated by Tables 3 and 4.

Table 3 is arranged to show the time available, time lost, production, and stop-watch data observed on about eighty concrete paving jobs during 1926, 1927, 1928, and 1929. The code numbers in Columns (5) and (21) denote: 1, new; 2, very good, or excellent; 3, good; 4, fair; 5, poor; and 6, very poor. The distribution of time losses for various causes is recorded by the Bureau of Public Roads as illustrated in Table 4. The major losses, involving stops of 15 min. or more, each, are segregated in a record form identical with Table 4, except for some modifications in corresponding column headings. The totals and the column headings for this table, on the jobs listed in Tables 3 and 4 are, as follows:

Total time that should have been available, and the percentage of this time that was lost for various causes, in definite stops of 15 min., or more:

Column (3), total available time, in hours	33 309.72

Total time that the mixer was idle:

Column (4), hours	13 342.46
Column (5), percentage of total available time	39.95

Causes from which time losses (in percentage of total time) were incurred:

Column (6), miscellaneous	2.63
Column (7), operation	0.47
Column (8), shortage	2.15
Column (9), moving mixer or plant set-up	3.62
Column (10), mixer trouble	2.04
Column (11), lack of materials at yard	3.55
Column (12), trouble at batcher plant	1.47

Column (13), lack of, or trouble with, water	2.15
Column (14), finishing	0.50
Column (15), wet sub-grade	7.29
Columns (16) and (17), joints, or steel	0.10
Column (18), cold	1.05
Column (19), sub-grade not prepared	3.37
Column (20), rain	9.56

In road grading with the power shovel, much the same condition is found as in paving, except that the weather losses are much smaller and the minor or short-period interruptions or delays consume a much larger proportion of the working time. Thus, on the basis of more than 100 power-shovel, road-grading jobs, the Bureau of Public Roads has found that on the average, after the contract is secured and the equipment is on the ground, the major losses are about 30% of the total available calendar hours, these being in definite stops each of 15 min., or more, in duration. Such major delays are due to the following causes (in percentage of total losses):

Rain and wet ground	9.4
Repairs to shovel and other equipment	10.5
Moving from cut to cut	2.8
Drilling and blasting	2.1
Hauling equipment trouble, or shortage	1.4
Taking on, or lack of, fuel or water	0.9
Miscellaneous causes of various kinds	3.0
Total	30.1

Stop-watch studies also show that about 27% of the total available calendar hours, or about 39% of the time the shovel is supposedly at work, is unproductive. These minor delays or interruptions to continuous operation are due to the following causes (in percentage of total available calendar hours):

Lack of sufficient hauling equipment	8.2
Improper operation of hauling equipment	5.4
Moving shovel within cut	3.3
Checking grade	0.3
Shovel repairs, minor	2.3
Handling large rocks, boulders, stumps, etc.	2.5
Blasting boulders, rocks, etc.	0.4
Taking on fuel	0.7
Operator	1.1
Miscellaneous causes of various kinds	2.9
Total	27.1

These figures are averages of a great many jobs and must not be confused with the performance on individual jobs. Weather and other uncontrollable causes often affect one job seriously, but may leave another practically untouched. Thus, the Bureau of Public Roads has found concrete paving jobs which have operated for a month or more at a time loss not exceeding 10% of the available calendar hours and which utilized more than 90% of the time at work in useful production. This, however, is exceptional and prob-

ably could be expected to be attained only during the most favorable part of the construction season. The studies also indicate that as contractors become better aware of the losses incurred, the percentage of such losses decreases.

METHOD OF DETERMINING REQUIRED NUMBER OF HAULING UNITS

When hauling units are used in different types of road construction an immediate problem confronts the contractor as to the number of units required in hauling material. Usually, a contractor does not predetermine the proper number of trucks, wagons, or other typical hauling equipment that is necessary to handle the particular material which is involved. If it appears that he started with an insufficient supply he orders more, but not until an unnecessary amount of time and money has been lost.

In concrete road construction or similar work, trucks are usually hired and paid for at so much for each batch or each batch-mile. This price is influenced by the length of the haul. If too many trucks are on the job they eliminate one another by the income they receive, or they are discharged by the contractor's superintendent. If not enough trucks are present, more are hired. It is only by careful planning and management on the part of the superintendent that a sufficient number of trucks are present to supply the mixer. This is true in other lines of construction where hauling units are employed.

In power-shovel grading where the haul is relatively long, large-sized hauling equipment is frequently used. In shorter hauls, teams and wagons, light trucks, and iron mules are often used. With the larger units extreme care must be taken when deciding on the proper number of hauling units. It may appear that an insufficient number of units is employed, yet, if another large-sized unit is added, it may not be economical; but whether large or small units are employed it is necessary to keep all of them busy. If they are not sub-contracted, it is necessary, if possible, to shift part of them to longer hauls when an over-supply of units is available. The foregoing statements concerning power-shovel grading may be applied also to the elevating grader.

In any construction it is absolutely essential to maintain a good haul road. After a rain the road is soft and becomes rutted and full of "chuck" holes. One or more men with the proper equipment should be assigned as rapidly as possible to the constant maintenance of the hauling road. Failure to observe these rather elementary requirements probably explains why the average contractor loses more money through shortage of hauling equipment than from any other controllable cause.

EFFICIENCY IN PRODUCTION

These time losses would not be so serious if the cost of operation varied with the output. Unfortunately, however, the daily or hourly cost of operating almost any kind or type of modern well-equipped road-building outfits is nearly the same whether production is at only a fraction of its capacity or at its maximum rate. In concrete road construction, for instance, the operating cost of a modern outfit, exclusive of materials, but including all labor, supplies, overhead, and rental value of the equipment, is seldom less than $40 per actual working hour and may readily exceed $50 per working hour. Frequently, however, a plant with an operating cost of, say, $45 per working hour and an actual capacity of 45 to 48 batches per hour is, at least at times, producing only 20 batches per hour. The operating cost is then $2.25 per batch, whereas capacity production would cut the cost to about $1.00 per batch.

It is thus quite plain that the contractor should do everything in his power to increase production. Frequently, the observation is made by engineers that it is no concern of the engineer whether the contractor makes or loses money. With but few exceptions, the cheapest method of construction is by contract, and a prosperous contracting fraternity is essential if work is to be well done. Increased efficiency in contract work will ultimately be reflected in lower bid prices. Probably without realizing it, highway contractors are bidding on a basis of doing work at a little more than 50% efficiency. Some of the contractors are doing a profitable business and some are not. The proper procedure for all of them, in order that they may do a more profitable business, should be more efficient management rather than increased prices.

The Bureau of Public Roads, therefore, believes it is working in a worthy cause and in a fertile field when it undertakes to assist highway contractors in increasing production. To this end the Bureau has met with gratifying success. In some few cases it has been possible nearly to double the rate of production with little or no addition to the cost of operation. These cases are exceptional, of course, but still fewer are the cases in which it has not been possible to show some improvement in the rate of production without entailing a corresponding increase in the cost of operation.

Having in mind the causes of low production, attention then logically turns to their elimination or reduction. Frequently, it is an easy matter to remedy some of the causes which have been most influential in keeping down the rate of production. For example, it is not uncommon to find that in power-shovel grading improper placing of the hauling units imposes an unnecessarily long boom-swing which increases the bucket cycle by as much as 5 sec. In good common excavation the elimination of this one delay alone may mean an increase of from 20 to 25% in the rate of production, an item surely worth while.

As a specific example of what was accomplished in the summer of 1929 by ascertaining losses and bringing their meaning to the attention of the contractor the following is given:

On a Portland cement concrete paving job 12.41 miles long and 18 ft. wide, with a thickness of 8 in., 6 in., and 8 in., the pavement was being laid during the summer months. Standard, modern equipment was used throughout, and production studies were conducted between August 19 and October 5. The daily record of production and time losses before these studies were

Total														

* Truck supply and operation delays comprise greater part of this total: September 21, 6.84 hours; September 28, 2.43 hours.

† Water supply delays comprise greater part of this total: September 21, 5.09 hours.

‡ Rain delays comprise greater part of this total.

§ Wet sub-grade delays comprise greater part of this total.

‖ Move pipe line delays comprise greater part of this total.

started, is not given. Paving operations had been in progress for one month prior to August 19 and during this time only 1.53 miles, or 16 157 sq. yd. of pavement were laid. The biggest day's run during this period was 330 batches, or 991 lin. ft. of pavement. On only one or two days did the outfit lay more than 800 lin. ft. of pavement. During the seven weeks that the study was in progress, 6.76 miles of pavement were laid. During the week ending September 21, 2 168 batches, or 6 406 lin. ft. of pavement were laid. The biggest day's run was 411 batches, or 1 226 lin. ft. of pavement in 11.5 hours. The summary in Table 5 shows that the efficiency of the job increased from 78.8% for the week ending August 24, to 88.4% for the week ending September 14, and to 98.2% for the week ending October 5 (see Column (15)).

Another example of increased production with unit costs decreased is shown in the results of studies made on Wisconsin Federal-Aid Project No. 460-A. This was a Portland cement concrete paving job, 14.7 miles long, in Dane and Columbia Counties. Studies were conducted between June 3 and August 24, 1929.

The contractor's major operations were analyzed and the cause and extent of all time losses determined. This information was furnished to the contractor who used it as a guide in his efforts to increase production. The trend of operations during the studies is shown in Table 6.

TABLE 6.—PRODUCTION STUDIES, FEDERAL-AID PROJECT NO. 460-A IN 1929

Item No.	Description	June	July	August
	DISTRIBUTION OF TIME LOSSES, IN PERCENTAGE OF TOTAL TIME SPENT			
1	Mixer (operator)	2.3	2.8	1.7
2	Mixer (mechanical)	1.4	1.2	1.2
3	Truck (operation)	4.6	4.0	3.7
4	Truck (supply)	13.0	7.6	1.6

11	Dry batches	0.0	0.7	1.0
12	Total delays	31.3	26.1	19.4
	COSTS			
13	Cost per square yard	$1.44	$1.30	$1.26
14	Reduction, in percentage, of June costs	....	9.7	12.5
	MISCELLANEOUS DATA			
15	Number of days in which concrete was poured	24	23	15
16	Average length of working days, in hours	11	11.5	11.5
17	Total production, in square yards	36 636	40 285	30 381
18	Average production per day in which concrete was poured, in square yards	1 526	1 749	2 025

The greatest cause of lost time, as shown by the studies, was due to a shortage of hauling equipment. This was pointed out to the contractor early in the studies and, as a result, he realized the importance of supplying a sufficient number of hauling units for full mixer production. This delay was materially reduced. The reduction in unit cost is due to the increase in production resulting from the elimination of delays as a result of the studies.

The foregoing are only a few of many studies in which production was materially increased without a proportionate increase in unit costs. It is not always possible to increase production at the rates shown in the examples given, but on the other hand failures to record some improvement are rare.

CONCLUSIONS

A general observation of the following rather elementary suggestions should do much to increase the efficiency with which the average road construction outfit is operating:

1.—The rate of production is so dependent on the performance of the key equipment as to demand that it always be maintained in good mechanical condition, and to forbid the employment of any other than a high-grade operator.

2.—Auxiliary or dependent equipment which is of insufficient capacity or which cannot maintain the rate demanded by the operations of the key equipment, should not be tolerated. This applies also to the operators of such equipment.

3.—The use of equipment or methods of operation which cannot readily be adapted to operating efficiently in connection with the assembly or outfit as a whole, or to sustain economically the production rate of the key equipment, should be avoided.

An assembly of men and equipment, no matter how fine, is practically worthless as a producing unit until supplied with a directing head, because on the managerial ability which it exercises depends not only the rate of production obtainable from any construction outfit, but also the unit cost at which such production is secured. A man with real managerial ability, free to run the job as a whole, is essential to high rates of production, low unit costs, and best possible profits; but if the construction industry is to reap the full advantages which management offers in translating designs and plans into realities, it must also develop a spirit of mutually helpful co-operation and understanding between those who manage and those who plan and supervise. The relation of costs and quality are so interwoven that the ideal adjustment can never be attained except through mutual co-operation and assistance.

DISCUSSION

A. E. HOLCOMB,[4] M. AM. SOC. C. E. (by letter).—This paper is both interesting and instructive. The cost of work is frequently affected materially by its location and its timeliness with reference to other work. Unfortunately, economy of construction is seldom the controlling factor in the passing of a bond issue; the volume of noise made by the respective interested parties is usually much more potent. In fact, the psychology of selfish interest is quite often as important a study as the engineering problems involved.

The politician makes the welkin ring with his pre-election grief over the hardships of his constituents and promises to raise them "out of the mud" if he is elected. After election, that locality containing the most votes gets the improvements regardless of whether the work in that section forms a link in a system that will serve the greatest number or, due to location, is more expensive to build than it would be later after another section has been constructed.

Insufficiency of funds and the necessity of giving some relief frequently compel the construction, for instance, of an inadequate drainage system or other project that later must be reconstructed and enlarged at an increased unit cost. Many other reasons of expediency often affect ultimate costs. These are practical considerations that have to be borne in mind. Mr. Allen, however, refers to controllable factors subject to job management.

One of the most frequent decisions that a contractor is called upon to make, is whether to use the equipment he already owns, which is not properly adapted, economically, to the particular job in question, or to purchase new and proper equipment of a size and type to handle the work to the best advantage. In other words, will the increased earnings of new equipment exceed the depreciation and interest charges of the idle equipment? Also, will he be justified financially in depleting his liquid assets at that time by purchasing the needed new equipment? It may be more expedient, or even more profitable, in the end to use his old and less efficient equipment.

On the other hand, because of an inherent, natural reluctance on the part of every one to scrap anything of value, contractors will frequently keep and use obsolescent equipment that is still mechanically in good condition, but "out of step" with newer methods and faster operation. A study of relative output and cost of operation will often show that it would be more profitable to run the obsolescent equipment over the bank—use it as a part of the fill—and buy more modern equipment.

There is often a wide range between the cost to own and the cost to operate. One can well afford to pay considerably more than the average price for equipment, provided the increased earnings within a reasonable length of time will exceed the sum of the increase in first cost, depreciation, and interest charges.

---

[4] Sales Mgr., Koehring Shovel and Crane Div., National Equipment Corporation, Milwaukee, Wis.

Among the major delays, Mr. Allen mentions 10.5% lost time due to repairs to the shovel and other equipment. However, he does not state the nature of the other equipment. The writer's records covering eleven shovels and dragline excavators, over a period of six years, show an average of only 7.8% delay for repairs of sufficient duration to cause a record on the daily report blanks. Such delays are affected by so many things that may or may not be controllable by management that it is impossible, in estimating, to depend on any given range of minimum and maximum repair time figures that would not be excessive. For ordinary and usual conditions, a range of 8 to 10% would be adequate where equipment is maintained in reasonably proper condition. The closer the inspection and the better the upkeep management, the less will be the amount of upkeep delays.

Speaking generally, the more common causes of major delays are unbalanced equipment and lack of foresight in planning operations. For example, in rock work the drilling and blasting are frequently allowed to tie up expensive equipment through the use of the wrong size or kind of drills, lack of sufficient drilling equipment, or improper placing and character of charges. On other work, as Mr. Allen very clearly indicates, one of the greatest causes of loss is the difficulty in balancing and dispatching the hauling equipment.

The real savings, however, are usually to be effected through close personal supervision to keep down the minor, or Class B, delays, since they are largely subject to management control. Mr. Allen refers to improper placing of hauling equipment with relation to the shovel on grading work as an influential factor in the production rate. The writer would suggest in connection with this, the study of the proper width of bench and height of cut to give the most economical results in bank work through deep cuts.

Pre-analysis of jobs, with determination of general plan and layout of work before bidding, supplemented afterward with time studies and distributed costs, is the great need, instead of so much blind and hungry bidding with ever-springing hope and faith in Providence to show the bidder how to cut his costs in two after the award has been made.

CHESTER MUELLER,[5] ASSOC. M. AM. SOC. C. E. (by letter).—This paper forcefully calls attention to the avoidable waste prevalent in the highway construction industry and the efforts of the U. S. Bureau of Public Roads to reduce it. As shown by Mr. Allen, this branch of engineering is in need of, and is entitled to, the painstaking form of research heretofore confined to the realms of pure science and only recently applied to manufacturing processes by the Mechanical Engineering Profession through the media of time studies.

A few comments on some of the features of the construction industry that were treated by the paper might not be amiss, particularly if they are examined in the light of municipal paving projects.

Policies.—Wisely, Mr. Allen foregoes a lengthy discussion of policy. While "economic necessity and priority" are proper topics for engineering consideration, nevertheless, a pavement is frequently constructed at the insistence of an organized group of citizens—when the cost is not to be locally assessed—

---

[5] Prin. Asst. Engr., Dept. of Public Affairs, Newark, N. J.

in spite of the lack of necessity for it. Likewise, a much needed pavement may be opposed by abutting property owners when such improvement is to be paid for by assessment against such owners. Preparation of data clearly will be expected of an engineer, but where local sentiment or the pocketbook is involved, the exercise of well-founded engineering judgment will be denied him.

Contracts.—The paper, dealing essentially with the execution of work, implies that an eingineer must do his share to foster efficient methods. He can do this in the very beginning by making the time of letting a paving contract seasonable. Receiving bids during the period of uncertain markets, for work under adverse weather conditions, and with unreasonable time clauses, will certainly affect bid prices and will have considerable bearing on subsequent construction administration.

By making the "Information to Bidders" clear and complete, the contractor may better formulate his plan of operation. Adequate plans of the work will also aid better planning.

It is possible that, even though they are poorly executed, the foregoing items may not prevent efficient administration; but if they are properly constituted, they will certainly be conducive to it.

Subsurface Work for Utility Companies.—In cities, probably the largest single problem handicapping successful administration, is the subsurface work that public utility companies perform in advance of paving. Such work is essential, and in order to reduce the disruption of traffic to a minimum, it often becomes necessary for a paving contractor to begin his operations while underground work is also in process. In co-ordinating this work and in expediting the subsurface work the engineer can do much to obtain for the public and the contractor a paving job efficient in time and in cost. Subsurface work by utility companies in the public streets and highways certainly tends to resist efficient highway construction administration, and in the extensive field of endeavor which it covers, much is yet to be found to aid the paving industry.

Specifications.—Engineers are generally prone to let existing specifications do service from year to year without any changes other than the addition of clauses occasionally, as local experience dictates.

Specifications should be kept modern by elimination and alteration as well as by addition. In other words, complete revision may be desirable after existing specifications are scrutinized in the light of recent researches and practices. As Mr. Allen states clauses that require a mixing time for concrete in excess of the time actually required with modern equipment, result in wasteful administration. In some communities and localities, clauses of that nature may persist in specifications for years after they have been proved obsolete by competent investigators.

Design.—Failure to consider the utility of roads and approaches, and the sequence of contracts, as illustrated in the paper, is indicative of poor design and thwarts efficient administration. The writer does not fully subscribe, however, to the author's suggestion that paving design should attempt to provide for the 100% economic use of the contractor's equipment. In establishing lines and grades it should be only a minor influence since in most present-day designs the cost to the public of operating vehicles over a road after the improvement is completed, is as important as the initial construction cost. In the illustration given by Mr. Allen, the average loss of about $46.63 per day, due to irregular requirements for hauling units, may add about 4 cents per sq. yd. to the cost of the pavement, whereas changes in grade may cost far more than that, if not in construction, possibly in the operating cost of the vehicular traffic using the road. A design permitting a practically uniform daily number of hauling units and the efficient use of a contractor's equipment, is, of course, highly desirable provided other essential elements are not sacrificed. To determine to what extent the design of a road can be influenced, without adding to its cost, requires considerable additional research, and the efforts of the Bureau of Public Roads in this direction will be most helpful.

If the provision of suitably located disposal areas is considered as a function of design and as the task of the engineer rather than that of the contractor, then the design of the improvement, in so far as these areas are concerned, is most vitally associated with efficient administration. Most contracts leave the question of disposal of excess earth to the contractors, which is one reason why an alert contractor who plans his work can under-bid his competitors.

Equipment.—Equipment is given an important place by Mr. Allen, a place that it well deserves. Serviceable equipment with readily available spare parts, used and maintained in a proper fashion, determines more than any other factor, the speed and smoothness with which a paving job can be completed. The forceful and convincing sales data of leading equipment manufacturers prove to be a boon to contractors in compelling them to keep abreast of the times.

Personnel.—Many contractors are short-sighted with respect to the employment of labor on the maintenance of approach and utility roads. Use of men in what is sometimes referred to as "non-productive" work frequently has a direct bearing on the efficiency with which a contractor can operate his equipment and almost always indirectly contributes to it.

Time Losses.—In this part of Mr. Allen's paper, the most important and most convincing results of the studies conducted are brought to the reader's attention. It sets an example that many engineers could emulate, in some measure, in the study of highway jobs under his supervision. Any improvement that the engineer can introduce to the contractor will certainly benefit the contractor and ultimately the public that the engineer serves.

CONSTRUCTION MANAGEMENT[1]

BY RICHARD HOPKINS,[2] ESQ.

WITH DISCUSSION BY MESSRS. EDWARD W. BUSH, AND A. P. GREENSFELDER

SYNOPSIS

Management of construction work may well be classified into two departments: (1) The objective art of bidding for the contract, planning the work, and bringing it to completion; and (2) the subjective art of combining the elements in Part (1) to discover leaks in profit due to avoidable time losses in the various steps involved. This paper is confined to the first of these departments.

Standards of success in conservative bidding are discussed, as are also the ideal qualifications of the most important men on any job, namely, the superintendent, master mechanic, and the foreman. The paper deals, specifically, with the best attitude to hold concerning the maintenance of a construction schedule.

Intelligent bidding is the first requisite of good management. Anything that is well bought is half-way along the road to being well sold. A "lemon" on the day of the letting scarcely ever becomes a "ripe plum" when the final ledger accounts of the job are closed.

Each organization should appreciate what class of work it is best equipped to handle. Doing work in one locality only is generally not a good policy. Because two jobs lie close to each other is no reason why the same organization should attempt to build them, if they are dissimilar. Furthermore, in some years, the volume of work let may be small and the competition severe in the region where the contractor has been doing business. Prices, however, may be much better in another section. The contractor must meet the market price, but he can always choose the market in which to sell.

As a general rule, a man who obtains more than 20% of the work on which he bids is not a good bidder. He is bidding below the market. Good bidding is more often found among those who are awarded contracts for fewer than 10% of their bids. It is much better to let machinery depreciate, and parts of an organization stay idle, than it is to lose cash from a bank account. From two to six months before a job is planned to be finished the contractor should be looking over prospective work and putting in occasional bids on desirable jobs. There is no more pitiful figure in the construction world than the man who has a smoothly running and efficient organization on a particular job and waits until a week or two before it is finished to start bidding on new work. The result is likely to be bad from three angles: The new work may not be the right kind, it may not be obtained in time, and the price may be much too low.

---

[1] Presented at the meeting of the Highway Division, New York, N. Y., January 16, 1930.

[2] Richard Hopkins Co., Albany, N. Y.

The head of an organization should be introspective and critical of the quantity of work that he can have under way at one time. Most contractors do too much work rather than too little. The financial strain and lack of proper attention, both to general planning and small details, are generally harmful to profits under such conditions.

It is assumed that the bidder makes up an estimated field cost which is based on his own records. It is further assumed that to this field cost he adds his estimated over-head which includes such items as interest, depreciation, insurance, repairs, workmen's compensation, camps, office, and freight and loading charges, in moving equipment to the job. This estimated total should be close to his real total cost if labor, the elements, and the supervising engineers all act in a perfectly natural way. At this point in making up the bid, the question of contingencies enters. What are the soil conditions? How much harm will a week of rain do to progress? Will some other contractor or some public service company be working on the job at the same time, and, if so, what are their records for co-operation? Are there bridges or other structures on the job that will slow down the entire program? The bidder should judge what these contingencies will amount to in dollars and add them to the previous total.

The bidder is then ready to decide what percentage of profit or what lump-sum profit he will add to his total estimated cost. The sum added for profit will depend on whether or not the bidder is "hungry." It will depend on whether or not the job is in a market that has more than its share of labor troubles. It may vary through a wide range, depending on whether it is largely a labor job or largely a material job, and on the definiteness or indefiniteness of the engineering inspection that can be expected.

Planning the Work

It is assumed that the contractor has a head office that directs all field operations on the different jobs and handles all administrative work. A superintendent may be assigned to a particular job because he is the only one available, or because the job is suited to him and his organization. If possible, the latter reason should be the one for giving him the job. The superintendent is the all-important man on the job. His personality is of vital importance, very much more so even than that of the contractor himself. It is not always possible to have a halo around the head of the superintendent, but all construction men are learning to appreciate that nothing pays better dividends than sentiment. The superintendent should be a real leader, a friendly czar, a man who knows all the letters of the construction alphabet. Above all, he should be a man who knows how to plan and how to get performance and who knows how to dovetail the different operations into a completed whole.

Every foreman should have such ability as to command the respect of his men. They may find fault with his temperament and with some of his methods, but they must respect his ability if he is to be successful. They must feel that he knows his job. There should be a foreman on each particular operation; there should be definite responsibility for each task. If only two men are working by themselves, one of them should have the responsibility for getting the task done in the right way. Co-operation among the foremen is a prime necessity. Personal feeling and jealousy between two foremen should never be allowed to interfere with the progress of the work.

A large number of contractors are coming to realize that it is wise to combine their engineering and accounting work on a job, and place both under the control of a trained engineer. There is a close inter-relation between accounting and engineering, and nobody should be able to interpret cost figures better than an engineer. His costs will be up to date, and, with his help, it will be possible to "lock the barn door before the horse is backed out of the stall." On account of his training, the engineer is able to suggest changes in methods and personnel and even in equipment when the proper costs are not being obtained. The items of extra work, special measurements, necessary departures from plans and specifications—all have engineering and accounting woven so closely together that it is best to have them handled by one man.

The selection, purchase, and care of equipment were never so important as at present. In 1910, or thereabouts, 85 to 90% of the cost of a grading job was the payroll. About 1915, when hard-surfaced roads came to be the National vogue, the payroll was still more than 50% of the total cost. Now (1931) all the major operations and most of the minor operations on a job are done by machinery. Steam machinery has been greatly improved, the automotive engine has taken a preponderant hold on all construction equipment, and the Diesel engine is making steady progress. No construction organization can long face the present competition without being machine-minded.

Next to the superintendent the master mechanic is the most important man on the job. He should be an all-round mechanic, of course, but with the present-day machinery he should be particularly competent on automotive work. He should have enough help to make quick repairs in the event of the inevitable break-down. Most of the minor repairs and some of the major ones should be made nights, Sundays, and rainy days. If the master mechanic is not given authority to employ and discharge machine operators, he should at least be consulted by the superintendent on both employment and discharge. When the purchase of any piece of equipment is contemplated, his opinion should be asked on three questions: (1) Is the machine staunchly built? (2) Is it well designed? (3) Is a large repair bill or a small repair bill being bought with the machine?

He should see and approve all repair bills before they are paid. He should have authority to keep on hand whatever repair parts his experience teaches him are most often needed. He should be "construction conscious"; and should appreciate thoroughly the earning power of each machine and the consequent loss when the machine is not in operation.

The importance of the master mechanic's duties has been particularly stressed, but no good master mechanic can show results unless he has the help of experienced and competent operators on the different machines. Good foremen can show only indifferent results when key machines have poor operators. The machine cannot function without a hand to guide it. Often the major portions of big jobs are run with old equipment that has long since been charged off, but in the hands of good operators it is earning dividends every working day. On the other hand, a visit to a similar job with new machinery, manned by incompetent operators, often reveals numerous breakdowns which cripple any effective schedule, and, at the finish of the job, there remains a pile of junk and a depreciation charge double or even triple what a reliable estimator had a right to expect. Physicians and hospitals exercise a big part in every-day life to keep the public in good health. The construction physician is the master mechanic and when he and his internes—the machine operators—all know their job, the piece of construction under their hands is in good financial health.

Saving one shovel, one roller, or any other piece of equipment by speeding up the production of those units working on the job, cuts down the machinery charge against a job. Loading a job up with unnecessary machinery increases the machinery charge. Moving, loading, and freight charges on heavy machinery constitute a cost that is not sufficiently appreciated. Frequently, if a heavy machine is to be transported a long way and the work required of it will take only a few weeks, it is cheaper to rent a machine close at hand.

A point about which there is a sharp difference of opinion among contractors is that of maintaining a schedule. All will agree that a job that drags is seldom profitable. One school of thought upholds the ideal of 110 cu. yd. of earth per hour for the small shovel and 50 cu. yd. of concrete per hour for the paver, and there is the continual drive to equal these figures on a few big days. A few trucks and a few teams as well as a number of men are added to the payroll. The other school of thought insists on an orderly progress of the work along the line of a well-planned schedule. There are no big days, but there are some good weeks and some wonderful months. All work proceeds at an orderly consistent pace. The advocates of this method argue that the job that is built the quickest is not always built the cheapest. Final unit cost is the yardstick, to decide on the relative merits of the arguments put forth by these two widely divergent points of view.

There is an old axiom that no well-conceived military operation can be a success without good infantry. No construction operation can hope to be successful without good laborers, who are satisfied with their tasks. Their length of service is measured in years—not in days or weeks—and turn-over is small. Their camps are clean, their food is good, they know that the superintendent is a fine boss and always treats them square. They boast a little about how much better they are than the outfit on the other side of the ridge. Underlying it all is the firm conviction that they know their job and that the boss knows his.

DISCUSSION

Edward W. Bush,[3] M. Am. Soc. C. E. (by letter).—No doubt members of the Society feel greatly indebted to the author for this instructive paper. It deals with questions about which little has been written, but concerning which much can be said.

The author points out that "it is much better to let machinery depreciate, and parts of an organization stay idle, than it is to lose cash from a bank account"; also, that "most contractors do too much work rather than too little. The financial strain and lack of proper attention, both to general planning and small details, are generally harmful to profits under such conditions." The files of any large surety company will disclose cases without number which affirm the correctness of these statements. Bankers as well as surety underwriters recognize over-extension as one of the leading causes retarding the financial advancement of contractors. Analytical studies of the technical records and financial information of contractors, such as the surety underwriters are constantly making in their daily work, will disclose that advancement in financial strength is more likely to occur when the contractor makes a gradual increase in activities, rather than when he is trying to become a big contractor within a short period of time. The author has stressed the importance of a good superintendent and organization, and these are best developed by the contractor through a moderate expansion.

The contractor must be an optimist to be successful, as the business demands that he have the utmost faith in his own ability to perform, and in many cases it is this optimism which leads him to over-extend. Especially is this likely to occur after getting the "breaks" on a few contracts and thus "cleaning up" some nice profits. Under such conditions the business of contracting looks very attractive indeed and it is only a strong-minded person who can resist the temptation to load up with about everything that can be taken. Many contractors have traded net quick assets or working capital for new construction plant to find to their sorrow that there was nothing left with which to operate. A contractor may be "plant poor" and not fully realize it until he tries to keep all of it at work.

A. P. Greensfelder,[4] M. Am. Soc. C. E. (by letter).—There is a fair difference of opinion, particularly in this time of depression, as to how much a construction organization should specialize or diversify its bidding. Specialization is seemingly the order of the day. An organization with specialized machinery and crew, theoretically, should have the advantage over one that does not. On the other hand, unless there is a great deal of that particular class of construction work continuously at hand in the community, it means that the organization must enlarge its territory and follow such class of work wherever it may be found. Diversification, on the contrary, permits a smaller radius of travel and guards against having all one's organization and capital tied up in one particular type of work.

---

[3] Engr., Aetna Casualty & Surety Co., Hartford, Conn.

[4] Pres., Fruin-Colnon Contr. Co., St. Louis, Mo.

Mr. Hopkins' comments are sound relative to percentage of work secured from the volume bid. Post-bidding comments always indicate that the marginal loss between the low and the next low bid is the hardest money to regain actually. The statement is correct that one should not undertake too great a volume of work for the capital of the company. Over-eagerness in this respect has too often proved fatal.

It would seem vital that contractors, together with engineers, should evolve practical measuring rods for determining the relation between volume of work, quick and deferred assets, and construction equipment for various classes of work. The Bureau of Contract Information, Incorporated, set up jointly in Washington, D. C., by surety companies, is determining the performance record of contractors throughout the country. It should presently have sufficient experience rating to serve as a guide in making these determinations.

Unbalanced bidding is another feature which should be guarded against. One is likely to feel that his practical experience will warrant certain manœuvering of unit bid prices. There is usually enough gambling in construction without this and it is only warranted through the viewpoint of equity of the owner when the engineer's quantities are themselves unbalanced (which is, unfortunately, quite often the case). Engineers too frequently guess the quantities of excavation classification instead of predetermining them by making borings.

All estimates should include equipment rental or there will soon be no equipment to rent to oneself. Depreciation of construction equipment necessarily goes on at a very rapid rate. Obsolescence also plays its part. American inventors are daily producing new equipment so much more efficient than previous machinery that construction equipment five years old is frequently obsolete.

In planning the work, contractors should realize the value of time studies. The current studies of the U. S. Bureau of Public Roads indicate that these are indeed worth while. Lost time can be minimized when one realizes the extent.

The increasing prevalence of including engineers in contractors' organizations is noteworthy. Such engineers, on the other hand, must realize the need of being practical as well as theoretical. Regardless of cost brains are the cheapest purchase an organization can make. The analytical mind of the engineer is essential to proper cost-keeping, provided such cost-keeping furnishes, daily, the current trends of costs.

Mr. Hopkins very truly stresses the need of having on hand repair parts of machinery. Time lost awaiting repairs is expensive when a large organization is delayed. On the other hand, contractors are too apt to think in terms of labor-saving devices. They should analyze their jobs and consider machine-saving costs by not over-equipping them. Too frequently they use theoretical costs and realize to their sorrow that they have not found the operator whose hands fit the levers, or whose mind is sufficiently quick thinking or his body sufficiently active to make the operation of that machine profitable.

The preparation of advance schedules of work is essential. Such schedules serve as guides to the superintendent in the field as well as to the "boss" at his desk. They also furnish the necessary check as to the average performance. One hears of the wonderful day's over-run when records are broken, but not of the many days of under-run when machinery or organization is broken.

Construction management is rapidly becoming more and more scientific. It takes mind and matter jointly to produce smooth running construction jobs.

SOIL MECHANICS RESEARCH[1]

BY GLENNON GILBOY,[2] JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. J. C. MEEM, H. DE B. PARSONS, JACOB FELD, JOHN R. JAHN, C. H. EIFFERT, A. A. EREMIN, F. N. MENEFEE, E. G. WALKER, D. P. KRYNINE, J. STUART CRANDALL, FRANK ALWYN MARSTON, GEORGE PAASWELL, JOHN H. GRIFFITH, H. E. GRUNER, F. KÖGLER, AND GLENNON GILBOY

SYNOPSIS

In the fall of 1925, Charles Terzaghi, M. Am. Soc. C. E., joined the staff of Massachusetts Institute of Technology for the purpose of inaugurating advanced courses and establishing a program of extensive research in the field of Soil Mechanics. Under his direction a great amount of pioneer work was carried on, which served firmly to establish the importance of research in foundation engineering and allied subjects, and to define clearly the most promising lines of endeavor.

It is the purpose of this paper to summarize briefly the salient elements of this work. The problems described fall into two main groups: (1) Soil Physics, comprising studies of the composition and grain distribution of soils, permeability, compressibility, consolidation, compressive strength, internal friction, and cohesion; and (2) Soil Engineering, including investigations on the bearing capacity and settlement of foundations, on hydraulic-fill dams, on the frost heaving of highway sub-grades, and on the lateral pressure of earth against retaining walls.

The first group includes studies of the physical properties of soils and of the interrelation between these properties, with the ultimate object of understanding the nature of the effects observed in soils under various conditions. The second group comprises investigations of the behavior of soil as an engineering material forming part of a structure. The two groups are closely interrelated, inasmuch as a knowledge of the behavior of a soil mass connotes a knowledge of the physical properties of its component parts.

---

[1] Presented at the meeting of the Structural Division, Boston, Mass., October 11, 1929.

[2] Asst. Prof. of Soil Mechanics, Mass. Inst. Tech., Cambridge, Mass.

In the last analysis, engineering problems control the trend of development of soil mechanics. A thorough knowledge of soil physics in itself is interesting and valuable from a scientific standpoint; but it is economically worthless unless it provides a means for answering the questions that puzzle the practicing engineer. It has been the aim of Dr. Terzaghi and his associates to keep this principle constantly in mind, and to plan the research work accordingly.

RESEARCH IN SOIL PHYSICS

Mechanical Analysis.—The oldest and most obvious method of soil analysis is the separation of a soil sample into fractions on the basis of grain size. The results of such an analysis are usually represented by a curve showing the weight of all grains smaller than any given diameter, expressed as a percentage of the total weight of the sample. A typical curve is shown in Fig. 1. Point *A*, for example, indicates that 30% of the sample is made up of grains smaller than 0.1 mm. in diameter.

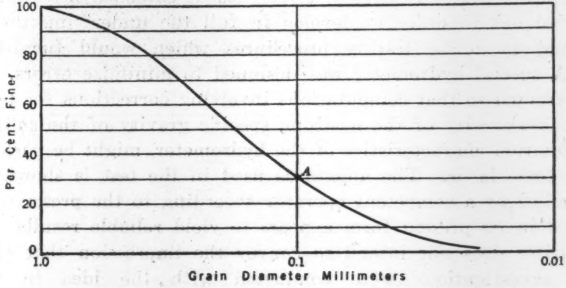

FIG. 1.—TYPICAL MECHANICAL ANALYSIS DIAGRAM

For coarser materials, such as sand and gravel, the analysis is made in a simple manner by passing the sample through a series of screens. In separating soils composed of grains which are finer than the openings in the finest screen available, one of the many sedimentation methods may be used. Such methods are based on the principle that the rate at which a sphere sinks in a liquid is directly proportional to the square of the diameter of the sphere.

Considerable research on sedimentation has been done at the Massachusetts Institute of Technology with a view to standardizing equipment and procedure. Simple sedimentation in jars was first used, but it was found tedious and inaccurate. Attention was next directed to Wiegner's method.[8] In this system the soil suspension is contained in a long vertical cylinder, which communicates near its lower end with a small stand-pipe. The latter contains distilled water. Since the specific gravity of the suspension is greater than that of water, the level in the stand-pipe is higher than that in the cylinder. As sedimentation proceeds, the difference in level decreases, approaching zero as the suspension clears. A plot of the difference in level against time affords a means of constructing graphically a mechanical analysis curve for the sample.

---

[8] "Über eine neue Methode der Schlämmanalyse," von G. Wiegner, *Zentralblatt* für die gesamte Landwirtschaft, Bd. I (1920), No. 1.

The principal source of error in the simplest form of the apparatus is the difficulty of making an accurate visual measurement of the level difference, which is initially about 1 cm. Gessner has devised a photographic apparatus which is reported to give good results.[4] It was felt, however, that something simpler and less expensive would be advisable. The scheme finally adopted was based on magnification of the level difference by means of an inclined gauge glass connected to the stand-pipe. After the apparatus had been carefully calibrated and charts had been worked out to simplify the computations, the method was used successfully for a considerable length of time.

An even simpler method was later developed from ideas suggested by the investigations of Professor G. J. Bouyoucos.[5] The basic principle resembles Wiegner's, in that it involves time observations on the variation in density of a soil suspension as the particles settle. Instead of a piezometer, however, an immersion hydrometer is used to measure the density. In co-operation with the United States Bureau of Public Roads extended investigations have been carried out in order to develop in full the underlying theory of the method and to devise testing procedures which would furnish accurate results. A special hydrometer was designed to minimize errors, and charts were constructed so that computations involving corrections for temperature, density, and viscosity of the medium, specific gravity of the solid particles, and the flotation characteristics of the hydrometer, might be performed with relatively little labor. The apparatus used in the test is shown in Fig. 2. When handled by a competent operator according to the prescribed schedule the method in its present form appears to yield reliable results.

The writer does not intend to convey the impression that these rather elaborate investigations were conducted with the idea in mind that mechanical analyses could be expected to furnish conclusive information as to the character of a given soil. It was fully recognized that other factors, such as grain shape, chemical and mineralogical composition, structure, density, and previous geological history, are of such importance that any analysis based on size alone will constitute at best only a rough indication of the properties of the material. Nevertheless, a grain-distribution curve is of considerable assistance to an experienced soil analyst, and the writer feels that the time and effort expended in the investigations have been fully justified.

Limits of Consistency.—Among the many routine tests proposed for cohesive materials, the limit tests made by A. Atterberg[6] were considered of sufficient importance to warrant investigation. A sample of clay containing

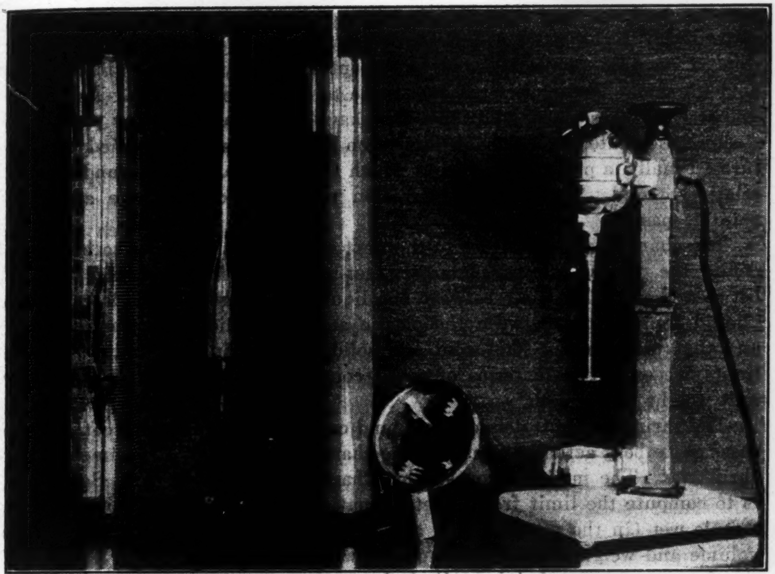

FIG. 2.—APPARATUS FOR HYDROMETER TEST

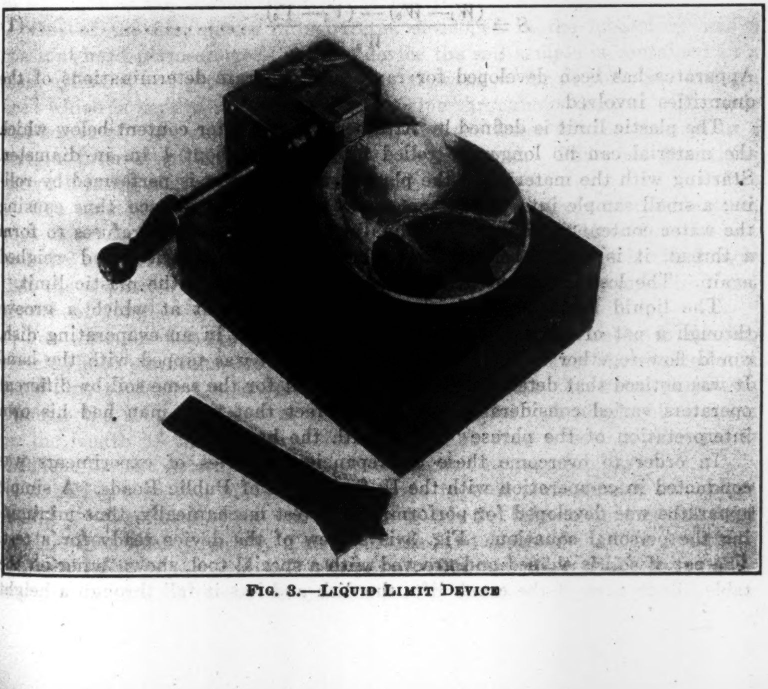

FIG. 3.—LIQUID LIMIT DEVICE

excess water acts like a liquid; it will not hold any definite shape unless restrained. If the water escapes by evaporation, the clay shrinks, loses certain of its fluid properties, and passes into the plastic state. It will now hold its shape, but offers little resistance to a change in shape. As further evaporation takes place, additional shrinkage occurs, and the clay passes into a semi-solid state, in which an alteration of shape is accompanied by fracture. Finally, a point is reached at which the clay changes color and becomes relatively solid. Continued evaporation produces no shrinkage after this point is passed.

The change from one state to the next is gradual. In order to be able to define the various states, Atterberg set up and defined certain "limits" between them. The limit between the liquid and plastic states is called the "liquid limit"; that between the plastic and semi-solid, the "plastic limit"; and that between the semi-solid and solid, the "shrinkage limit." All the limits are expressed in terms of water content, that is, weight of water per unit weight of dry soil.

The shrinkage limit defines itself, and can be determined with comparative ease. Atterberg actually measured the change in length of a specimen during shrinkage. The method proposed by Charles Terzaghi, M. Am. Soc. C. E., is to compute the limit from a determination of the weight and volume of a sample wet (in the plastic state) and bone dry. If V_1 and W_1 represent the volume and weight, respectively, of the wet sample, and V_0 and W_0 those of the dry sample, the shrinkage limit is,

$$S = \frac{(W_1 - W_0) - (V_1 - V_0)}{W_0} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

Apparatus has been developed for rapid and accurate determinations of the quantities involved.

The plastic limit is defined by Atterberg as the water content below which the material can no longer be rolled into threads about $\frac{1}{8}$ in. in diameter. Starting with the material in the plastic state, the test is performed by rolling a small sample into threads on an absorbent paper surface, thus causing the water content to decrease continually. When the sample refuses to form a thread, it is placed between watch glasses, weighed, dried, and weighed again. The loss in weight divided by the dry weight is the plastic limit.

The liquid limit was defined as the water content at which a groove through a pat of the soil about 1 cm. high, formed in an evaporating dish, would flow together at the bottom when the dish was tapped with the hand It was noticed that determinations of this limit for the same soil by different operators varied considerably, due to the fact that each man had his own interpretation of the phrase "tapped with the hand."

In order to overcome these discrepancies, a series of experiments was conducted in co-operation with the U. S. Bureau of Public Roads. A simple apparatus was developed for performing the test mechanically, thus minimizing the personal equation. Fig. 3 is a view of the device ready for a test. The pat of soil is shaped and grooved with a special tool, shown lying on the table. Each turn of the crank lifts the dish and lets it fall through a height of 1 cm. Instead of trying to work the soil exactly to the liquid limit, it has been found advisable to determine, for several water contents, the number of blows required to close the bottom of the groove over a distance of $\frac{1}{2}$ in. The higher the water content, the fewer the number of blows will be. A curve of water content against number of blows is plotted, and the water content corresponding to twenty-five blows, as read from the curve, is taken as the liquid limit.

Limit tests are in somewhat the same category as mechanical analyses, inasmuch as their results have only an indirect bearing on engineering problems. They are valuable, on account of their simplicity, in a rapid preliminary grouping of a set of soil samples prior to performing more elaborate tests.

Permeability.—One of the most important problems in soil mechanics is the study of the percolation of water through soils. In the normal case, with laminary flow throughout, percolation takes place in substantial accordance with Darcy's law, which states that the rate of percolation per unit area is directly proportional to the hydraulic gradient. The constant of proportionality is known as the "coefficient of permeability" of the soil. Symbolically, if Q represents the quantity flowing through an area of soil, A, in time, t, under a hydraulic gradient, i, Darcy's law may be represented by the equation,

$$Q = k\ i A\ t \qquad (2)$$

in which, k is the coefficient of permeability.

One of the first pieces of apparatus developed in the laboratory was a constant-head permeameter. In this device the soil sample is contained in a glass cylinder, and provision is made for allowing water to percolate under a head which is kept at a known constant value throughout the test. The area and length of the sample are determined, and the water flowing through in a certain interval of time is collected and measured. Thus, all quantities except k in Equation (2) are determined.

The constant-head apparatus is suited only to relatively permeable soils, such as sands. In finer soils, the rate of percolation is so slow that the test occupies an extremely long period of time, during which there is the danger that the character of the soil may be altered by organic decomposition and growth of fungi.

For tests on fine-grained materials, it was found advisable to develop variable-head permeameters. In these devices the feed-water is contained in a stand-pipe of known area just above the sample. As the water percolates through the soil, the level in the stand-pipe drops. A single observation on the length of time required for the head to drop a certain distance is sufficient for the determination of the coefficient of permeability.

A half-section and half-elevation of one type of permeameter are shown in Fig. 4. The level of the tail-water in which the base is immersed is kept constant by a waste overflow. The apparatus is so designed that the resistance to flow offered by the stop-cock, the porous disk, and the various channels is negligible compared to that of the soil itself. Hence the height of the water surface in the stand-pipe, measured from the tail-water surface, represents the energy available to drive the water through the soil.

Let *a* represent the area of the stand-pipe; *A*, the area of the sample; *L*, the length of the sample; and *h*, the head at any time, *t*. Then, in the next succeeding interval of time, *dt*, during which the head drops a distance, *dh*, conditions may be represented, according to Equation (2), by the relation,

$$-a\,dh = k\frac{h}{L}A\,dt \qquad (3)$$

FIG. 4.—VARIABLE HEAD PERMEAMETER

If the measured head at any time, t_1, is H_1, and at some later time, t_2 is H_2, Equation (3) may be integrated between these limits, giving the following general value for the coefficient of permeability,

$$k = \frac{aL}{A}\,\frac{1}{t_2 - t_1}\,\log_e \frac{H_1}{H_2} \qquad (4)$$

Thus, the coefficient may be evaluated from the observed data by a single computation.

By proper selection of the various component parts, apparatus of this type may be applied to a wide range of soils. The porous disks are commercially available in three grades, fine, medium, and coarse. If the soil is too porous to permit the use of the coarse-grade disk, a perforated rubber disk covered with wire mesh may be used. The stand-pipe may be of any convenient size, ranging from a small pipette, for fine-grained soils, to graduated tubes $\frac{3}{4}$ in. in diameter for coarser materials. Very pervious sands may be tested by an extension of this method, in which the entire apparatus consists of a long glass tube with a screen across the bottom. The sample is placed in the lower part of the tube, and the upper part serves as a stand-pipe.

Another important application is found in the direct testing of the permeability of soils in their natural state. Methods have been developed whereby undisturbed samples may be removed from the earth and encased in paraffin at once, thus being well protected until the tests can be made. A portion of the sample may be placed in the permeameter in its original paraffin jacket, as indicated in Fig. 4, so that it is subjected to a minimum of handling in preparation for the test. The method is at present applicable only to soils which possess at least some degree of cohesion.

Measurements of permeability by observation of the rate of capillary saturation have received considerable attention. Extended studies were made on the relation between the permeability of a soil and the rate at which water is drawn up into a dry sample of the material contained in a vertical glass tube with its lower end immersed. As a result of these studies, the method was successfully applied to field control of the embankment material of an earth dam.[7]

Certain fundamental defects associated with the vertical capillarity test, which necessitate careful and extensive preliminary calibration, seem to disappear in the horizontal capillarity test, first proposed by Mr. Arthur Casagrande. The dry pulverized sample of soil is contained in a glass tube with a screen at one end and a vented stopper at the other, as indicated in Fig. 5. The tube is immersed in a horizontal position in a shallow depth of water, and observations are made upon the rate at which the line of capillary saturation proceeds through the soil. If x represents the length of saturation in time, t, it may be shown theoretically that,

$$x^2 = t \sqrt{k F \frac{1+e}{e}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

A plot of observed values of x^2 against t is, therefore, a straight line, of which, $\sqrt{k F \frac{1+e}{e}}$ is the slope. The void-ratio, e (ratio of volume of voids to volume of solid) can readily be determined by measuring the volume and the dry weight of the sample. Thus, if the factor, F, is known, the coefficient of permeability, k, is readily found.

Experiments made on a wide range of soil types give a mean value of F of 100 000, when t is in minutes and k is in centimeters per second.

---

[7] "Soil Studies for the Granville Dam at Westfield, Mass.," by Charles Terzaghi, M. Am. Soc. C. E., *Journal*, New England Water Works Assoc., Vol. XLIII, No. 2.

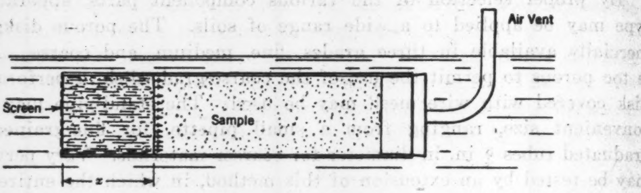

FIG. 5.—HORIZONTAL CAPILLARITY TEST

Deviations from this mean are ± 50% for ordinary soils. The value of F is smallest for very mixed-grained soils and largest for very uniform soils.

For a rapid approximate determination of the permeability, the result of a capillarity test, using a value, $F = 100\,000$, will in many cases be sufficiently accurate. For closer determinations, a series of calibrating tests should be made in order to furnish a value of F applicable to a particular range of soil types. The method appears at present to be reliable, and by far the simplest ever devised, especially for rapid field determinations.

***Compressibility and Consolidation.*— The compressibility of a soil is studied by measuring its change in volume produced by a change in load. Under the pressures usually encountered, the compression of the solid material is negligible, so that a decrease in volume of a soil mass under load is almost entirely due to decrease in the volume of voids. Results of compressibility tests are usually represented as curves of void-ratio (ordinates) against unit pressure (abscissas). The curves have a characteristic shape as shown in Fig. 6.**

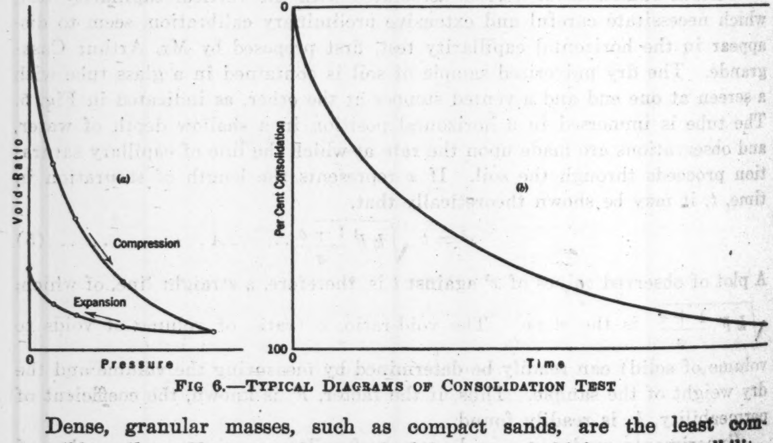

FIG 6.—TYPICAL DIAGRAMS OF CONSOLIDATION TEST

Dense, granular masses, such as compact sands, are the least compressible soils. Clays are characterized by a much higher compressibility. Dr. Terzaghi[8] has shown that the compression diagrams of sands and clays

---

[8] "Erdbaumechanik," pp. 86 and 90.

could be represented by the same logarithmic equations, the only difference being in the scale of void-ratio.

A rational explanation for the high compressibility of clays was furnished by a study of the compressibility of mixtures of sand and mica.[9] Both were granular, non-cohesive materials, and exhibited none of the characteristic properties of clay; yet it was found possible to select a mixture of sand and mica such that the compressibility characteristics of typical clays could be reproduced in detail. The researches showed definitely that the shape of the grains has an extraordinary influence on this important property of soils.

If a coarse, dry, granular material is placed under load in such a manner as to prevent lateral displacement, a decrease in void-ratio takes place almost instantaneously. A quantity of air corresponding to the change in volume is forced out, but there is practically no resistance to its escape. If the air is replaced by water, that is, if the mass is saturated, the change in volume is necessarily accompanied by a forcing out of some of the water. Since the resistance offered by coarse-grained soil to the passage of water is relatively small, compression is again almost instantaneous. If the soil is fine-grained, however, it may offer considerable resistance to the escape of the excess water. The compression in this case does not take place instantaneously, but occupies an appreciable period of time. The gradual compression of fine-grained, saturated soils under load is known as consolidation.

Consolidation tests are made with an apparatus which has been gradually developed from the primitive device first used by Dr. Terzaghi.[10] A half cross-section and half elevation of this instrument is shown in Fig. 7.

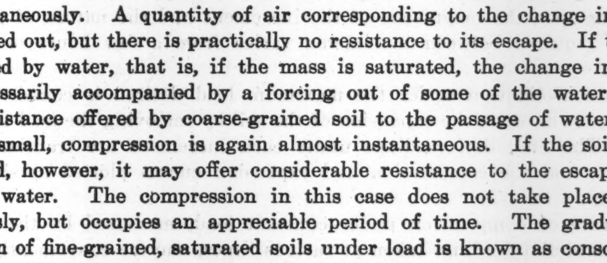

FIG. 7.—CONSOLIDATION APPARATUS

The soil sample is retained within a cylinder (2) and is compressed by means of load applied to a piston (5). The aligning pin (8) holds the piston immovable within the cylinder while the test is being prepared, and is removed when the first load is applied. The amount of compression produced by a given increase of load is measured by two Ames dial gauges reading to 0.0001 in. Free passage of water at the two faces of the sample is provided by the porous disks in the base and cylinder. By filling the base stand-pipes and the interior of the piston with water, the test may be performed with the sample entirely submerged, so that a state of complete saturation exists at all times.

---

[9] "The Compressibility of Sand-Mica Mixtures," by Glennon Gilboy, Jun. Am. Soc. C. E., *Proceedings*, Am. Soc. C. E., February, 1928, Papers and Discussions, p. 555.

[10] "Erdbaumechanik," p. 83.

In performing the test, loads are applied in definite increments. While any given increment is acting, the dial readings are noted at convenient intervals of time. The dials are allowed to come to rest—that is, consolidation is allowed to proceed to completion—before the next increment is added. Depending upon the magnitude of the increment and the nature of the soil, the time required between increments varies from a few hours to one or two days.

After consolidation under the maximum load desired is complete, it is customary to measure the expansion of the soil by removing the load in increments. The final dial readings under each increment are translated into void-ratio, and the compression and expansion curves plotted as shown in Fig. 6(*a*).

The rate of compression under constant load, measured by the various intermediate dial readings taken at various times, may be conveniently represented by a curve such as that of Fig. 6 (*b*). The total compression under the given increment is taken as 100%, and the intermediate dial readings, expressed in percentage of total movement, are plotted against the corresponding values of time. Although only one curve is illustrated, actually as many curves may be obtained as there are increments of load applied. The curves are all of the same shape, but do not, in general, coincide.

The consolidation diagrams offer a means of determining the permeability of very fine-grained soils. The quantity of water which is forced out of the sample by a given increment of load depends upon the compressibility of the soil, and the rate at which the water can escape depends on the permeability. Therefore, the rate of consolidation, as indicated by the time-consolidation curve, depends upon both these factors. The compressibility is determined from the pressure-void-ratio diagram, thus leaving the permeability as the only unknown to be evaluated mathematically.[11]

True clays are relatively compressible and impermeable. Their time curves are flat and well defined, permitting accurate computation of the constants. Border-line materials, such as mixtures of very fine sand and silt, are much more permeable and much less compressible than clays. Consequently, the time curves are rather steep in the first stages, and the dials move so rapidly that accurate readings are difficult to obtain. To overcome this difficulty an arrangement has been devised whereby direct permeability tests can be performed on the sample while the compression test is going on. One of the stand-pipes in the base of the apparatus is closed, and the other is connected to a vertical pipette tube hung above the device in such a manner that water from the pipette flows into the base, up through the sample, into the piston, and out of the holes previously occupied by the aligning pin. The action is analogous to that of the variable-head permeameter previously described.

---

[11] "Principles of Final Soil Classification," by Charles Terzaghi, M. Am. Soc. C. E., *Public Roads*, Vol. 8, No. 3, May, 1927.

The combined consolidation and permeability test furnishes a means of checking the accuracy of the permeability coefficients computed from the consolidation curves. The close agreement obtained in two tests selected at random is shown in Fig. 8.

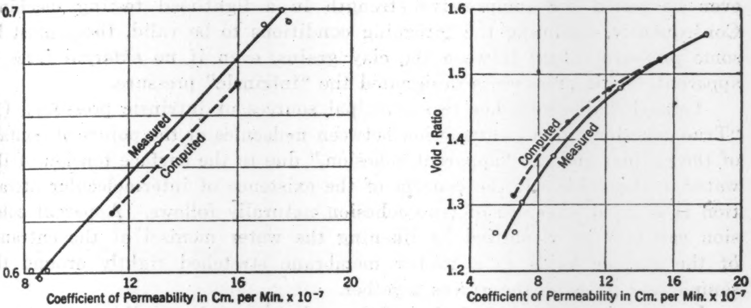

FIG. 8.—COMPARISONS OF DIRECT AND INDIRECT PERMEABILITY DETERMINATIONS

Inasmuch as the consolidation test yields information upon the amount of compression which a soil sample will undergo under load and upon the rate at which this compression proceeds, it ranks as one of the most important soil tests ever devised. In addition to its purely scientific value, it has many practical applications, among which may be mentioned the analysis of settlements of buildings underlaid by clay strata, and the consolidation characteristics of hydraulic-fill cores.

Internal Friction and Cohesion.—One of the most important physical properties of soil, especially with regard to stability and lateral pressure, is the shearing resistance. Attempts have been made by numerous investigators to develop methods for evaluating this property, but the problems involved are still far from a final solution.

The underlying conceptions of the nature of shearing resistance are not difficult to visualize. If two soil grains are pressed together, the resistance against sliding of one grain on another is equal to the pressure between the grains multiplied by the coefficient of friction of grain on grain. The shearing strength of an accumulation of grains is the sum of a great number of such individual sliding resistances. Therefore, in order that a mass of soil shall exhibit shearing strength, two conditions must be fulfilled: (1) There must be pressure between the grains; and (2) there must be a definite coefficient of friction between the grains. If one of these quantities is zero, the mass behaves like a liquid, no matter what the value of the other factor may be.

A familiar illustration of this statement is furnished by the so-called "quicksand" phenomenon. The dynamic energy of a current of water flowing upward through a mass of sand tends to counterbalance the downward force of gravity. If the energy of the water is sufficiently great to counteract entirely the action of gravity, the effective weight of each individual sand particle is zero. Hence, the intergranular pressures are reduced to zero, and the mass behaves essentially like a liquid.

On the other hand, a stiff clay exhibits the properties of a solid. A cylindrical specimen cut out of the mass retains its shape unaided, and may even be tested for compressive strength in a light-load testing machine. Consequently, assuming the foregoing conditions to be valid, there must be some pressure acting between the clay grains, even if no external force is apparent. This pressure is designated the "intrinsic" pressure.

Terzaghi[12] distinguishes two principal sources of intrinsic pressure: (1) "True cohesion," due to attraction between molecules at the points of contact of the grains; and (2) "apparent cohesion," due to the surface tension of the water in the voids. If the concept of the existence of intermolecular attraction is granted, the idea of true cohesion naturally follows. Apparent cohesion can best be visualized by likening the water menisci at the entrance of the surface voids to a rubber membrane stretched tightly around the sample and pressing the grains together.

It should be noted that neither of these phenomena is peculiar to clay alone. They are usually associated with clay, because their effects are most pronounced in very fine-grained material; but they can occur to a certain degree in any type of soil. For example, a moistened sand can be moulded into a cylinder, because the surface tension of the water produces some apparent cohesion. If the cylinder is immersed in water, the surface tension disappears, and the cylinder disintegrates. True cohesion also exists in a mass of sand, but its magnitude is vanishingly small on account of the relatively small number of points of contact per unit area.

True cohesion depends upon a great number of factors, such as grain size, grain shape, structure, density, and previous geological history of the deposit. It also appears to be influenced by chemical factors and electrolytic effects about which relatively little is known. Apparent cohesion is a function of many such variables as those mentioned, and, in addition, is subject to wide variations produced by changing moisture conditions. Thus, it is fairly evident that considerable time and study are required before the complications involved in the shearing resistance of soils can be properly understood.

The first method used at Massachusetts Institute of Technology in the study of these effects was based upon tests of the compressive strength of clay cylinders. When the sample fails in compression, shear cracks become visible on the surface, as indicated in Fig. 9(*a*). According to Mohr's theory,[13] the angle, α, between two such shearing planes is $90° - \phi$, wherein, ϕ is the angle of internal friction of the material. With the compressive strength, p_c, also determined from the test, it is possible to construct a rupture diagram for the specimen, as shown in Fig. 9(*b*). The intrinsic pressure is represented by the distance marked p_i. The vertical intercept marked *c* is the cohesion as defined by Coulomb. Thus, it is theoretically possible from this test to determine the important strength constants of the material.

[13] "Technische Mechanik," by Otto Mohr, Ernst, Berlin, 1906.

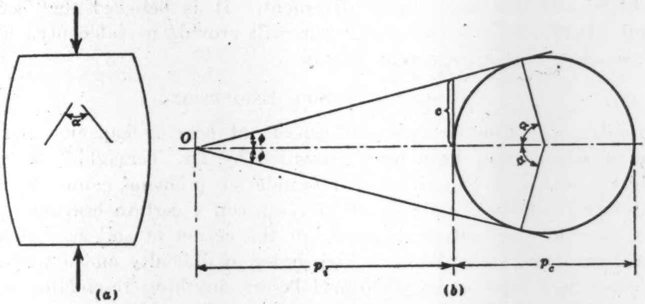

FIG. 9—RUPTURE OF A CYLINDER ACCORDING TO MOHR'S THEORY

Many investigators have endeavored to measure the shearing resistance of soils by subjecting samples to direct shearing stress. An important contribution in this line was made under Dr. Terzaghi's direction in 1929. Under a co-operative agreement with the New England Power Construction Company, a large and elaborate shearing device was constructed, based on the principle of applying a known vertical pressure to the soil sample, and measuring the amount of horizontal force required to produce failure in shear. A brief description of the apparatus and an outline of the results of the first series of tests are available in published form.[14]

Subsequently, a second machine was constructed, embodying certain of the principles of the first device, but designed to be simpler, more accurate, and more flexible. A close-up of one of the shearing units and a general view of the apparatus are shown in Figs. 10 and 11. A distinct advantage of this machine is that six units may occupy the table simultaneously, whereas only one rig for producing horizontal shear is required.

The apparatus has been in constant use since its construction, and has yielded new and valuable information upon various types of soil. It is impossible to formulate any general conclusions from the data at present available. Certain interesting indications, however, may be enumerated tentatively. A sand in a dense state exhibits a definitely higher angle of friction than the same sand loose. The difference appears to decrease with decreasing grain size. Shear failure in sand is accompanied by marked deformations of the mass normal to the failure plane. Saturation does not decrease the angle of friction of sand. The clays thus far tested exhibit considerably higher angles of friction than were expected. In stiff clays possessing high true cohesion it is difficult to develop the full shearing strength of the material;

---

[14] *Engineering*, June 13, 1930.

the soil appears to fail progressively, due to local concentrations of high stress, which in turn are due to the inability of the material to undergo sufficient plastic yield to equalize the stress distribution. If this hypothesis proves to be correct, it may have an important bearing upon the question of the stability of slopes cut into soil of this character.

Opinions as to the physical nature and effect of shearing resistance in soils have been, and still are, widely divergent. It is believed that continued research along the lines outlined herein will provide useful contributions to the knowledge of this important subject.

RESEARCH IN SOIL ENGINEERING

Foundations.—The fundamental aspects of bearing capacity and settlements of foundations have been presented by Dr. Terzaghi.[15] It may be readily seen from his exposition that foundation problems cannot be resolved into the simple task of assigning to a given soil a certain bearing value per unit area. On the contrary, a study of the action of soil as a supporting material involves mechanics of a high order of difficulty and a vast amount of research will have to be performed before anything resembling a simple solution can come into being.

Studies of the load-settlement characteristics of footings resting on sand have shown that even in this material wide variations are to be expected. The same sand exhibits quite different properties according to whether it is loose or dense. Under loads applied to the surface of a loose sand, a settlement of ½ in. was produced by a load of about ½ ton per sq. ft.; when the same material was tested in a compact state, the same settlement occurred under a load of about 5 tons per sq. ft. Results of this type indicate the need of a more accurate classification of sand, especially with regard to density, than is usually found in foundation codes. Corroborating previous evidence, the tests showed that the settlement under a given unit load, not too near the ultimate, is practically independent of the size of the loaded area.

A promising method for field exploration of sand deposits was successfully tried on the Houston-Essex Subway, in New York City, in co-operation with the contractors, the Corson Construction Corporation. The variations in the force required to press a steel cone into the soil were measured, and the results were correlated with a series of loading tests performed at various levels. The penetration device appeared to be very sensitive to changes in the density of the deposit, and these changes were also reflected in the loading tests. Similar investigations made later at the Massachusetts Institute of Technology, under controlled conditions, agreed very well with the field explorations. A distinct advantage of the method is that it permits of testing the soil in place, thereby avoiding the errors which are associated with sampling operations. Descriptions of the apparatus and procedure and outlines of the results thus far obtained have been published.[16]

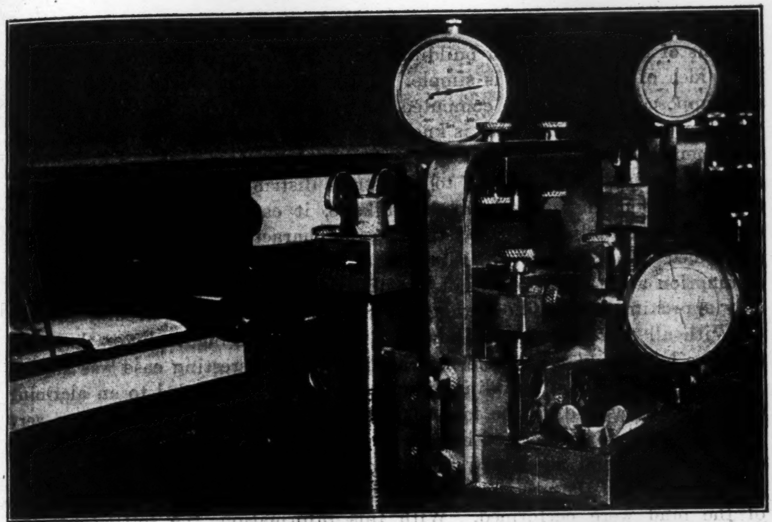

FIG. 10.—VIEW OF SHEARING UNIT

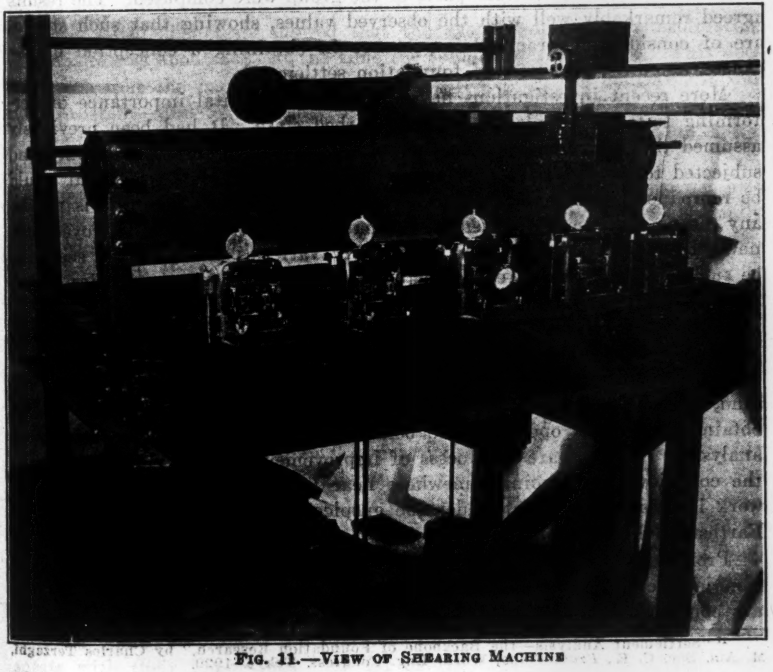

FIG. 11.—VIEW OF SHEARING MACHINE

A practical application of the theory of consolidation is found in the analysis of the settlement of buildings underlaid by deep strata of clay. The basic idea of the analysis is simple. If the stresses produced in the soil by superimposed loads can be computed, and the deformation that the soil will undergo under a given stress is known, it should be possible to determine the settlement of the structure, both in magnitude and in rate. Actually, the problem is very complex. As to the stress distribution, while the classical theory of Boussinesq is the best available, it can yield only approximate results. The analysis of the stress-strain characteristics of soils thus far performed includes only the simplest cases. Most important of all, some assumption as to homogeneity of the underground must be made, and this is only approximately fulfilled, even under the most favorable circumstances.

With all these drawbacks, however, it is encouraging to know that such analyses have yielded valuable information. An interesting case was studied in 1929.[17] A group of buildings founded on piles had settled to an alarming extent, notwithstanding the fact that the load applied to the piles was very low, compared with the rated bearing capacity. Borings disclosed the presence of a layer of mud about 120 ft. below the surface. A stress analysis was made, neglecting the presence of the piles, and consolidation tests on samples of the mud were performed. With this information, the settlements and rates of settlement of various parts of the group were computed. The results agreed remarkably well with the observed values, showing that such studies are of considerable practical importance in obtaining a conception of the causes, amounts, and rates of foundation settlements.

More recent investigations have established the vital importance of performing tests on samples in an undisturbed state. It had been previously assumed that if a sample were thoroughly remoulded to a liquid state and subjected to pressure, the previous geological history of the material would be reproduced on a laboratory scale. It seems, however, that this is not by any means the case. Apparently, the natural structure, once destroyed, can never be duplicated, and even in ordinary varieties of clay there seems to be sufficient structural effect so that the consolidation characteristics in the natural and the remoulded states are quite different.

In order to provide means for obtaining large undisturbed samples of cohesive material, a new type of rotary drill, operating without water, was designed. It has been used successfully in sinking a 6-in. hole through fill, sand, and clay to a depth of nearly 100 ft. The undisturbed samples obtained from this operation are being utilized in an elaborate settlement analysis. The tools are in process of improvement, with a view to bringing the cost down to a point somewhere near to that of wash borings. This work is being carried out under the auspices of the Special Committee on Earths and Foundations of the Society.

Progress along these lines would be greatly facilitated if every construction job were looked upon as a large-scale experiment. The data required are comparatively easy to collect. A schedule of loads, a series of bench-mark observations taken at various times, a geological profile of the underground, and a few soil tests on the different strata will furnish the material required for a settlement analysis. The additional cost of such observations would be a negligible item in the total cost of construction; the information obtained would be of highest value.

---

[17] "Settlement Analysis—the Backbone of Foundation Research," by Charles Terzaghi, M. Am. Soc. C. E., *Proceedings*, World Eng. Congress, Tokyo, 1929.

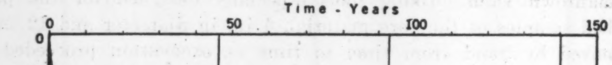
Hydraulic-Fill Dams.—In co-operation with the Miami Conservancy District, a thorough investigation of the properties and behavior of hydraulic-fill dams was started in the summer of 1927. A vertical shaft, 5 ft. in diameter, lined with concrete, was sunk to a depth of 80 ft. into the core of the Germantown Dam. Using tools especially designed for the purpose, undisturbed samples of the core material, 4 in. in diameter and 12 in. long, were removed by hand from time to time as excavation proceeded. The samples were sealed into iron containers, carefully packed, and shipped to the laboratory. Undisturbed samples, in 2-in. pipes, 2 ft. long, sealed at both ends, were removed from a drill hole near-by. Many unforeseen difficulties impeded the progress of the field work, and the District is to be commended for its persistence in mastering these difficulties and for the thoroughgoing manner in which it fulfilled its part of the program.

The experimental work included extensive tests on the physical properties of the soil, with emphasis on permeability, consolidation, and compressive strength tests. The tests showed that the average degree of consolidation of the core was about 25% at the time the samples were removed. This does not mean that the material was soft or yielding. On the contrary, it was very resistant—due to its relatively high angle of internal friction (about 27°)—and exhibited a compressive strength varying from 1 kg. to 2 kg. per sq. cm.

A mathematical analysis of the rate of consolidation of the core was also undertaken. The theory is extremely complicated, and the equations finally obtained present a forbidding appearance. It was found possible, however, to obtain from these equations a comparatively simple method of solution. Using this method, an investigator can construct a curve showing the progress of consolidation with time. The curve for the Germantown Dam is reproduced in Fig. 12. It is interesting to note that the dam was about seven years old when the samples were removed, and that the theoretical percentage consolidation corresponding to seven years is 25%, which checks exactly the results of the experimental investigations. It will be still more interesting to take samples from the core at the end of another ten or twenty years, to see whether the theory is still corroborated.

As studies on the general problem of the stability of hydraulic-fill dams progressed, it became increasingly apparent that a major rôle is played by the cohesionless, permeable outer sections of the dam, which the writer suggests might be designated by the term "shell." The impression was obtained that the emphasis usually placed upon the composition and behavior of the core had tended to obscure the functions of the shell to a degree incommensurate with their importance. As far as the core is concerned, the worst that can happen is that it does not consolidate at all. If the shell is sufficiently strong to hold the core in place under these circumstances, the structure should be stable.

In accordance with this idea, an attempt was made to evaluate the stress conditions in the shell with the core assumed to be in a liquid state. Mathematical analysis leads to rather complicated equations, but it was found possible to develop a graphical solution whereby the position of the weakest plane through the shell and the angle of friction which the shell material must develop in order to insure stability, can readily be determined. From the standpoint of safety, therefore, it appears that studies of the physical properties of the shell material, with a view to selecting proper constituents and designing an adequate section, are even more important than the tests usually made on the material of the core.



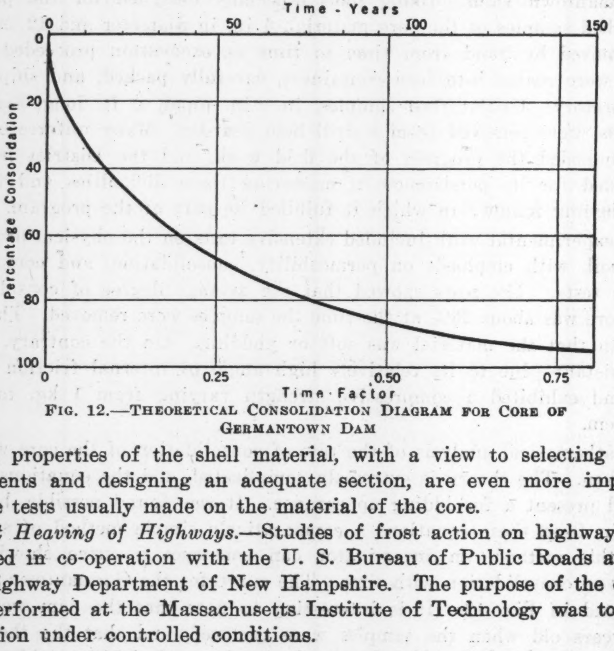


FIG. 12.—THEORETICAL CONSOLIDATION DIAGRAM FOR CORE OF GERMANTOWN DAM

Frost Heaving of Highways.—Studies of frost action on highways were conducted in co-operation with the U. S. Bureau of Public Roads and the State Highway Department of New Hampshire. The purpose of the experiments performed at the Massachusetts Institute of Technology was to study frost action under controlled conditions.

The experimental unit consisted of a wooden box, 3 ft. square and 3 ft. deep. On one side of the box was an observation well, 1 ft. square, communicating with the interior of the box at the bottom. A gravel filter was placed in the bottom of the box and well, thick enough to cover the opening between them. In this manner, the water level within the box could be controlled from the well, because the gravel prevented any soil from entering. The sides of the box were coated on the inside with a thin layer of grease, over which were laid small overlapping sheets of Manila wax paper. The object of the grease and paper was to minimize the retarding effect of friction between the soil and the sides of the box. The soil to be investigated was carefully tamped into the box, filling it level full. On top was placed a slab, 2 ft. 8 in. square, of concrete or macadam, representing the road surface.

Eight such units were buried to full depth in the ground, and observations on water level, depth of frost, heaving of the slabs, etc., were continued throughout the winter of 1928-29. Difficulties were experienced in holding the water levels constant; the boxes appeared to leak continuously, in spite of all precautions. Nevertheless, the experiment was successful in general, and paved the way for more detailed investigation of the phenomenon.

The researches showed that frost heaving cannot occur to any appreciable extent unless there is a continuous supply of water from below the frost level. The pressures associated with freezing water are due to the growth of ice crystals in layers which, in turn, is due to the travel of the large trihydrol molecules $(H_2 O)_3$, toward the focus of crystallization. As long as trihydrols are supplied, crystal formation will continue, and pressure will be exerted to lift the soil above the ice layer. If the supply of trihydrols is cut off, equilibrium will be established and the heaving will cease.

It has been observed that ice layers will grow in mixed fine-grained soils, while the water in the voids of clean sands will freeze without causing growth of the ice crystals beyond the usual increase in volume associated with the change in state. This behavior is due to the fact that water in very small spaces exhibits the property of remaining in a liquid state at temperatures considerably below the normal freezing point. Since the freezing temperature of water in very fine voids decreases with decreasing void diameter, it can be seen that the water will crystallize in the larger voids, while in the surrounding smaller voids it will remain in a liquid state, thus keeping supply channels open for the growth of the ice crystals.

As the frost effect penetrates deeper into the soil mass, another ice layer will start to form lower down. As the lower layer grows, it gradually cuts off the water supply, so that further growth of the upper layer is prevented.

The frost effect is thus shown to be controlled by three factors: First, the position of the ground-water level, or of veins and pockets of water which may serve as a source of supply for excess ice accumulation; second, the void-size distribution of the soil in which freezing occurs; and, third, the capillary properties of the soil between the source of water supply and the frost level.

Earth Pressure on Retaining Walls.—The most elaborate research project undertaken at the Soil Mechanics Laboratory was a large-scale experimental study of the lateral pressure exerted by earth behind a retaining wall, conducted in co-operation with the New England Power Construction Company. The project was laid out in detail by Dr. Terzaghi in December, 1928, and construction was started the following month. The apparatus was ready for operation in the latter part of April.

An isometric sketch of the device is shown in Fig. 13. The soil to be tested is contained in a concrete bin, 14 ft. square and 10 ft. high. The retaining wall, forming one side of the bin, consists of a structural steel frame, *F*, faced with a concrete slab, *K*. By means of counterweights, *Q*, at each end of the wall, the center of gravity of the entire wall assembly is made to lie in the face of the slab. The wall is suspended from hangers,

V_1 and V_2, the points of suspension being also in the face of the slab. Thus, when it is free, the wall hangs in a strictly vertical position; and any vertical component exerted by the earth on the face produces a direct pull on the hangers. The hangers are supported by scales above, which, in turn, rest on Columns C_1 and C_2 and on structural members supported by heavy columns

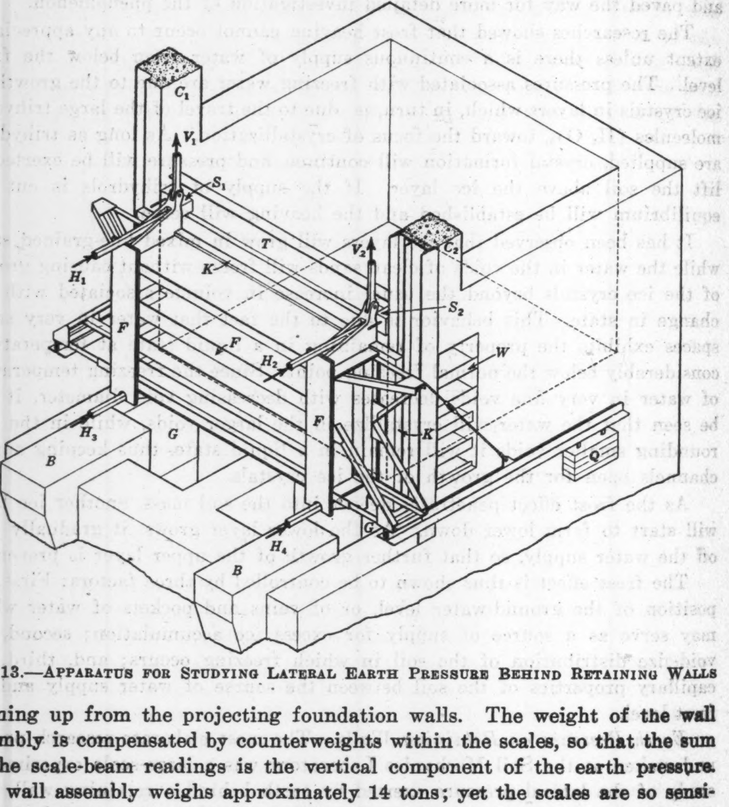

FIG. 13.—APPARATUS FOR STUDYING LATERAL EARTH PRESSURE BEHIND RETAINING WALLS

running up from the projecting foundation walls. The weight of the wall assembly is compensated by counterweights within the scales, so that the sum of the scale-beam readings is the vertical component of the earth pressure. The wall assembly weighs approximately 14 tons; yet the scales are so sensitive that they will record the weight of a man standing on the wall, with an error of ± 2 lb.

The horizontal pressures on the wall are balanced by thrust rods at the four corners, H_1, H_2, H_3, and H_4. The magnitudes of the thrusts are recorded by four scales. The two lower scales rest on concrete bases, B, in the substructure; the upper scales are supported by a rigid structural frame tied to the bin, the frame being supported by the same columns which carry the rear ends of the vertical scales. Thus, the bin, wall, and scales are included in a rigid unit which is independent of the building enclosing the apparatus. The unit is supported by a heavily reinforced concrete raft, 3 ft thick, resting on fifty piles, 20 ft. long. The space above the raft and below the floor-slab of the bin forms an inspection gallery, *G*.

A window, *W*, of 1-in. plate-glass in a structural steel frame, is inserted in one wall of the bin to allow inspection of the earth within. The tie-beam, *T*, is introduced to prevent excessive deflections of the bin walls under the lateral earth pressure. Four studs, arranged to bear on the inside faces of the thrust castings directly opposite the horizontal thrust bars, are operated by hand-wheels through gear-boxes, two of which, S_1 and S_2, are visible. The four horizontal scales are geared to move forward and backward. The combination of movable scales on one side and movable studs on the other gives a very accurate control of the horizontal movements of the wall. The two vertical scales can likewise be moved backward and forward to keep the hangers always vertical. The vertical scales are further provided with gearing to move the wall up or down. All wall movements can be controlled to within 0.0001 in.

The method of determining the magnitude, direction, and point of application of the earth pressure is practically self-evident. The vertical component is $V_1 + V_2$. The horizontal component is $H_1 + H_2 + H_3 + H_4$. The point of application is determined by the relation between $H_1 + H_2$ and $H_3 + H_4$.

In the design of the apparatus, an attempt was made to eliminate the shortcomings of previous installations of similar character, particular attention being given to the rigidity of the retaining wall and the possibility of moving the wall at will through an appreciable distance from the bin. The distinguishing features of the apparatus are as follows: The model wall is practically rigid, deflections under maximum pressure being less than 0.001 in.; the wall can be tipped or moved parallel to itself through a distance of more than 1 in.; and the joint between the bin and the wall is equipped with a water-tight rubber bellows or diaphragm so that the back-fill can be completely saturated without any leakage of water.

The apparatus has been designed with a view to making all manner of retaining wall tests. Surcharges up to 50 tons can be applied to the surface of the back-fill. The effects of different slopes of the surface of the back-fill can be measured. The action of filters and drains, as well as the effect of partial and complete saturation, can be studied. A brief summary of the results of the first series of tests has appeared in published form.[18]

ACKNOWLEDGMENTS

In addition to the acknowledgments and references embodied in the text of this paper, the writer wishes especially to mention the work of Mr. Arthur Casagrande, of the U. S. Bureau of Public Roads. Together with other important contributions, Mr. Casagrande has been chiefly responsible for the development of the liquid limit device, the hydrometer analysis, the horizontal capillarity test, the latest type of shearing device, and the frost-heaving experiments. Much valuable assistance has been obtained from the work of students, whose researches have been presented as theses to the Faculty of the Massachusetts Institute of Technology.

DISCUSSION

J. C. Meem,[19] M. Am. Soc. C. E. (by letter).—This paper is a contribution of unquestioned value to the profession, particularly if or when the further research in connection with foundations and lateral earth pressures shall have been carried out.

The writer believes that it is practicable to establish definitely, through practical tests:

(*a*) The actual subsidence of various soils under varying loads at various depths; and

(*b*) The actual lateral pressure of soils at varying depths.

In order to conduct such tests so that the results will be of definite practical value, it will be necessary first, as to Test (*a*), to re-arrange tables for the so-called bearing values of soils so that they will show the expected settlement or subsidence under loading rather than the load which such soils may be expected to carry; that is, the writer advocates making a simple classification of soils, such as loam, clay, sand, gravel, and rock, with combinations of each, and testing them:

(*c*) Superficially to loads of 1, 2, 4, and 8 tons;

(*d*) At depths of 10 to 20 ft., unconfined to loads of 4, 8, 10, and 20 tons; and,

(*e*) At depths of 20 ft., or more, confined (as at the base of piles or small shafts) to loads of 20, 40, 60, and 80 tons per sq. ft.

The subsidence under the various loads should be noted in each case. The tests should be made:

(*f*) On normally dry soils; and,

(*g*) On saturated soils.

With proper co-ordination and co-operation the results of tests made in accordance with an established procedure could be collected from widely varying sources and tabulated; and, eventually, tables of real practical value, showing the subsidence of soils under loadings, could be permanently established.

In connection with Test (*b*), the apparatus for testing lateral pressure, the writer is convinced that the use of the apparatus described in the paper will mark an important step in the advancement of soil testing, but that it does not go far enough.

He is convinced that the most effective apparatus for making such tests would be a box, rigidly braced externally and having four or more sliding bulkheads confining one side; that is, in a box of a 20-ft. cube, there should be four superimposed bulkheads, 5 by 20 ft., to confine the soil on one face. These bulkheads or louvers should be of beam or box-girder construction, having arms extended and designed to slide independently of each other on cross-arms or tracks extended beyond the box. Four adjustable weights to each louver operating through pulleys and cords attached to the extending arms of the louvers, should be arranged to offset or balance the sliding friction, so that light pressure applied at any point in the louver face will cause it to move. Then, by filling the box with kiln-dried sand, and increasing the inside weights to balance the pressure of the soil, the exact pressure on each independent louver can be determined.

---

[19] Cons. Engr., Brooklyn, N. Y.

The tests should be made with dry sand or dry disintegrated materials only, such as kiln-dried sand, pea gravel, ordinary gravel, broken stone, and, if desired, wheat, and buckshot. In the writer's judgment, any attempt to make these tests on soils or materials which are cohesive, or are made so by moisture, will be abortive and misleading. It will be a simple matter to co-relate the results of the tests on the dry materials with those having cohesive properties, by observing or measuring and comparing the "break" lines of each.

The writer believes that if exhaustive tests are made on the dry soils, as noted, they will establish conclusively the fact that arching properties and lateral pressures in soils are definitely measurable; and that they will further confirm the fact that the pressure of soil due to its lateral transmission is non-accumulative vertically, as in tunnels, although it increases laterally in direct ratio to the depth, being always at a maximum at a point slightly above the center of the vertical face.

In suggesting further procedure, which the writer feels may be of value, he does not wish to imply any lack of his appreciation of the paper itself, which is of great interest and value to the profession.

H. de B. Parsons,[30] M. Am. Soc. C. E. (by letter).—The writer, having read this interesting paper, would like to ask Professor Gilboy why temperature does not enter Equation (2), for finding permeability, or the quantity of water flowing through a soil? Perhaps the author had in mind experiments made in a laboratory where variations in temperature were small.

In a study, made by the writer, of water in a pervious soil in its natural state, the effect of temperature was very marked. In this study, the temperature range was about 30° Fahr. Furthermore, the formula used for determining the flow of water through filter sands shows that the velocity varies with the temperature.

Jacob Feld,[31] Assoc. M. Am. Soc. C. E. (by letter).—It is an ambitious program which Professor Gilboy outlines, and his reports of progress will be watched with great interest. It is a hopeful sign that he permits engineering problems to control the trend of research in soil mechanics, for only in that way can the practical observations collected in the field of construction be tied into the same network of facts.

The Wiegner method for mechanical analysis of finely pulverized materials brings out an important fact. The pressure of water containing suspended soil or any other material is greater than that of pure water. This fact applies even to such suspensions as freshly mixed concrete. The pressures are in direct proportion to the specific gravities of the suspensions. In other words, as far as engineering data are concerned, suspensions are liquids and follow the laws of liquids. Large-scale experiments by Professor E. B. Smith and by Shunk on concrete pressure, and work by Résal on clay fills, and by La Habra Dam Commission on mud, give results on various materials which check the theoretical values.

[31] Cons. Engr., New York, N. Y.

The tests developed for the various consistency limits may result in methods for distinguishing and classifying various soils. However, the writer cannot see any value in the definitions of the limits, as given in this paper. For example, under "Limits of Consistency," the author states: "All the limits are expressed in terms of water content, that is, weight of water per unit weight of dry soil." How is the unit weight of dry soils to be determined? What packing or loose condition can be taken as a standard, so that all experimenters will agree on a unit weight for any given sample?

A more serious objection, in addition to this one, applies to the definition of the shrinkage limit as given in Equation (1). It is a fundamental check in mathematical analysis of physical phenomenon that all equations must balance in dimensions. The definition requires the shrinkage limit value to be without dimension, that is, a pure number or ratio of weight to weight of equal volumes. The equation is weight minus volume, both divided by weight, and cannot truly represent the factor defined.

In studying the permeability of soils, it must be pointed out that Equation (3) is true only if: (1) The soil is entirely saturated before any reading is taken; (2) the flow through the soil sample is constant under constant pressure, that it is not clogging up or washing out; (3) the value of the constant, k, is independent of the pressure head, h; and (4) the temperatures of soil and water are the same. A very fine discussion of the variables controlling the flow of water through earth has been given[22] by John H. Griffith, M. Am. Soc. C. E.

The further data on the compression, tension, and shear values of soils add to the store of knowledge started by the very earliest experimenters in soil physics. It is these functions of a soil which distinguish it from the fluid and solid states of matter.

The author's statement under "Research in Soil Engineering," to the effect that, "corroborating previous evidence, the tests showed that the settlement under a given unit load, not too near the ultimate, is practically independent of the size of the loaded area," is interesting if it can be proved, even for sand. It is the writer's impression that, from recent observations of existing structures as well as from experiments, exactly the opposite has been the general trend. It is hoped that a detailed description of facts from which this conclusion is drawn, will be presented.

The work on lateral pressure on walls has been of special interest to the writer. The report of the experimental work performed for the New England Power Construction Company to which the author refers, is not complete enough to be conclusive. Apparently, from the results reported,[23] a great number of tests have been performed.

[22] "Physical Properties of Earths," *Bulletin 101*, Iowa Eng. Experiment Station.

[23] *Engineering*, May 30 and June 13, 1930.

Professor Gilboy is to be complimented on his work in continuing Dr. Terzaghi's research, and for his clear exposition of the various lines of research in soils which he is covering.

JOHN R. JAHN,[24] **ASSOC. M. AM. SOC. C. E.** (by letter).—This interesting paper by Professor Gilboy shows the amount of careful study and the number of mechanical devices needed to produce complete information concerning the physical properties of soils. The writer was particularly interested in the short description of the hydrometer method of size analysis and feels that it was unfortunate that more was not written of the details of laboratory work and mathematical analysis. The author has wisely pointed out that accurate knowledge of size distribution is not vital to soil mechanics, since other factors are of such importance that size analyses give only a rough indication of the properties of the material. If he has found a method of making accurate analyses, however, it would be of interest to many laboratories that are attempting to make determinations. It would also be of assistance to laboratories in other industries which depend on fine comminution, such as the sliming of ores, fine grinding of paints and pigments, cements, inks, etc.

The writer feels that the Bouyoucos method, with some of its improvements, is a useful tool for engineering information, but that it has inherent faults which will eliminate its use if accurate information is sought. These faults are fundamental, as will be brought out.

The hydrometer is shown at the left in the author's Fig. 2. It consists of an enlarged bulb portion with a weighted point and a thin stem with graduations, and at the level of submersion it registers the grammes of suspended matter per liter of liquid. A known weight of sample is thoroughly deflocculated and diluted to a known volume in the test cylinder. At various time intervals after the start of the analysis the hydrometer is lowered into the cylinder and the decreasing densities of the system give the data from which the size analysis of the sample is computed. Stokes' law[25] is used to determine the size of particle which will fall from the surface of the liquid to a critical depth point on the hydrometer in the observed time, t, and some quantitative method is used for the mathematical analysis.[26]

The following faults in the hydrometer method are apparent:

(*a*) With its irregular shape and conical point, the hydrometer does not have a practicable bottom level, to which to refer the amount of fall of particles.

(*b*) Due to its bulbous shape, too much emphasis is given to the density of the suspensoid opposite the region of the enlargement.

(*c*) The hydrometer must be withdrawn after each observation to avoid deposits on its upper shoulder. This causes turbulence, with an indeterminate translation of particles.

[25] *Transactions*, Cambridge Philosophical Soc., Vol. 8, p. 287, and Vol. 9, p. 8.

[26] "The Hydrometer Method for Making a Very Detailed Mechanical Analysis of Soils," by G. J. Bouyoucos, *Soil Science*, September, 1928.

(*d*) The meniscus on both the cylinder and the hydrometer at the level of the liquid prevents close reading of the scale unless other means, such as external gauges, are used.

(*e*) Unless due correction is made, an error of considerable magnitude will remain in the analysis because of the settling out of particles smaller than the size determined by Stokes' formula, which have fallen beyond the hydrometer, from their initial subsurface positions, that is, from less than the full depth. If the semi-log graph of "the hydrometer reading" plotted against logarithm of "the elapsed time of settlement" is straight, the error will be constant throughout, but if the graph is curved, as is usual, the error will be variable in the different size classifications.

Corrections for all these faults, except (*c*), are being made in the laboratory of Charles H. Lee, M. Am. Soc. C. E., to adapt the hydrometer method to a more accurate size analysis of fine-grained engineering material, such as muds, soils, etc. Fault (*e*) is being corrected by a modification of Rubey's method[27] adapted to semi-log graphs; Fault (*d*) is avoided by arranging a mirror against which an index point is reflected; Fault (*c*) cannot be eliminated, but is minimized by very careful manipulation; and Faults (*a*) and (*b*) are corrected by a calibration method in which the errors are grouped and the correction factor ascertained by control tests, using a similar cylinder, but having a parting plane of separation at the lower limit of the hydrometer's subsidence. Its purpose is to establish the actual average density of the suspension at the instant of reading the hydrometer. The depth of the parting plane being known, it is possible to obtain a correction curve to convert hydrometer readings into average densities of a standard height of column at the same instants. These calibration corrections will have to be established for each class of material or until its character can be anticipated. The corrections are not constant over the range of the analysis, but have varied, according to texture, from 0 to 12%, within a period of a few minutes in the "run."

During the fall of 1924, the writer was seeking a method of making an accurate size analysis, using an adaptation of the Oden method[28] as developed at the University of Upsala, at Upsala, Sweden. This method weighs the accumulations of sediment on a scale pan, suspended from a balance and situated near the bottom of a test cylinder. At the Soil Technology Laboratory, of the University of California, Professor E. V. Winterer had assembled a well-designed apparatus for weighing the sediment and recording the time intervals for equal weight accumulations. It had close thermostatic control and was automatic in every particular after commencement of the test. The method was found to be grossly inaccurate in a very unusual way, in that the particles refused to fall vertically, but migrated away from the center line of the cylinder, that is, horizontal layers did not have uniform distribution of suspensoids. Errors of from 10 to 35%,[29] all of under-registry, were found, and experiments with cylinders of glass, metal, rubber, and wood and having electrical charges of from 1.5 to 30 000 volts impressed thereon in various combinations, were found to be ineffectual. The cause of the trouble was finally decided to be the electrostatic repulsion of particles away from the center line of mass of the test cylinder with concentration at the side walls. The method was abandoned as unreliable, and rather definitely disposed of sedimentation methods depending on a collection of particles in fractional areas of containers.

[27] *Professional Paper 165A*, U. S. Geological Survey, p. 25.

[28] *Soil Science*, v. 19.

[29] *Proceedings and Papers*, First International Congress of Soil Science, by Charles F. Shaw and E. V. Winterer, June 13–22, 1927, Vol. 1.

The writer feels that a more elaborate method of utilizing the changing suspension densities offers a solution of the problem. While the hydrometer method is unsuitable for exact laboratory work, its objections or faults can be met in an apparatus in which a rod of uniform cross-section is suspended to a fixed level in a sedimentation cylinder and instantaneous records of its apparent weight are found by its being hung from one arm of a sensitive balance. As the suspended matter in the liquid settles out, the apparent weight of the rod will increase. The time rate of change in weight may be obtained by noting the times at which a given weight is equalled, electrical contacts on the balance recording the instant. A magazine can then release a known weight increment upon the opposing balance pan, the balance will swing back, and a new time interval will be recorded following sufficient change in density. The vertical travel may be kept less than a millimeter, by the use of stops under the pan or arms.

The proposed apparatus would avoid Fault (*a*), by having a constant subsiding range; Fault (*b*), by having a truly cylindrical body; and Fault (*c*), by not disturbing the rod after the test had started. Fault (*d*) would not exist, and Fault (*e*) could be avoided by Rubey's graphical, or Oden's mathematical, methods.

The falling range for subsiding particles will be the distance from the surface of the liquid to the lower end of the rod. This fact was established by the writer during the 1924 work. It was found that a cup submerged in clear water, carrying suspended material, registered its computed weight when the bottom was impervious, but registered only the weight of the matter resting on the bottom of the cup, when an aperture was opened therein. The change in weight was immediate and indicated that that weight was transmitted as a pressure due to frictional effects on the falling particles and not as an increased suspension density which would have affected the weight of the cup until slow diffusion through the aperture had taken place. Hence, the suspended rod will be acted upon vertically upward by all the displaced suspended matter above its lower end and by none of the matter that has passed this horizon.

An automatic data-recording device is desirable to avoid the need of close personal attention during 24-hour runs. The weight increments should be no larger than is necessary to bring the balance back promptly. In the 1924 work, small steel ball-bearings weighing 0.05 gramme were found to be uniform in weight. They can be discharged upon the balance pan from a magazine actuated by the same electric current that marks the swing of the balance.

The writer regrets that he has not had an opportunity to experiment with this apparatus. Inasmuch as he believes that other devices have failed to give much more than approximate results, this is suggested as a possibility, with the hope that some dependable analytic procedure can be developed. If such procedure were found, it would then be possible to compare less elaborate analytical devices, such as Bouyoucos' hydrometer, to determine the extent of their reliability and establish calibration corrections thereto.

C. H. EIFFERT,[30] M. AM. SOC. C. E. (by letter).—Since the completion of the dam of the Miami Conservancy District the plan of exploring the cores of one or more or these dams had been under consideration. The desire to make such an exploration was prompted by the lack of knowledge of core conditions in the completed structure and by the difference of opinion among prominent engineers as to the exact nature of the core material some time after the completion of a dam. It was maintained by some that the core remained in a semi-liquid condition for a long period, while others were of the opinion that there might be a possibility of the core drying out and cracking to such an extent as to destroy its imperviousness. That the cores of the Miami Conservancy Dams did not long remain in a fluid or semi-liquid condition was indicated by the Goldbeck pressure cell readings and by some of the exposures made during construction.[31] These readings showed that the core material possessed considerable inherent stability at that time. Further knowledge as to the nature of the cores was not available until the recent experiments were made.

One reason for not making explorations prior to those under consideration was that facilities for testing samples and experimenting with the materials to the best advantage were not available. When it became possible to enter into a co-operative agreement with the Massachusetts Institute of Technology, it was arranged for the District to do the field work and the Institute to make the laboratory tests and experiments.

Two general methods of obtaining samples were available. One was to sink a shaft large enough for men to work in and obtain samples, and in which the materials could be inspected in their undisturbed condition. The other method was to secure the samples from some type of drill hole or boring. In order to obtain the relative value of the two methods, it was determined to use both. The shaft, of course, would be much more expensive than the boring, but it was fairly certain that good samples could be obtained by this method, whereas some uncertainty existed as to the value of those from a drill hole or boring. The primary consideration in either case was to obtain the samples as nearly as possible in an undisturbed condition.

During the construction of these dams Goldbeck pressure cells[32] had been installed at Germantown and Taylorsville. The most satisfactory results from these cells were obtained at Taylorsville, and it was at first thought desirable to obtain the samples from this dam, but because of the paved roadway and heavy traffic conditions a vertical shaft appeared impracticable there, while a sloping shaft or drift would have been more expensive and a lesser depth of core would have been penetrated by it. On account of its greater height and the accessibility of the core, the Germantown Dam was finally selected.

---

[30] Chf. Engr. and Gen. Mgr., Miami Conservancy Dist., Dayton, Ohio.

[31] *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), pp. 1195–1197.

[32] *Loc. cit.*, p. 1188.

The shaft was located about 12 ft. west of the center line of the dam at a point where its height was approximately 110 ft. A shaft on the center line would have been more desirable, but was impracticable on account of its obstruction to traffic over the dam which is traversed by a public road.

It was decided to sink a vertical shaft with a circular concrete casing, with walls 5 in. thick and 5 ft. in internal diameter. A sheet-metal form somewhat similar to those used for monolithic concrete silos, was provided. The casing was cast at the ground level in sections about 3 ft. high. As the excavation proceeded the concrete sank under its own weight and new sections were cast in place on top of the old ones as the sinking proceeded. As there is no true core in the upper 15 or 20 ft. of the dam and the shaft was located to one side of the center line, no core material was encountered until a depth of 33 ft. was reached. The first set of samples was secured at this elevation, Professor Gilboy being present when they were taken.

The excavating for the shaft was done by hand by one man, and the material elevated with a hand-hoist and derrick (see Fig. 14), the boom being placed so that in a lowered position the bucket could be dumped into a wagon beyond the shaft. A small shed to house materials, tools, and samples was constructed to act as a counterweight for the boom. Being placed to one side of the center line more layers of fine gravel and sand were encountered than would have been the case had the shaft been directly on the center line of the dam. This led to the unexpected difficulty of handling a considerable quantity of water contained in these layers, which entered the shaft beginning at a point within 30 ft. of the top of the dam and far above the maximum water level ever recorded in the reservoir. A hand-pump was installed but as the excavation proceeded pumping by hand became too tedious and a small gas engine and pump-jack were provided for this work.

The water encountered had undoubtedly remained from the construction operations, with some possible addition due to the rainfall on the dam. It is retained by layers of core material which project outward from the main core between the layers of gravel, all the layers sloping downward toward the center of the dam. The retention of this water is evidence of the imperviousness of the core material.

The tools for obtaining samples are shown in Fig. 15. They were designed by Professor Gilboy under the direction of Charles Terzaghi, M. Am. Soc. C. E. At (*a*) is shown a seamless steel sampling tube, 4 in. in diameter, and 12 in. long, with one end turned down to a knife-edge, and this edge burnished in 0.001 in. to give clearance to the sample. The tube, which had been wiped with an oiled rag before using in order to reduce friction on the inside, was forced into the core material by hand, the material around it being removed with a trowel as fast as the tube penetrated. As soon as the tube was filled it was carefully removed and the surplus material at the ends was cut off by means of a fine wire in a hack-saw frame. Sheet metal caps (*b*) were then placed over the ends and the sample was brought to the surface. Samples were taken in pairs at each location, one vertically and the other horizontally, at right angles to the axis of the dam.

On the work table were two circular iron bases, $\frac{3}{4}$ in. by $4\frac{1}{2}$ in. (*c*). When a sample was brought to the surface to be prepared for shipment, the iron base was covered with a thin layer of melted paraffin and the sample set vertically on it after the caps had been removed. The steel tubing was then slipped from the sample. If it did not come off easily, a wooden disk slightly smaller in diameter than the tube, was placed on top of the sample and held down while the tubing was pulled up off the sample. A cylinder (*d*) of 24-gauge galvanized iron, $4\frac{1}{2}$ in. in diameter, and $13\frac{1}{2}$ in. long, was then placed over the sample, the bottom sealed with modeling clay, and the space around and above the sample filled with melted paraffin. When the paraffin had hardened the cylinder was reversed, heat being applied to the iron disk if necessary to loosen it, and the other end poured full of the paraffin. The entire sample was thus enclosed in paraffin, the structure of the sample and its water content being well preserved until it arrived at the laboratory. The tube (*e*) was used for obtaining samples from the drill hole.

When the work began it was the intention to obtain a pair of samples every 10 ft. This was found to be impracticable and only four good sets of samples were secured. The first 30 ft. was not in core material, and the shaft was sunk to a depth of only 80 ft. At a depth of 40 or 50 ft., the casing separated at one of the joints and side-slip occurred as it continued to sink. It was necessary to install some timber braces to prevent this. At this time the sinking process was very slow, and it became necessary to weight the casing and to force it down with jacks. At a depth of about 60 ft. it appeared impracticable to sink it any farther because it moved out of alignment and some cracks occurred. At this point a new casing was started inside the first one, the concrete being taken down in buckets. This was sunk to an additional depth of 20 ft. After a depth of 40 or 50 ft. had been reached it was necessary to supply air to the workman at the bottom of the shaft. This was done by a small compressor attached to the engine which ran the pump. At the depth of 80 ft. progress had become rather slow. The shaft also appeared to be somewhat dangerous. The four good sets of samples were thought to be sufficient and, therefore, the work was stopped.

The writer believes that if another shaft were to be sunk in material similar to that at Germantown, it could be done very satisfactorily by the methods herein described, but that the walls should be 8 in. thick to give them additional weight for sinking and that they should be reinforced to prevent any separation at the construction joints.

In order to determine whether or not any of the porous strata encountered, extended across the center line of the dam, 4-in., horizontal holes were bored at right angles to the center line in the two heaviest layers of this kind. In both cases, solid core material was encountered within a few feet of the shaft.

FIG. 14.—ARRANGEMENT AT SHAFT HEAD, GERMANTOWN DAM, FOR SINKING TEST PIT.

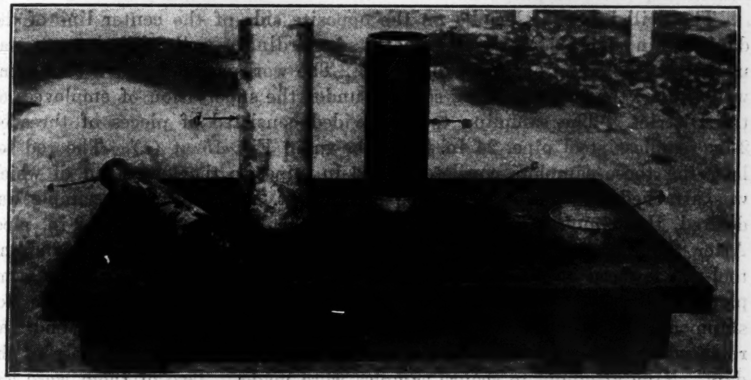

FIG. 15.—APPARATUS FOR TAKING SAMPLES OF CORES, GERMANTOWN DAM.

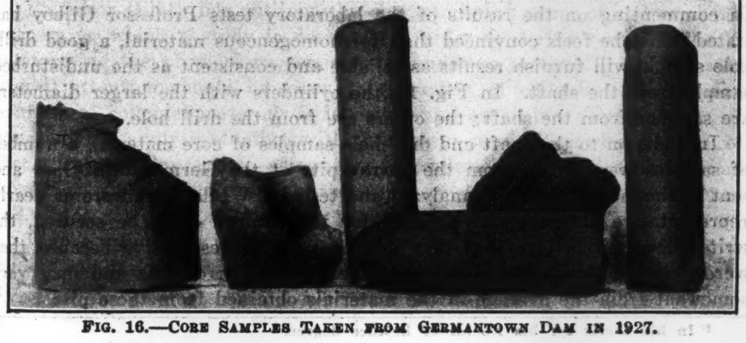

FIG. 16.—CORE SAMPLES TAKEN FROM GERMANTOWN DAM IN 1927.

The samples secured were approximately of the nature of rather stiff putty and would stand on end unsupported, when removed from the sampling tubes. Pieces of the excavated core material would stand a great deal of handling without losing their shape, and considerable pressure was necessary to indent them with the fingers. Professor Gilboy states that the laboratory experiments show the core material to be 25% consolidated and explains that this does not mean that it is soft or yielding, but that it is quite resistant due to its relatively high angle of internal friction. This point should be emphasized. The simple statement that the core is 25% consolidated may be misleading to some unless a comparison is made with other materials, the qualities of which are better known. The writer has been informed that Boston blue clay, which is considered a satisfactory material for building foundations, is only 10% consolidated by the same standards. The future rate of consolidation of the Germantown core is necessarily somewhat uncertain, but from a practical standpoint this is unimportant. The quantity of water encountered in sinking the shaft shows that there is no danger of it becoming too dry while its present state of consolidation makes it entirely satisfactory for core purposes.

The drill hole was located on the opposite side of the center line of the dam within about 25 ft. of the shaft. An ordinary well-drilling outfit was used, the pipe being 5⅝ in. in diameter. The work was done by a competent well driller, the samples being secured under the supervision of employees of the District. The sampling tools provided consisted of pieces of threaded 2-in. seamless steel pipe, 24 in. long, shown in Fig. 15 at (*e*). The rod for lowering these samplers consisted of 1¼-in. pipe, to the lower end of which was attached a piece of 2-in. pipe about 2 ft. long. When a sample was desired, the sample tube was screwed into the lower end of the 2-in. pipe. After the well had been carefully cleaned out with a dipper the sampling tool was lowered and driven into the core about 3 ft. This insured the complete filling of the sampling tube. The samples remained in these tubes for shipment, about ¾ in. of the sample being removed from each end and replaced with melted paraffin. The drill hole was driven to the base of the dam. Nine attempts to secure samples were made. Two of them were lost by slipping from the tube, but the others appeared to be very satisfactory. In commenting on the results of the laboratory tests Professor Gilboy has stated,[33] that he feels convinced that, for homogeneous material, a good drill-hole sample will furnish results as reliable and consistent as the undisturbed sample from the shaft. In Fig. 16, the cylinders with the larger diameters are samples from the shaft; the others are from the drill hole.

In addition to the shaft and drill-hole samples of core material, a number of samples were taken from the borrow-pits at the Germantown Dam and sent to the laboratory to be analyzed and tested. While these were as nearly representative of the materials used for the dam as could be secured, the writer does not believe that they can be truly representative because they were necessarily obtained from the edges of the borrow-pits and may vary somewhat from the average of the materials obtained from these pits.

---

[33] In his thesis for his Doctor of Science degree.

At the laboratory, mechanical analyses were made of the core samples. They were also tested for permeability, compression, compressive strength, angle of internal friction, water content, and specific gravity. It was necessary to design a new permeameter at the laboratory and other pieces of apparatus were modified to better meet the requirements.

The mechanical analyses were consistent with those made during the construction period. The average rate of permeability, as expressed by Professor Gilboy, was approximately 100×10^{-7} cm. per min., a very low rate.

Tests for compression and compressive strength showed that the material possessed a high degree of stability. The friction angle averaged about 27 degrees. The water content for a number of samples, expressed in percentage of dry or solid matter, averaged approximately 25 per cent. The specific gravity was found to be 2.67 for the solids and 2 for the mass. This gives a weight of 125 lb. per cu. ft. for the undisturbed core.

As a result of this work the following conclusions may be drawn:

1.—The samples from the drill hole were fully as satisfactory as those from the shaft, and were obtained with much less expense.

2.—The mechanical analyses showed the core material to be well graded from fine sand to clay in such proportions as to make a combination ideally adapted for a hydraulic-fill core.

3.—The water content does not differ materially from that found at Englewood and Lockington at the end of the construction period. While the Germantown Dam was not tested for water at that time, the mechanical analyses show the material to be quite similar. This would seem to indicate that there has been little change in the cores during the seven years between 1920 and 1927 and that they will change but little in the future.

It is hoped that the tests may be repeated at intervals of five or ten years, and that similar tests will be made on other dams.

A. A. EREMIN,[34] ASSOC. M. AM. SOC. C. E. (by letter).—Present interpretation of soil behavior under sustained loads is erroneous and unsafe. The soil problem is complicated, due to the facts that no two foundation materials can be found alike and that it is difficult to obtain test samples under natural conditions.

Professor Gilboy has outlined the characteristic factors of soil mechanics concerning which a study is desirable in order to derive reliable rules for interpreting the physical properties of foundation materials. In the study of soil attention should be given to the effect of colloids. The chemical analysis of colloidal materials is laborious and expensive. Furthermore, the results of the analysis obtained with the present state of knowledge often conflict with actual practice. However, to neglect the colloidal effect would introduce considerable error in the study of permeability and cohesion of soil, which are the most important factors in soil mechanics.

Tensile strength of loams and clays increases with the increased colloidal content, as has been shown[35] by John H. Griffith, M. Am. Soc. C. E. Therefore, the angle of internal friction of the test cylinder, Fig. 9, may also vary due to the binding effect of the colloidal particles between soil grains.

---

[34] Asst. Designing Engr., Bridge Dept., State Highway Comm., Sacramento, Calif.

[35] "Physical Properties of Earth," by John H. Griffith, M. Am. Soc. C. E.

Likewise, the permeability of soil varies, due to expansion and contraction of the colloidal materials and to its reactions with the chemicals in the ground. From research on soil mechanics for hydraulic dam cores, Mr. F. E. Hance has stated that soil chemically treated may become from 200 to 1 000% more impermeable than the same material when neutral.[36]

In the study of foundation materials an investigation of the bearing on piles in compressible soils should be included. In the future, estimation of the bearing capacity of piles will probably be based on the physical properties of the foundation material. Moreover, the penetration curve of piles may give useful information about the character of the soil.

F. N. MENEFEE,[37] M. AM. SOC. C. E. (by letter).—The subdivision of this study into (1), soil physics, and (2), soil engineering, is good. It is analogous to the division of other studies of an engineering nature. The very refined, detailed, and sometimes little used, although valuable, properties of a material correctly belong in a classification by themselves, for a larger part of the engineer's professional knowledge is based upon scientific studies which at the time they were made had no direct application. In the case at hand Charles Terzaghi, M. Am. Soc. C. E., and the author have aptly called that part of their study soil physics, and that which follows, soil engineeering.

Due to studies by Duff A. Abrams,[38] M. Am. Soc. C. E., and the late William B. Fuller,[39], M. Am. Soc. C. E., on concrete aggregates, American engineers in general have adopted the practice of plotting their mechanical analysis curves with the smaller diameter at the origin, thus giving a curve of positive rather than of negative slope, as does the author. There is no question of right or wrong to either method, but standardization of method in presenting data does assist interpretation and facilitates the use of an idea.

Since Mr. Fuller's ideal curve gave the densest mixture of sand and gravel it probably would assist in determining the permeability as applied to soils because, aside from the possible influence of colloids and swelling tendencies of, or chemical changes with addition of, moisture, the hydrostatic head lost in water flowing through soil is inversely proportional to the diameter of the voids. To state it in another way, the velocity of water through soil increases or decreases with increase or decrease in diameter of the inter-granular space. An ideal gradation from fine to coarse fills up the interstices and reduces the permeability.

Atterberg's choice of terms—"liquid limit," "plastic limit," and "shrinkage limit"—seemed very good to the writer, but the methods of determining them were subject to at least some personal equation. The methods described by the author seem to be an improvement.

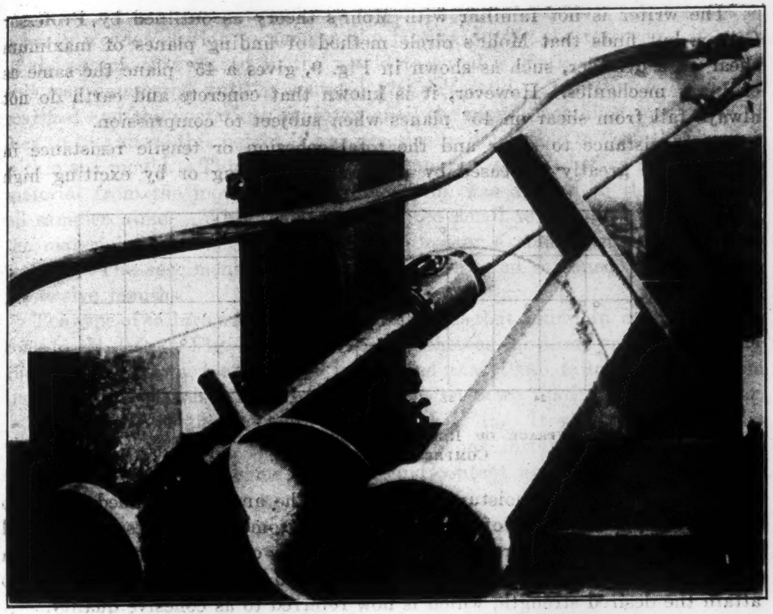

FIG. 17.—APPARATUS USED FOR MAKING SPECIMENS.

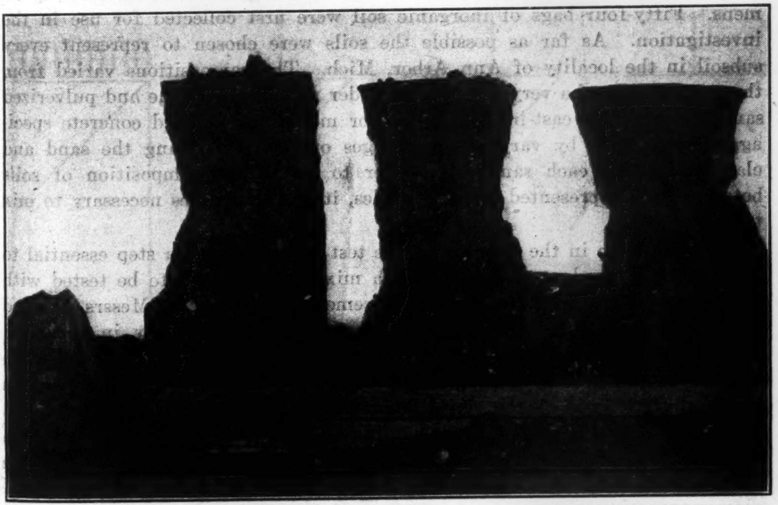

FIG. 18.—CHARACTERISTIC FAILURES.

The writer is not familiar with Mohr's theory as outlined by Professor Gilboy, but finds that Mohr's circle method of finding planes of maximum shear on a cylinder, such as shown in Fig. 9, gives a 45° plane the same as ordinary mechanics. However, it is known that concrete and earth do not always fail from shear on 45° planes when subject to compression.

The resistance to shear and the total cohesion or tensile resistance in soil may be greatly increased by mechanical working or by exciting high pressure under proper moisture conditions. The ancients rammed soils into forms for building walls of dwellings and, in some cases, these walls stood for centuries. Such literature as can be found on the subject describes a method of ramming or tamping the earth into wooden forms in order to attain the desired strength, which is now referred to as cohesive quality.

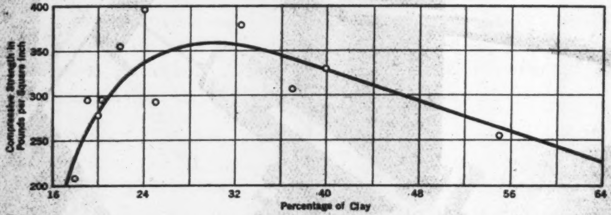

FIG. 19.—AVERAGE OF RELATIONS BETWEEN CLAY CONTENTS AND COMPRESSIVE STRENGTHS.

The writer has performed a series of experiments on mixtures of clay and sand rammed into cast-iron cylinders for moulding standard concrete specimens. Fifty-four bags of inorganic soil were first collected for use in the investigation. As far as possible the soils were chosen to represent every subsoil in the locality of Ann Arbor, Mich. The compositions varied from the one extreme of a very heavy clay binder mixed with a fine and pulverized sand rammed into cast-iron cylinders for moulding standard concrete speci-aggregate bonded by varying percentages of clay. Knowing the sand and clay analysis of each sample, in order to obtain the composition of soils between those represented by the samples, it was sometimes necessary to mix two or more.

The first step in the forming of the test cylinders, and a step essential to uniformity of product, was a thorough mixing of the soil to be tested with sufficient water to fulfill the rough requirements described[40] by Messrs. Edward W. Coffin and H. B. Humphrey. A sample squeezed tightly in the hand should adhere in the form of a ball, but will break into small pieces when dropped to the ground from the height of the waist line. This property is essentially governed by the clay content of the sample, but the writer found that over a large range of soils, varying in clay content, a tempering with water to fulfill this test gave a mixture that could be best handled with the air-hammer.

---

[40] Handbook on "Building Walls with Rammed Earth."

These moulds were clamped to a metal base which, in turn, was screwed to a heavy wooden section to dampen the jarring during the tamping. Enough of the sample was placed in the mould to equal a depth of about 5 in. and this was hammered until it sounded and felt solid. The surface was then scarified and the operations repeated until the mould was filled to a depth of 9 or 10 in.; above this height it was practically impossible to keep the rammer within the mould. This left the surface uneven, so that before removing the material from the mould a load of 4 000 lb. was applied to the surface of all samples alike. While this load was too small to change the density of the material appreciably it did tend to present a smooth surface for later testing. The specimens were then stored away and seasoned, most of them for twelve months.

The type of failure was very much the same as that found in concrete. The cone to the left in Fig. 18 is of concrete, whereas the three specimens to the right are of rammed earth. It is believed that these failures depart from the 45° plane because they are due to tension more than to diagonal shear.

The results of the tests are shown in Fig. 19. It will be noted that a value of 400 lb. per sq. in. was attained in one instance. At a later date a cylinder of about the same clay and sand content was attained which withstood nearly 500 lb. per sq. in. of compression. The apparatus used for making specimens is shown in Fig. 17.

The author's Fig. 9(*a*) shows a barreling effect of the clay cylinder which in itself indicates that the diameter increases between the top and bottom, introducing tension.

Fig. 20 represents a clay cylinder subject to compression; *P* is the total load, and *f* is the frictional resistance tending to keep the ends from spreading or increasing in diameter. This friction is a maximum at the periphery and diminishes to zero at the center or axis of the cylinder. If *f* could be eliminated the maximum shear would be,

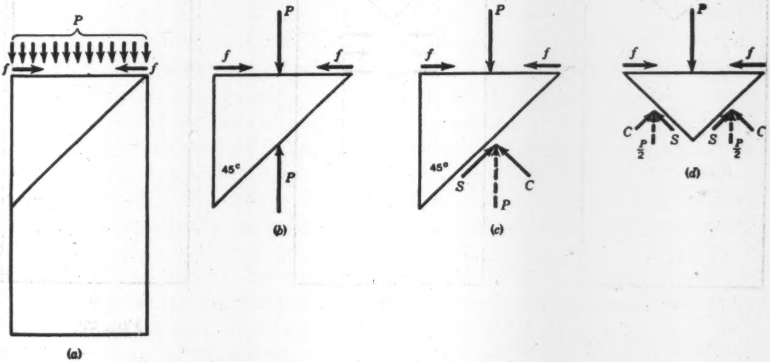

FIG. 20.

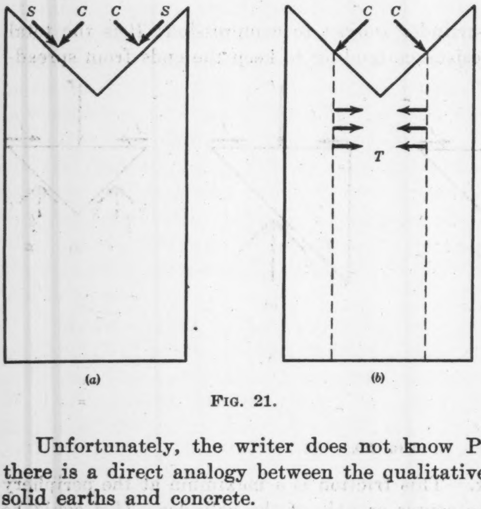
$$S = \frac{1}{2}\,\frac{P}{A} \qquad \text{......................} (6)$$

in which, A is the cross-sectional area, and would be on planes 45° with the upper and lower faces. (Fig. 20(a), Fig. 20(b), and Fig. 20(c)). With f always existing to a certain extent the plane of maximum shear will be less than 45° with the upper and lower faces, or the cone will be flatter than shown; but actual tests show that the failures in earth cylinders and concrete as well, are along planes of greater slope than 45°, as indicated in Fig. 18.

From a purely static consideration, the shearing and comprehensive forces on the slant faces of the cone neutralize each other and the resultant splitting tendency is nil; but when the load is applied the forces actually produce deformation, and the cone settles into the cup (Fig. 21(a)), through shearing deformation. Thus, the values of S are reduced, the values of C increase, and spreading action takes place introducing tension in concentric cylinders from top to bottom (Fig. 21(b)).

The illustration is made clearer by assuming a highly polished cone placed into the correspondingly polished cup (Fig. 21(b)). The values of S disappear, and the values of C increase until the sum of their vertical components is equal to P, their horizontal components pushing outward, increasing the diameter of the cylinder. Although there are no external forces pulling the sides of the cylinder outward the internal horizontal forces pushing outward radially from the axis produce diametral strain and corresponding stress.



(a) (b)

FIG. 21.

(c)

FIG. 22.

Unfortunately, the writer does not know Poisson's ratio for earth, but there is a direct analogy between the qualitative analyses of the behavior of solid earths and concrete.

Knowing Poisson's ratio for concrete to be about 0.12 and taking $E = 3\,000\,000$, a compression of 4 000 lb. per sq. in. will produce $\dfrac{4\,000}{3\,000\,000}$

= 0.00133 in. per in. of strain or shortening (Fig. 22). This will be accompanied by a diametral elongational strain of 0.12 × 0.00133 = 0.00016 in. per in. The corresponding tensile stress would be 3 000 000 × 0.00016, or 480 lb. per sq. in., which is enough to cause a tension failure that is becoming known as "longitudinal split." The failures of earth cylinders shown in Fig. 18 indicate a similar behavoir.

E. G. Walker,[41] M. Am. Soc. C. E. (by letter).—This paper is of value to engineers interested in the practical application of the mechanics of soils because it is a concise account of the lines along which research in this comparatively new branch of engineering science is being pursued. It would appear from the paper that the laboratory investigations into the physical properties of soils are being developed with a view to obtaining data on four general properties, namely: (1) Their mechanical analysis; (2) their "limits of consistency"; (3) their permeability; and, (4) their internal friction and cohesion.

As far as these properties are real physical values, a knowledge of their variations relative to one another and to external phenomena may be expected to be of considerable use to the engineer in the future in assisting him to deal with the many practical problems which arise from day to day in civil engineering practice. At present, most of these problems can only be solved, in the light of previous experience.

The subject is undoubtedly one of the greatest complexity and—no matter how successful laboratory research ultimately may be in connecting the various physical properties of individual soils with their behavior in Nature—the practical application of the results is almost certain to be fraught with uncertainties. At the same time, this is no argument against the pursuit of laboratory research, because this should enable engineers to predict the behavior of soils under the ideal conditions of experimental work, and in this way guidance may be given to the application of practical experience.

The methods described for measuring consistency certainly seem very empirical and it would be of interest if the author would elaborate this section of the paper by explaining what is really obtained from the measurements therein described. The change from the state of wet consistency in which the clay acts practically as a liquid down to that in which, all the water having been removed, it may act as an imperfectly elastic solid, is a gradual one and is not marked by any complete changes of properties, such as occur, for example, when an increase of temperature converts a solid, successively, into a liquid and a gas. It seems undesirable, therefore, to attempt to define limits in the manner suggested in the paper, since this straightway leads to the deduction that there are points at which definite changes of properties exist.

The writer suggests that the line of research should rather be to attempt to correlate, with the variation of moisture content, some representative property of the clay, such as the force necessary to produce some agreed distortion of the sample. If a detailed study of the phenomena should show points to exist at which changes of properties become apparent, a more scientifically defined limit could be designated.

---

[41] (Maxted & Knott), London, England.

The writer would like some further explanation of Equation (1). The quantity, $\frac{W_0 - W_0}{W_0}$, is the change in weight due to drying divided by the weight of the dry sample and is, therefore, the ratio of the weight of water to clay in the wet sample. The quantity, $\frac{V_1 - V_0}{W_0}$, is the ratio of the shrinkage to the weight of the dry sample and is, therefore, the reciprocal of the apparent change of density of the clay. Hence, this equation requires that a measure of bulkiness, which cannot be dissociated from units of weight and volume, be subtracted from an abstract ratio in order to obtain a value which is called a "shrinkage limit." The task of defining limits becomes doubly difficult when it is proposed to measure them in so obscure and empirical a manner.

The portable capillary permeameter shown in Fig. 5 would appear to be a good type of apparatus for approximate field determinations when the more exact apparatus shown in Fig. 4 would not be available. The author states that the coefficient, F, in the formula used for reducing the measurements made with the horizontal capillary permeameter, may be taken as 100 000, with a range of deviation of ± 50 per cent. Equation (5) reduces to $k = \frac{x^4}{t^2} \times \frac{e}{1 + e} \times \frac{1}{F}$; that is, for any given set of observations the permeability varies as $\frac{1}{F}$. Hence, if F may vary within the stated limits the actual permeability may vary from two-thirds to twice that calculated by assuming a mean value, $F = 100\,000$. Therefore, unless calibration of the instrument against the standard type of permeameter can reduce the range of possible variation of F, the capillary type does not appear to be of much practical value.

Research with the consolidation apparatus, in which the sample is constrained laterally, together with mechanical tests in compression and shear on the lines described under "Internal Friction and Cohesion," should lead to results of considerable practical value. It is hoped that this part of the work of the laboratory will be developed to the fullest extent in combination with the field testing of foundation soils described under "Foundations."

The four classes of engineering researches described in the second part of the paper foreshadow great possibilities of adding to the knowledge facts that will enable the design of civil engineering works to be placed on a more satisfactory basis.

As far as the writer is aware, no organized research on the pressures on retaining walls has ever been attempted before with so large an apparatus as that shown in Fig. 13. Many experiments have been made on earth pressures during the last hundred years and more, but the great majority have been useless as far as the direct practical application of the results to engineering design is concerned, solely because the scale upon which the experiments have been conducted, has been too small. It has not been recognized sufficiently in the past that there must be a distinct scale effect in experiments of this nature. Whereas a model wall quite conceivably may be constructed to a small scale to represent the original in dimension, weight, distribution of material, etc., to a close degree of exactness, it is impossible, proportionately, to scale down the soil which presses against it, or to represent adequately the effects of consolidation or loosening of the soil resultant from actual practical works of construction. The only hope of obtaining better design data than are now available is to carry out experiments on a large scale. The writer has more sanguine hopes of the success of the large apparatus described in the paper, therefore, than he has had of previous researches of this nature.

There is one detail, however, which the writer ventures to criticize. The bin in which the earth is to be retained is 14 ft. square and 10 ft. high. That is, the ratio of width to height of the measuring panel is only 1 to 4. With so low a ratio, unless special precautions are taken, the measurements are likely to be distorted considerably by end effects. The introduction of watertight joints between the movable panel and the side walls, when experiments on saturated soils are to be undertaken, will only accentuate this difficulty. As no mention of this point is made in the paper, it would be of interest to learn how it is proposed to deal with it.

D. P. KRYNINE,[42] M. AM. SOC. C. E. (by letter).—Prior to 1925, when Charles Terzaghi, M. Am. Soc. C. E., published his findings in the field of soil mechanics[43] that science was a rather weak sub-division of engineering mechanics. It dealt with imaginary dry substances affected by friction, and sometimes cohesion. The development of the science was accelerated when it was emphasized that the backbone of engineering soil research is the study of the physical properties of the material.

Rôle of Soil Physics.—In the present epoch a new science of soil mechanics is being created and no necessary tool should be disregarded. Soil physics has proved to be a mighty "base" on which engineering theories may be erected; therefore, a thorough knowledge of it should not be underestimated. Obviously, such knowledge is economically worthless, as Professor Gilboy rightly states, unless it provides a means for answering engineering questions. Unfortunately, the branch of soil physics that may happen to be necessary in the future is not known at present; and a modern worker in soil engineering research should be able to study any new branch of soil physics, at any time, and even to develop it independently if necessary. For this purpose a certain training and familiarity with soil physics and related sciences are required.

---

[42] Research Associate in Soil Mechanics, Dept. of Civ. Eng., Yale Univ., New Haven, Conn.

[43] "Erdbaumechanik auf bodenphysikalischer Grundlage," by Charles Terzaghi, Leipzig and Vienna, 1925.

Some time ago soil colloids were considered to be the cause of many phenomena in soils. Professor Terzaghi did not hesitate to plunge into a detailed study of the mechanics of adsorption, and he published a paper on the subject that would have done credit to any specialist in physical chemistry.[44] The attitude of any modern soil engineer should be similar; otherwise, the development of the science will be retarded. However, his writings, addressed to the general technical public, should be different from those addressed to specialists. They should be concise and should contain as little as possible of complicated formulas and physical speculations not directly applicable in engineering practice.

Mechanical Analysis.—Civil engineers received their first knowledge of soil research procedure from the agriculturalists, and from that source came a tendency to over-estimate the value of mechanical analysis. Those who work in soil mechanics know how much time has been spent in studying and improving methods of making mechanical analyses.

Considerable research on sedimentation has been done by most investigators. Sedimentation methods depend on the fact that in a viscous medium, such as water, particles sink at different speeds depending on their weight, specific gravity, and configuration. The relation between their diameter and their velocity of sinking is given by the well-known formula introduced by Stokes.[45] This equation is valid for spherical particles. However, clay particles are scale-like and, therefore, Stokes' formula can give only the "effective diameter" of the particle, which is defined as the diameter of an imaginary sphere of the same material which would sink in water with the same velocity as the given particle. The general idea of the test consists in stirring the soil solution well and allowing it to stand for a given time, *t*, when the turbid liquid is poured or siphoned into a receptacle; it does not contain particles coarser than a certain diameter, *d*, computed from Stokes' formula.

The quantity of suspended particles in the turbid liquid may also be measured directly, without pouring or siphoning (hydrometer method). Results obtained by even the most refined sedimentation methods, however, are only approximate. The Russian physicist, G. J. Pokrowski, studied[46] some optical properties of soils and found that variations of such properties correspond only to variations in the size of particles more than 0.3 microns in magnitude. In other words, it seems to be inadequate to apply Stokes' formula to particles less than 0.3 microns in magnitude, that is, to small colloidal particles and to those somewhat coarser. The walls of the container exert a certain influence on the particles according to their electric charge; and the path of sinking particles is not at all straight, as Stokes' formula assumes.

The conclusion to which engineering soil investigators have come lately, may be formulated as follows. Since complicated methods give only approximate results, it is preferable to save time and energy by using simpler methods provided the degree of accuracy remains practically the same. In this way, the methods of Wiegner, of Gessner, of Sabanine (used in Russia),"[47] of Robinson, and others, which may be adequate for agricultural purposes, have become merely of historical interest to a civil engineer. For engineering routine research, sieve analysis for coarser particles and the Bouyoucos hydrometer test for minute particles are to be recommended.

---

[44] "The Mechanics of Adsorption and of Swelling of Gels," by Charles Terzaghi, Colloid Symposium Monograph, 1926.

[45] "The Physical Properties of Soil," by Bernard A. Keen, Lond., 1931, p. 39 *et seq.*

[46] "Optical Investigation of Soil Suspensions," by G. J. Pokrowski, Soil Investigations in 1927 (in Russian), Moscow, 1928, p. 57 *et seq.*

A full description of methods of procedure for mechanical analysis for the combined sieve and hydrometer method has been published by the U. S. Bureau of Public Roads.[48] In applying the Bouyoucos test, proper use of deflocculating agents should be emphasized (sodium silicate solution for soils having a plasticity index of less than 20 and hydrogen peroxide for heavier clays). Professor Bouyoucos himself describes[49] this procedure in a manner somewhat different from that of the Bureau of Public Roads.

The accumulated percentages of particles of different effective diameters may be plotted to a logarithmic scale as shown in Fig. 1 of Professor Gilboy's paper, and thus a particle—size accumulation curve—may be obtained. In his routine research for highway purposes the writer seldom makes the complete hydrometer test. It has been felt that in the majority of practical cases, the 15-min. Bouyoucos test is all that is needed. Admittedly this is rather empirical; but it gives a fair idea of the amount of colloidal matter in the soil. This is especially true of low percentages when obtained in the 15-min. test.

Moisture Equivalent.— The writer understands that no research on moisture equivalent has been made at the Massachusetts Institute of Technology. Possibly this fact may be explained by the lack of interest in this item on the part of foundation engineers. On the contrary, highway engineers consider the study of the moisture equivalent as an important feature. For reasons which follow, the writer wishes to suggest the importance of a certain familiarity with the moisture equivalent in foundation engineering as well.

The moisture equivalent represents the percentage of water, based on the dry weight of the soil sample (usually 5 grammes), retained by the soil after first being soaked in water for about 6 hours, then drained in a humidifier for 12 hours, and, finally, subjected to the action of a centrifugal force with an acceleration one thousand times that of gravity, for 1 hour. This is the procedure of the U. S. Bureau of Public Roads; the duration of soaking and draining, as recommended by the U. S. Bureau of Soils, is different. The centrifuge method was introduced by Messrs. Lyman J. Briggs and John McLane[50] about 1907; a few years ago a field method was proposed[51] by A. C. Rose, Assoc. M. Am. Soc. C. E. However, on applying the centrifuge method difficulties arise. In the case of heavy clays, especially of the sticky type, the water is not thrown out through the holes in the bottom of the container (Gooch crucible), but collects on the top of the layer. This phenomenon, called "water-logging," should be of interest to foundation engineers. According to computations by Professor Terzaghi the process of centrifuging is equivalent to the application of a load equal to 2 kg. per sq. cm.

[50] "The Moisture Equivalent of Soils," by Lyman J. Briggs and John McLane, U. S. Dept. of Agriculture, *Bulletin 45*, Washington, D. C., 1907. A great number of papers along these lines are to be found in *Soil Science* and other magazines.

[51] "Foundations and Drainage of Highways," by Albert C. Rose, *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 64 *et seq.*

The theory of hydrodynamic phenomena in soils requires the pressing out of water under load. Possibly in a loaded soil layer the tendency is for water to be squeezed out at both top and bottom. Owing to the sticky nature of some gels the clay may become impermeable at the bottom of the layer, or close to it. This is analogous to the phenomenon of water-logging in the process of centrifuging. The same may happen close to the top, or in the middle, of a layer. Thus, instead of being thrown out, water remains in the interior of the layer, which may conserve its voids-ratio close to the liquid limit. Such cases have been disclosed in some borings and, as far as the writer knows, have not been thoroughly understood.

Further study will possibly establish closer relationship between the values of both the moisture equivalent and the coefficient of permeability. Furthermore, there is interdependence between the contrifuge moisture equivalent and the colloidal content of the soil as determined by the 15-min. Bouyoucos test. This fact has been stated by Professor Bouyoucos;[52] an analogous interdependence has been found by the writer in testing more than one hundred samples of soils in New Haven County, Connecticut.[53]

Limits of Consistency.—The procedure of determining the limits of consistency has been fully described in *Public Roads.*[48] The method of determining the liquid limit is stated as follows: "The dish is held firmly in one hand, with the groove parallel to the line of sight, and tapped lightly with a horizontal motion against the palm of the other hand ten times." Obviously, the apparatus constructed by Mr. A. Casagrande[54] minimizes the personal equation and is therefore superior to that adopted by the Bureau of Public Roads. The Bodman and Tamaschi method[55] involves dropping a flat-bottomed, straight-sided, metal container (50 mm. in diameter, and 13 mm. high), holding the plastic mass of soil (weight, 20 grammes when in water-free state), from a height of 30 cm. A ditch of triangular cross-section is excavated along the dish with two razor blades held at an angle of 45° to the earth's surface. The number of impacts is plotted against the moisture content. The equation of the curve is:

$$N = aw^n \qquad (7)$$

[55] "Studies of Soils in the Plastic State," by G. B. Bodman and M. Tamaschi, *Soil Science,* Vol. 30 (1930), p. 175 *et seq.* Another example is the method of Mr. Roy C. Roberts, as described in the Report of the Am. Soil Survey Assoc., Ames, Iowa, 1930, p. 56 (mimeographed copy).

in which, N is the number of impacts needed to fill the ditch; w, the percentage of water as referred to the dry weight of the sample; and a and n are constants. Obviously, the Bodman and Tamaschi method has much in common with the idea developed by Mr. Casagrande.

There have been many other attempts to measure plasticity, advantage of which may be taken by a soil engineer. Dr. J. W. Mellor takes[56] a clay ball of standard size, applies a sufficient stress on a standard area to cause steady compression, and measures the total motion required to split the ball open at the edges. Thus, two factors may be obtained—stress and strain—both depending on the water content. Plasticity is expressed by the product of these two factors, when this product reaches a maximum. In Bischoff's test,[57] mixtures of soil powder, sand, and water are prepared. After drying, a moist brush is passed twenty-five times back and forth on the surface of each cylinder. Some of the cylinders (the bulging ones) will still remain convex, while others will become concave. Suppose that after the test there are n convex cylinders; then, according to Bischoff, n is the plasticity coefficient. In the method introduced by Messrs. T. W. Talwalkar and C. W. Parmelee[58] a plastic clay bar is subjected to torsional stresses, and a curve showing the stress-strain relations is drawn. There are still other methods, as, for instance, that of Professor Zemiatchensky.

Attempts have been made to explain soil plasticity by colloidal content. Mr. M. L. Nichols[59] has found experimentally that the lower plastic limit and the plasticity index depend on the colloid content of the soil. According to Mr. Nichols, the lower plastic limit decreases with the increase of the "activity" of the colloids acting in a given soil; and the plasticity index (or "plasticity number") may be expressed by an exponential function of the colloid content. According to Mr. Nichols' computations, a soil with 15 to 17% colloid content would have a plasticity index of 1; and this is quite closely in agreement with practical data. The writer does not mean that the attempt to explain so many soil properties by its colloidal behavior should be revived in soil mechanics; but he wishes to point out that colloid content determined by even a rudimentary method represents a valuable datum which should never be lost sight of by the engineering soil investigator.

Influence of Scale-Like Particles.—Atterberg has found[60] that only soils having disk or plate-shaped (scale-like) particles showed signs of plasticity. Mr. L. D. Baver has attributed[61] plasticity to the orientation of plate-shaped colloidal particles. The influence of scale-like particles, such as mica, on the compressibility of soils has been evidenced by the research of Professor

Terzaghi and Professor Gilboy.[62] Scale-like colloids belong to the same category as mica. Possibly, Baver's opinion[61] relative to plasticity should be generalized and applied to compressibility as well. In other words, compressibility of soils should be explained, not by the "scale-likeness" of particles as such, but by their orientation, or by the possibility of such orientation in applying the load.

In order to clarify the idea of orientation, suppose a small paper slip is dropped on the floor. Its path of falling is more or less vertical, and the slip will be deposited with its face touching the floor; that is, it will be oriented horizontally. Let a great number of small paper slips be dropped simultaneously. Although most of them will be oriented on the floor, some will not be so oriented. Such is the case of sedimentary clays consisting of small scale-like particles; and the degree of orientation can be different in different clays. Therefore, in a disturbed sample all the particles are mixed and the degree of orientation has little to do with the natural state. Obviously, in using disturbed samples in the form of powder, not only the degree of orientation, but the voids-ratio and the character of the particle itself are not the same as in Nature. It has already been stated that according to Stokes' formula clay particles lying higher should be finer, as a rule, than those from lower layers. Therefore, if particles possessing different properties are mixed so as to form a "disturbed" sample, the testing would scarcely give very desirable data. The initiative of Professor Gilboy in studying the question of how to obtain large undisturbed samples is welcomed.

An attempt of Dr. Pokrowski to express the degree of orientation numerically should be mentioned.[63] The intensity of polarized light reflected by the surface of the soil was proved to depend on the degree of orientation. The latter may be measured by the ratio of two light intensities reflected in predetermined directions. The maximum value of this ratio was proved to be equal to 1.13 (talc), and it varies between 1.03 and 1.07 for clays.

Permeability.—Darcy's law (Equation (2) of Professor Gilboy's paper) may be written in the form:

$$v = \frac{Q}{At} = k\,N \qquad (8)$$

in which, v is the velocity of flow. Forchheimer showed[64] that generally:

$$v^m = k\,N \qquad (9)$$

in which, the limits of m are 1 and 2.

Smreker[65] proposed an equation in the form of Equation (9):

$$N = a\,v^2 + b\,v^{\frac{3}{2}} \qquad (10)$$

[64] "Wasserbewegung durch Böden," by Ph. Forchheimer, *Zeitschrift* des Vereins Deutscher Ingenieur, Vol. 45 (1901), p. 1781 *et seq.* This formula is also mentioned by Forchheimer in "Hydraulik," Berlin, 1914, p. 420.

[65] "Das Grundwasser, seine Erscheinungsformen, Bewegungsgesetze, und Mengenbestimmung," by O. Smreker, Leipzig und Berlin, 1914, pp. 29–33.

in which, *a* and *b* are constants. Afterward, he omitted the first member in the right-hand side of Equation (10) and obtained:

$$N = b\ v^{\frac{3}{2}} \quad \text{.........................(11)}$$

This formula provoked considerable discussion in Europe.

On proposing his formula Darcy had a limited application[66] in mind; therefore, its application in other cases may serve only as an approximation. Actual research, however, is generally based on the assumption that Darcy's law is an exact one. In this connection, it should also be emphasized that the coefficient of permeability, *k*, is not a constant, but fluctuates during the percolation. In the beginning of the percolation, the initial value of *k* decreases. This fact has been established by many investigators, beginning with Forchheimer[64] and others before 1901, to the modern research workers of the U. S. Bureau of Chemistry and Soils in 1931.[67] After a certain time, the value of *k* may increase again considerably. Strictly speaking, such fluctuations should be taken into account in designing permeameters.

Another inconvenience of the apparatus in Fig. 4 is the possibility of "colloid erosion" in using high values for hydraulic gradients. Under the action of a water column, colloids should migrate downward, rapidly, if the column is high, and slowly, otherwise. A proof of this statement is furnished by Nature herself; as known, colloidal matter from the upper soil horizons has been partly removed to form lower illuvial horizons that are richer in colloids.

The following simple device for determining the coefficient of permeability has been used by the writer for loams and sandy soils in Connecticut. In Fig. 23 there are two metallic containers, *A* and *B*. The bottom of the inner cylinder, *A*, is perforated and covered with a filter paper. The soil sample is placed on this paper so that its upper surface corresponds to the edge of the outer cylinder. The edge serves as an overflow device. First, the outer cylinder is filled full of water, and the sample is allowed to absorb as much as it can. Additional water should be added gradually in order to maintain a constant level in the outer cylinder. Afterward the inner cylinder is carefully filled without disturbing the surface of the sample; percolation begins immediately. Suppose that at a certain time, *t*, from the beginning of percolation, the water level in the inner cylinder has dropped to a distance, *a*, from the top. Let, $H =$ the vertical distance from the top of the inner cylinder to the top of the outer cylinder; $d =$ the thickness of the sample; and $k =$ the coefficient of permeability. Then, applying the Smreker formula:

$$k = \frac{3\ d^{\frac{2}{3}}}{t}\left(\sqrt[3]{H} - \sqrt[3]{H - a}\right) \text{...............(12)}$$

---

[66] "Les fontaines publiques de la ville de Dijon," by H. Darcy, Paris, 1856, p. 590.

[67] "A Laboratory Study of the Field Percolation Rates of Soils," by C. S. Slater and H. G. Byers, *Technical Bulletin No. 232*, U. S. Dept. of Agriculture, January, 1931, p. 9.

The height, H, and the thickness of the sample, d, are supposed to be known. For a given value of a,

$$k = \frac{c}{t} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(13)$$

in which, c is a constant, corresponding to the given value of a.

The apparatus is unusually easy to handle and adequate for rough work. The inner cylinder may be taken out and driven into the ground; and thus an undisturbed sample may be obtained and tested. In order to avoid mistakes in the beginning of the percolation, the writer generally observes the time, t, necessary for the water to drop from a level, $a = a_1$, to another level, $a = a_2$. Both levels are marked with white lines on the inner surface of the cylinder. In this case, the form of Equation (13) is the same as before; and the constant, c, has been computed once and for all. It should be added that the high level of the overflow permits one to keep the sample entirely saturated from the beginning of percolation. It is obvious that the results of permeability tests should be reduced to a standard temperature (usually + 10° cent.).

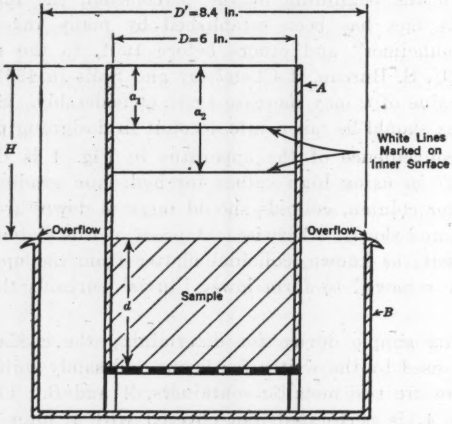

FIG. 23.—A SIMPLE DEVICE FOR MEASURING PERMEABILITY OF SOILS.

The horizontal capillarity test proposed by Mr. Casagrande should receive special attention because of its unusual interest (see Fig. 5). From Equation (5) of the paper, the following may be written.

$$\frac{x^2}{t} = C_1 \sqrt{k} \text{ (a constant)} \ldots\ldots\ldots\ldots\ldots\ldots(14)$$

in which, C_1 (for a given soil in a given condition) is a constant. The value of k is assumed to be constant.

As far as the writer knows, formulas for the speed of capillary movement, both vertical and horizontal, were first developed[68] by Diro Kitao, in 1897.

---

[68] "Handbuch der Bodenkunde," Edited by E. Blanck, Vol. 6, p. 104 *et seq.*; also, p. 172.

He was also the first to draw the attention of investigators to the meaning of the ratio, $\frac{x^2}{t}$.

Later investigators, for instance, J. S. Kozeny[69] also paid due attention to the study of the ratio, $\frac{x^2}{t}$. However, the idea of applying observations on capillary movement to the determination of the coefficient of permeability, k, was clearly expressed only in 1925, by Professor Terzaghi.[43] In 1930, Zunker[68] proposed the determination of the value of k from data referring to the downward capillary movement. His formula is:

$$\frac{x^2}{t} = 2k\ (H - Z + L) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

in which, Z and L are values of excess atmospheric pressure at the bottom and the top of the capillary column, respectively, and H, the pulling force of the meniscus. Approximately:

$$\frac{x^2}{t} = 2k\ H \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

or,

$$\frac{x^2}{t} = C_2\, k \text{ (a constant)} \ldots\ldots\ldots\ldots\ldots\ldots (17)$$

in which, C_2 is a constant for a given soil. The form of the right side of both Equations (14) and (17) being somewhat different, it would be interesting to see a development of the formula. It should also be emphasized, that the capillary saturation, mentioned by Professor Gilboy in introducing Fig. 5, does not accompany the moving meniscus at all. Saturation takes place gradually from the entrance of the experimental tube to its outlet; and sometimes many hours are needed for complete saturation. Observations were made on the gradual saturation of soil in the experimental tube without extracting samples therefrom for the determination of moisture content.[70] For this purpose the "reflectometer" of Dr. Pokrowski[71] was used. This is an apparatus which permits the determination of the moisture content of a given soil by observing certain optical phenomena on the visible surface of the moist soil through the walls of the experimental tube. Progressive saturation curves for tubes, 17 and 23 mm. in diameter, are shown in Fig. 24. In these curves, h is the time, in hours, from the beginning of capillary movement. The visible moisture line is not shown.

Compressibility and Consolidation.—The theories of soil mechanics referring to compressibility and consolidation, and the consolidation apparatus shown in Fig. 7, have been developed almost exclusively by Professor Terzaghi.[43] Fig. 25 shows, diagrammatically, the general installation of the same apparatus at Yale University: *A* is a wooden plank fixed by the clamps, *B,* to a solid laboratory table, *T.* A metallic column, *C,* carries the axis of rotation of a lever, *L,* on the other side of which a variable load, *P,* may be applied (bags containing different quantities of shot). Thus, loads may be applied to the experimental cylinder, *E,* in definite increments. The installation is very simple and inexpensive.

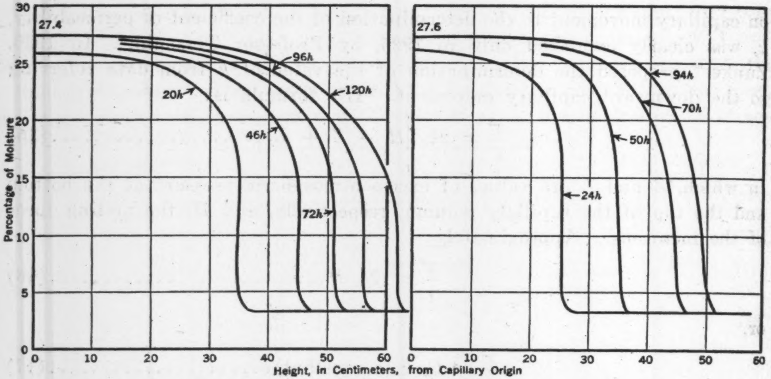

FIG. 24.—PROGRESSIVE CURVES OF CAPILLARY SATURATION IN A GLACIAL LOAMY CLAY.

In the writer's opinion the shape of the curves obtained for samples ½ in. thick, as shown in Fig. 6, may be considered only an indication (not conclusive) of the consolidation of a natural sedimentary clay layer. Obviously, it is understood that the difference in thickness should be taken into account. A simple consideration of Stokes' formula[45] leads one to the conclusion that, as a rule, a sedimentary clay layer cannot be homogeneous. The water in the basin where such a clay is being formed, is practically a col-

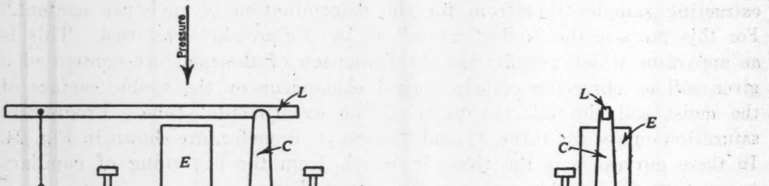

FIG. 25.—SKETCH OF A SIMPLE INSTALLATION OF THE CONSOLIDATION DEVICE.

loidal suspension; colloids settle gradually to the bottom, flocculating or simply mixing with fresh material reaching the basin from eroded localities. The influx of the eroded material is of intermittent intensity, and possibly it stops periodically. The topography of the bottom of the basin and the water level of the basin may change. In this connection superficial crusts may sometimes be formed. The mechanics of the formation of such crusts was developed by Professor Terzaghi.[48] Furthermore, clay may be sticky, and traps for percolating water may be formed under the action of loads as stated in the foregoing remarks under "Moisture Equivalent."

As a result, some faulty permeable or completely impermeable colloid "sheets" may exist in the interior of a clay layer. This sometimes should disturb the whole picture of consolidation. The writer believes, therefore, that special attention should be paid to the study of the geological profile in the particular case. Especially,.places at which the natural water content is close to the liquid limit should be examined carefully. These places in addition to disturbing the consolidation, may reveal the existence of lateral flow and thus cause the unexpected settlement of a building.

Internal Friction and Cohesion.—Both internal friction and cohesion are responsible for the shearing resistance of the soil as stated by Professor Gilboy (see, "Internal Friction and Cohesion"). Numerous investigations of friction have been made; and its nature is somewhat clearer than that of cohesion. An adequate definition of cohesion was given by Newton in his "Opticks," before 1721; and about 1773 the laws of friction and cohesion, as affecting a mass of soil, were formulated by Coulomb.[87] To-day, cohesion is being studied to a considerable extent by metallographists and physicists working in that field. Although some progress has been made, the question of cohesion in metals seems still to be open. Further details may be found in the publications of the Faraday Society.[72] The problem of cohesion appears to be even more complicated in soil mechanics than in metallography. In this case the investigator has to deal not with a "continuum" as in metals, but with millions and millions of small bodies, often surrounded by water films stuck to the surface of the particle, and separated one from another by cushions of water and air of variable thickness. Professor Terzaghi, as stated by Professor Gilboy, has distinguished between true and apparent cohesion. For practical purposes the apparent cohesion only is interesting in the majority of cases.

A short statement as to the nature of apparent cohesion may be formulated as follows:

(*a*) A mass of soil generally consists of air, water, and hard soil particles. The molecular forces of hard particles may cause water to stick to their surfaces; or particles may adsorb water in the form of films. In their turn, there are molecular forces between particles of water; and these forces are responsible for the tensile and shearing resistance of water in films. It should be emphasized that water in capillary films is rather hard, similar to hardened glue.

---

[72] "Cohesion and Related Problems": A General Discussion held by the Faraday Society, November, 1927. Attention should be drawn to the paper of N. K. Adam, entitled "Cohesion in Surface Films," p. 149.

(*b*) The molecular forces act within a very short distance from the surface of a particle (range of molecular forces). They are strong close to the surface and rapidly decrease toward the boundary of their range. When a surface of separation (or surface of rupture) passes between two particles surrounded by water films, a phenomenon takes place analogous, to a certain extent, to the shearing of a beam, relatively weak in the middle of the span and very strong on the ends (Fig. 26). In cohesive soils this span is microscopically small. The smaller the span (that is, the distance between the particles), the stronger is the beam, principally because of the dropping of the weak part from the middle.

The following conclusions may be drawn from Fig. 26, which may easily be checked in practice: (1) Ramming or packing of soil increases its cohesion, because of the decrease of the span of the imaginary beam (Fig. 26); (2) settlement of soil produces the same effect, for the same reason; and (3) saturation of soil with water makes the span of the imaginary beam increase; as a result, cohesion is reduced. Thus, the principal cause of cohesion in soils is water in proper proportion, capillary or even hygroscopic. There is also an opinion that a mineral binder may contribute to the increase of cohesion of smaller particles.[73]

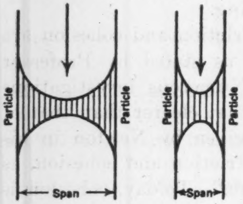

Fig. 26. — Graphic Representation of Increase of Shearing Resistance With a Decrease of Distance Between Particles.

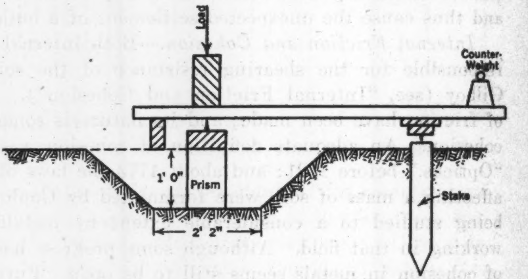

Fig. 27.—Determination of Shearing Resistance of the Soil After Buisman.

Although Professor Gilboy does not formulate conclusions drawn from working with the machine of Figs. 10 and 11, the few results he cites are very interesting, and that referring to the angle of friction of clays, should be especially emphasized. Contrary to a widespread opinion, the angles of friction of clay, ϕ, appear to be considerable. Perhaps this is the eve of important events in this branch of research.

The existing methods of determining cohesion are principally those of the laboratory. The well-known idea of pulling one box of soil along the surface of another was developed by the late William Cain, M. Am. Soc. C. E., and has appeared many times in literature. The method based on the rupture of a cylinder (Fig. 9), was elaborated by Professor Janicsek, of the Technical University of Hungary, when working under the supervision of Professor Terzaghi, at Cambridge, Mass. The procedure in question is simple and efficient, but inconvenient in some respects. In addition to a certain difficulty in measuring the angle, α, accurately, there remains unconsidered the influence of the friction between the top and bottom of the experimental cylinder, and the compression machine, as Professor Janicsek himself points out in his writings.[74]

---

[73] "Interrelationship of Load, Road, and Subgrade," by C. A. Hogentogler, Assoc. M. Am. Soc. C. E., and Charles Terzaghi, M. Am. Soc. C. E., *Public Roads*, Vol. 10, No. 3 (1929), p. 37 *et seq.*

Professor A. S. Buisman, of Holland, finds the coefficients of friction and cohesion by a similar procedure.[75] In addition to his laboratory work, Professor Buisman made experiments in the field destroying soil prisms as shown in Fig. 27. It is noteworthy that for a clay and a loam, tested in the laboratory, Professor Buisman found the values of ϕ to be between $27\frac{1}{2}$ and 29 degrees.

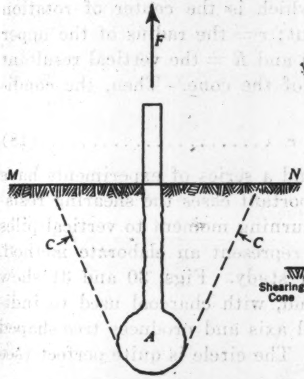

FIG. 28.—POSSIBILITY OF DETERMINING SHEARING RESISTANCE OF SOIL BY PULLING OUT A MALONE ANCHOR.

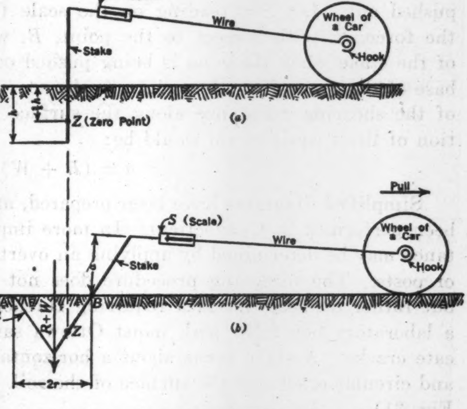

FIG. 29. — SIMPLE METHOD OF DETERMINING SHEARING RESISTANCE OF SOIL BY PULLING A STAKE WITH AN AUTOMOBILE.

Among his other experiments, the strength of earth in shear has been studied[76] by John H. Griffith, M. Am. Soc. C. E. He used a method somewhat similar to that proposed by Professor Cain, but dealt with blocks of natural earth about 12 in. wide and 24 in. long. The ratio of stress to strain, or the shearing modulus, was computed, and corresponding curves were drawn.

In 1923, dynamometer tests on a special type of anchors for transmission towers were conducted for the Blaw-Knox Company in Pittsburgh, Pa., and, in 1931, similar tests made in Java, were described[77] by O. J. Herz. The Java experiments consisted in pulling some buried concrete masses from the ground by applying a vertical force. Both the Pittsburgh and the Java experiments disclose the possibility of determining shearing resistance of soil. In Fig. 28, *MN* is the surface of the ground; *A* represents the anchor used in the Pittsburgh experiments; *F* is a vertical pulling force measured with the dynamometer; and *C* is the surface of the cone of destruction (shearing surface).

---

[74] "Alkalmas—e a Koska a Töröszilárdság Megallapitásápará?" by Jozsef Janicsek, *Technika*, Vol. 8, Nos. 3 and 4 (1927), pp. 73 and 101.

[75] "Eenige beproevingsmethoden ter bepaling van den inwendigen wrijvingeweers tand van grondsorten," by A. S. Buisman, *De Ingenieur*, Vol. 26 (1928), p. 135 *et seq.*

[76] "Physical Properties of Earths," by John H. Griffith, *Bulletin 101*, Iowa Eng. Experiment Station, Ames, Iowa, 1931.

In 1930 the writer proposed a field-stake method for determining shearing resistance of loamy soil. The method consists of driving a rigid metallic stake into the soil and pulling it with an automobile. In the beginning of the experiment the stake turns about a zero point, *Z* (Fig. 29). Cracks are then formed within a circle on the ground; and, finally, a conic body is pushed out. Let $S =$ reading on the scale (Fig. 29); $a =$ moment arm of the force, *S,* with respect to the point, *B,* which is the center of rotation of the stake when the cone is being pushed out; $r =$ the radius of the upper base of the cone; $W =$ the weight of the cone; and $R =$ the vertical resultant of the shearing resistance along the surface of the cone. Then, the condition of limit equilibrium would be:

$$S\ a = (R + W)\ r \quad \text{......................} (18)$$

Simplified diagrams have been prepared, and a series of experiments have been performed in Connecticut. In more important cases the shearing resistance may be determined by applying an overturning moment to vertical piles or posts. The foregoing procedure does not represent an elaborate method, but rather discloses an idea requiring further study. Figs. 30 and 31 show a laboratory box filled with moist Ottawa sand, with charcoal used to indicate cracks. A stake turns about a horizontal axis and produces tree-shaped and circular cracks on the surface of the soil. The circle is quite perfect (see Fig. 31).

Foundations.—The question of foundations has been thoroughly investigated by Professor Terzaghi.[78] The statics of foundations should not be studied further in the laboratory unless a completely new line of research is evolved. A great number of experimental data are available, and a large percentage of these data are known not only to investigators, but to practical engineers as well. For instance, transmission of pressure through soils has been the subject of many investigations since 1879, and a more or less complete bibliography thereof may be found in a German publication.[79] Its authors, Professor Koegler and Dr. Scheidig, conducted comprehensive experiments and made attempts to develop a theory of pressure distribution. In some directions their results are similar to those obtained[80] by A. T. Gold-

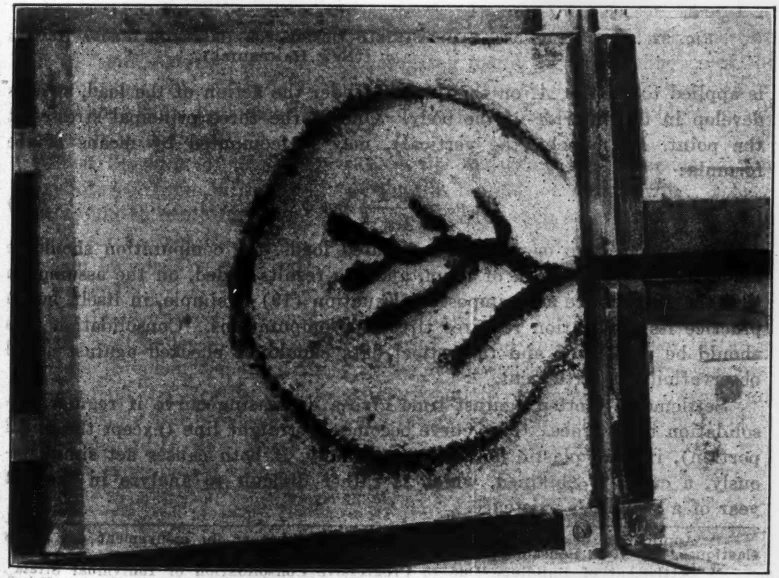

FIG. 31.—PLAN VIEW IN WHICH CHARCOAL INDICATES HOW NEARLY A TRUE CIRCLE IS FORMED.

beck, M. Am. Soc. C. E. The "pressure bulbs" have also attracted the attention of engineers.

For this reason, possibly, no research work along these lines has been conducted in the laboratories of the Massachusetts Institute of Technology. A comprehensive theory of pressure distribution is still lacking, however; possibly it will be elaborated in connection with observations on a larger scale.

A few years ago, the idea arose of applying the Boussinesq formulas to foundation problems. These formulas, derived by applying the theory of potential function,[81] have long been known to civil engineers; for instance, Professor S. Timoshenko discussed them before 1918. In 1928 the idea was formulated by Professor Koegler and Dr. Scheidig[79], and, in 1929, fully developed by Professor Terzaghi.[82] An endlessly wide and elastic body is assumed to be bounded by a horizontal plane above it (Fig. 32). A vertical load, *P*, is applied to a point *A*, on this plane. Under the action of the load, stresses develop in the interior of the body. One of the three principal stresses at the point, *B* (namely, the vertical), may be computed by means of the formula:

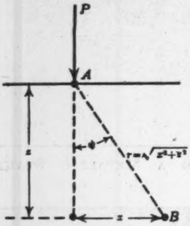

FIG. 32.

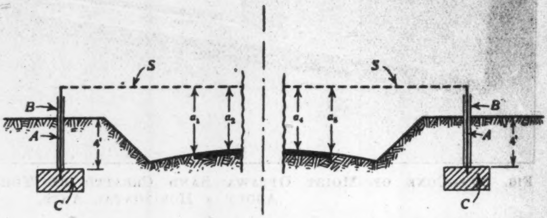

FIG. 33.—SAMPLE FIELD DEVICE FOR OBSERVING FROST HEAVING (NEW HAMPSHIRE).

$$p_z = \frac{3\,P}{2\,\pi\,z^2}\cos^5\psi \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (19)$$

If there are two or more concentrated loads, the computation should be made separately for each of them, and the results added, on the assumption that the stresses are superimposed. Equation (19) is simple, in itself, but in practice its application requires tiresome computations. Consolidation tests should be performed and theoretical data should be checked against actual observations of settlement.

Settlements plotted against time give a decreasing curve if regular consolidation takes place. This curve becomes a straight line (except the initial portion), if pure plastic flow exists. Finally, if both causes act simultaneously, a curve is obtained, which is rather difficult to analyze in the first year of a building's existence.

[81] "Application des potentiels à l'étude de l'equilibre et du mouvement des solides élastiques," by V. J. Boussinesq, Paris, 1885, p. 104 *et seq.*

[82] "Settlement of Buildings Due to Progressive Consolidation of Individual Strata", by Charles Terzaghi, M. Am. Soc. C. E., *Journal of Mathematics and Physics*, Vol. 8, No. 4 (1929), p. 266 *et seq.*

In this connection the necessity of obtaining good statistical material on settlements (as Professor Gilboy observes under the heading, "Foundations"), should be emphasized. At present, many superintendents and contractors consider even the possibility of settlement of their building as shameful; it should be borne in mind, however, that, as a rule, any building settles. The data on settlement should be surveyed and represented uniformly throughout the country. It would be better obviously, if the study of such settlements could be started on an international scale. Professor Terzaghi has collected numerous data along these lines in Europe, and the possibility of such an international study in close connection with him, deserves further consideration.

The subject of pile foundations has been well studied; especially valuable information has been presented[78] by Professor Terzaghi.[83] However, there is a branch of pile technique, somewhat different from foundations proper, that has scarcely been touched by research workers, namely, the stability of isolated piles and sheet-piles under the action of horizontal forces. Engineers require rules concerning the design of such features, but no adequate theory exists.

Hydraulic-Fill Dams.—It is rather difficult to discuss this important question so briefly outlined by the author in one and one-half pages of text. The research work described is more than interesting.

The writer believes that the path of hydrodynamical phenomena in the core should depend on the physical properties of the material of the shell; and this fact should be taken into account. In other words, the theoretical consolidation diagram (Fig. 12), which possibly has been traced for a certain homogeneous material, should vary according to the physical influence of the surrounding shell. This is because the shell forms a peculiar medium in which those hydrodynamical processes develop. If so, a new problem in soil physics is introduced.

Frost Heaving of Highways.—Generally speaking, the influence of low temperatures is not an important problem in foundation engineering. Exception should be made for permanently frozen soils, such as are met in Siberia and in some other localities. A vast literature on the subject exists in the Russian language; a short account in English may be found in a paper by the writer.[84]

The frost-heaving phenomena on highways have been thoroughly studied and are well understood by American scholars and engineers. For instance, Professor Stephen Taber, of the University of South Carolina, was the first to formulate the idea that the continuous supply of water from lower layers is responsible for heavings. The old theory assumed that frost heaving is due to change in the volume of water frozen in the voids; this theory was based on experiments with closed systems[85] In applied research the work of the late Mr. V. R. Burton and of Mr. A. C. Benkelman should be mentioned.[86] Progressive research in Michigan tends to introduce some corrections in the foregoing theories. Tests have disclosed some soil textures that are known to be productive of the majority of severe frost disturbances in Michigan and in other States in the frost area.

A simple field device used in the central part of New Hampshire for observing frost heaving, is shown in Fig. 33. In this diagram, *A* is a metallic pipe, $\frac{7}{8}$ in. in diameter, embedded in a concrete block, *C*. There is also an outer pipe, *B*, 2 in. in diameter. The space between the two pipes is filled with grease. The block, *C*, is located 4 ft. below the earth's surface and is thus protected from the action of the frost, since frost penetration is known to be less than 4 ft. The purpose of the outer pipe, *B*, is to insure the inner pipe, *A*, from any disturbance which may be caused by the frozen soil. A similar device is constructed on the other side of the road, and a horizontal string, *S*, may be drawn between them during the observation. The level of the string, *S*, is constant and may be considered as the datum plane. Vertical distances, a_1, a_2, a_3, etc., are recorded at predetermined points on the string every ten days during the winter. Thus, the rate of heaving may be determined. These experiments were begun under the supervision of Mr. Casagrande.

Retaining Walls.—Only a few years ago the theory of retaining walls constituted practically all the science now known as "soil mechanics."[87] Those who are attracted by the modern theory of a perfect fluid as acting on a retaining wall would possibly find new material for reflection in the descriptions of the tests cited by Professor Gilboy.[88] These tests demonstrate that, besides being characteristic of a given soil, internal friction is also indicative of its state of compactness, and that this varies within a wide range in the same structure.

Soil Mechanics Research Abroad.—As a rule, good scientific results may be reached when investigators are familiar with results obtained by others. Neither the branches of soil mechanics research in the United States, nor the names of American investigators have been specified completely in the preceding discussion. America is especially famous for its road and highway soil research. If, however, this country is far ahead of others in road soil research, its laboratories in some other branches are not as well equipped as some in Europe.

In the understanding of the writer, foreign countries in which soil mechanics research is being conducted may be divided into two categories: (*a*) Those with highly developed research, such as Germany, Austria, and Sweden; and (*b*) those with less developed research, such as England and its Dominions, Russia, Poland, Holland, Hungary, Japan, and others. France has given to the world many original theories of "classical" soil mechanics but is not participating in modern soil research as based on soil physics.

[88] *Engineering*, May 30 and June 13, 1930.

Great Britain is especially noted for excellent research work on the physical properties of soil, including soil dynamics, carried on in the Rothamsted Agricultural Experiment Station.[45] Isolated papers from other English-speaking countries appear from time to time in the technical press. Russia has followed principally the American path of research; but has developed several interesting ideas of its own. The influence of the highly developed and unique Russian agricultural soil science was evident in the initial soil mechanics research in that country. Roads and highways form the principal province of activity for the Russian investigators, who would carry their work much further with better laboratories. Poland has also conducted its research along road lines. Holland works very actively in the field of engineering geology, which is closely allied to soil mechanics, and in soil mechanics itself, as may be seen from Dutch technical publications. Hungary has such an efficient investigator as Professor Janicsek. Japan has studied earthquake problems as applied to civil engineering, and some research on soil mechanics proper has been done as, for instance, the study of shearing resistance.[89] A special Geotechnical Committee has been organized in Japan. Some soil research work seems to have been done in South America, in the Argentine Republic, in connection with the problem of dirt roads.[90]

As far as the writer knows, some of the well-equipped laboratories in Austria, Germany, and Sweden are: (*a*) Technische Hochschule, Vienna, Austria; (*b*) Preussische Versuchsanstalt für Wasserbau und Schiffsbau, Berlin, Germany; (*c*) Deutsche Gesellschaft für Bodenbaumechanik, Berlin, Germany; (*d*) Foundations and Hydraulics Institute, Hanover, Germany; and, (*e*) in Sweden, at the Technical University of Stockholm, and the Swedish Bureau of Public Roads.

In establishing the Laboratory of Soil Mechanics at the Technische Hochschule, in Vienna, Professor Terzaghi perfected the actual research equipment and developed new methods. The Austrian Government made a considerable appropriation for its installation.

At the "Preussische Versuchsanstalt für Wasserbau und Schiffsbau," in Berlin, special emphasis has been laid on soil mechanics research in the Department of Foundation Engineering.

The laboratory of the German Society for the Development of Soil Mechanics ("Deutsche Gesellschaft für Bodenbaumechanik") was formed by governmental engineers, with headquarters at the Technische Hochschule, in Charlottenburg, Berlin. Its principal aim is the study of emergencies in connection with earth structures (water-works failure, landslides, embankment failures, etc.).

The Soil Mechanics Laboratory of the Foundations and Hydraulics Institute, in Hanover, has a separate new building provided with good equipment; for example, a huge retaining wall is a part of it. The dimensions of the wall are about the same as those of the apparatus in the Massachusetts Institute of Technology, as described by Professor Gilboy.

Among the Swedish establishments there are two small separate laboratories of soil mechanics at the Technical University of Stockholm, and a small laboratory of the Goetechnical Commission of the Swedish Railroads. The soils laboratory of the Swedish Bureau of Public Roads ("Svenska Väginstitutet"), maintains an active contact with geologists, and there are members of the Swedish Geological Survey who have specialized in the problems of both soil physics and road engineering, approaching the latter, of course, from the geological point of view.[91]

J. STUART CRANDALL,[92] M. AM. SOC. C. E. (by letter).—This paper gives an excellent résumé of some of the progress made during the last few years in determining the nature and physical characteristics of soils. The importance to the engineer of these developments is apparent, because all structures must be supported by the soil through some type of foundation. The rate of settlement of these foundations over a period of years is important, and occasionally vital. Soil mechanics is a connecting link between geology and civil engineering. Further and more rapid advances may confidently be expected in the future. It must be admitted that, on the whole, the technique of foundation design has been rather empirical, with little actual rational basis. There is need for change. It is to be hoped that the profession may sincerely seek logically to apply the results of these studies to actual foundation design.

Most building codes are very definite as to the allowable load on different soils, but are rather vague as to the classification of these soils. The author might have pointed out the objectionableness of the present common practice of leaving to the foreman of a boring crew the identification of the type of soil under a foundation. He might have pointed out also the common lack of attention and care to preserve boring samples in the natural state. Frequently, soils are classified as "clay," when the material is actually silt. This occurred recently at Rochester, N. Y., where borings were taken at the site of the Charlotte Terminal at the mouth of the Genesee River. The boring foreman identified the underlying soil as "soft blue clay" and "medium soft gray clay." The proposed quay wall was of the L-type of reinforced concrete supported by wood piles, with a steel, sheet-pile bulkhead along the face, tied back by rods attached to a back-wall of steel piling. Analysis of the entire structure indicated a small factor of safety against rotation, on account of the low angle of internal friction and low shearing resistance of clay. Samples from the borings were then analyzed, which indicated that the material was not clay, but silt with a small admixture of clay. The coefficient of internal friction and shearing resistance of the silt being much higher than clay, there was no longer any question of stability. Such occurrences show the necessity for the adoption of a reliable and accurate method of classifying the type and condition of soils.

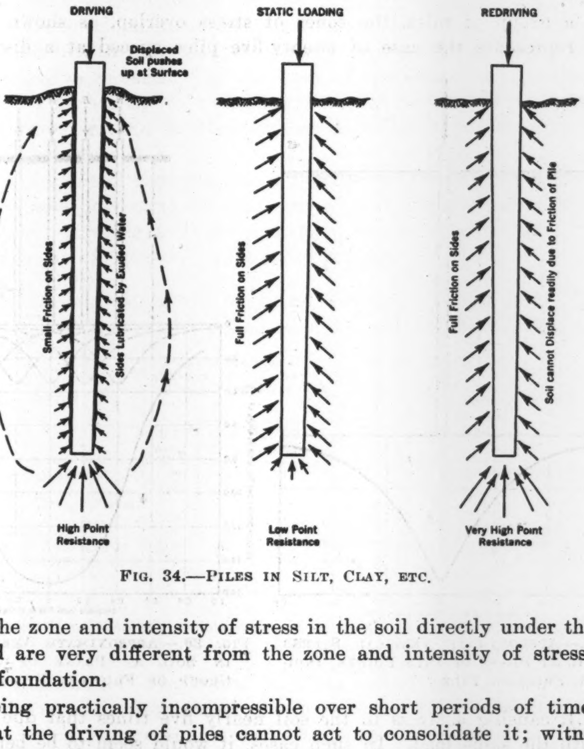
[92] Treas. and Engr., The Crandall Eng. Co., Cambridge, Mass.

Of great importance is the very evident fact that for cohesive, impervious soils, such as clay, the usual load-settlement tests required by various building codes are of little value, for within the usual short duration of such tests there is not sufficient time to determine the actual rate of settlement. Furthermore, the zone and intensity of stress in the soil directly under the small area loaded are very different from the zone and intensity of stress under the entire foundation.



DRIVING
Displaced Soil pushes up at Surface

STATIC LOADING
Full Friction on Sides
Low Point Resistance
REDRIVING
Full Friction on Sides
Soil cannot Displace readily due to Friction of Pile
Very High Point Resistance

FIG. 34.—PILES IN SILT, CLAY, ETC.

Clay being practically incompressible over short periods of time, it is evident that the driving of piles cannot act to consolidate it; witness the swelling of the surface when piles are driven in clay. This being the case, the very work of driving must disturb and knead the clay, and thus increase the rate of settlement. It is logical to assume, therefore, that the driving of piles into clay should be avoided, and that it is better practice in such soils to sink caissons or caisson piles so that there may be little disturbance and so that the foundation will bear on the material in its natural state.

Charles Terzaghi, M. Am. Soc. C. E., has demonstrated[93] that there is no known relationship between the dynamic resistance of piles driven in clay and the resistance to static load. In Fig. 34 is shown another way of illustrating the causes of this phenomenon.

This being true, the attempt to determine the bearing capacity of piles driven in clay by the use of some pile-driving formula has no logical or scientific basis and cannot give results of any value. Load tests of individual piles give no indication of the settlement of a group of piles with the same load per pile. The approximate distribution of the vertical component of stress in the soil at the plane of the point of a single pile is shown in Fig. 35.

For a group of piles, the zones of stress overlap, as shown in Fig. 36 (which represents the case of twenty-five piles spaced at a distance equal to 0.2L), causing a stress in the soil nearly five times that due to a single pile with the same load. In such cases, it would seem to be better practice to determine analytically the stress in the soil along the plane of the points, compare this with the bearing resistance of the soil, due allowance being made for probable settlement based on an analysis of the underlying material, and then, by trial and error, calculate the most economical length, spacing, and load per pile.

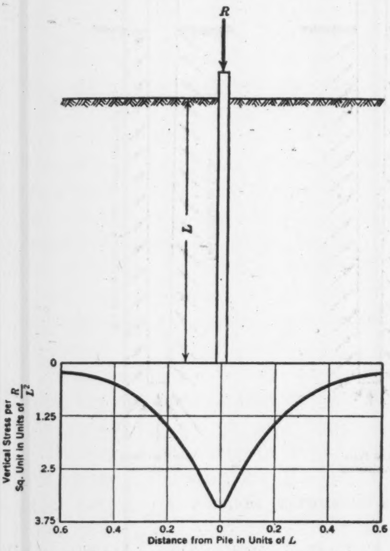

FIG. 35.—APPROXIMATE VERTICAL STRESS IN SOIL AT PLANE OF PILE POINTS, INDIVIDUAL FRICTION PILE.

---

[93] The Science of Foundations—Its Present and Future," *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 270.

Frank Alwyn Marston,[94] M. Am. Soc. C. E. (by letter)—Substantial progress was made during the five years, 1927 to 1932, in devising methods of determining the physical properties of soils. The practical application, however, of data concerning these physical properties to studies of the behavior of soil in engineering structures is somewhat less advanced. This paper is, therefore, a valuable contribution, because it gives in brief form a description of certain tests which have been found to be of distinct aid to judgment in passing on the suitability of soils for the building of dams and embankments and the solving of foundation problems.

The opportunities for research are great. Programs of scientific study such as are being carried on in various institutions of learning are most necessary for the development of methods of analyzing soils. Few laboratories outside of such institutions have the opportunity or the personnel that will permit of extensive research. To the work of the scientific laboratory must be added the opportunity to make practical application of the results of research by investigations in the field on full-sized structures, if tangible results are to be obtained.

Soil physics and soil engineering are destined to become of greater importance as time goes on because it will be more generally recognized that judgment aided by scientific soil analyses may be more dependable than the unaided judgment of even the experienced engineer.

§ Contained 64.8% of iron as Fe_2O_3.

Separation of the soil sample into fractions according to grain size is helpful, but if the analysis stops there, conclusions may be misleading. Table 1 gives data relating to several samples of soil in each of which nearly all the grains were less than 0.1 mm. in size, that is, of a size approximately, that would pass the 150-mesh sieve. On the basis of the sieve analysis, the samples are more or less comparable. The fine fractions, determined by sedimentation, vary widely. The china clay, containing 40% by weight of grains less than 0.002 mm. in size, has a low index of plasticity, whereas the fossiliferous earth with only 9% finer than 0.002 mm. has a plasticity index of 71.7. Generally, the larger the plasticity index the more plastic and slippery is the material. The index may be considered as a rough measure of the cohesion existing between the soil particles. A high index may indicate high compressibility and slow rate of consolidation. Non-plastic soils have an index of zero. It is evident from the examples given, that the percentage content of fine particles may not be a controlling factor in the relative behavior of soils from various sources. On the other hand, with a given soil, the proportion of fine particles may have a strong influence on the behavior of the composite sample.[95]

---

[94] Cons. Engr. (Metcalf & Eddy), Boston, Mass.

The mechanical analysis is useful, but should be supplemented by tests in order to determine other characteristics of the soil, as pointed out by Professor Gilboy.

After some studies of the results of analyses by the Wiegner and Bouyoucos sedimentation methods, the writer is of the opinion that the Bouyoucos method is the more convenient, and when conducted according to the procedure developed by the U. S. Bureau of Public Roads, is more likely to give reliable results.

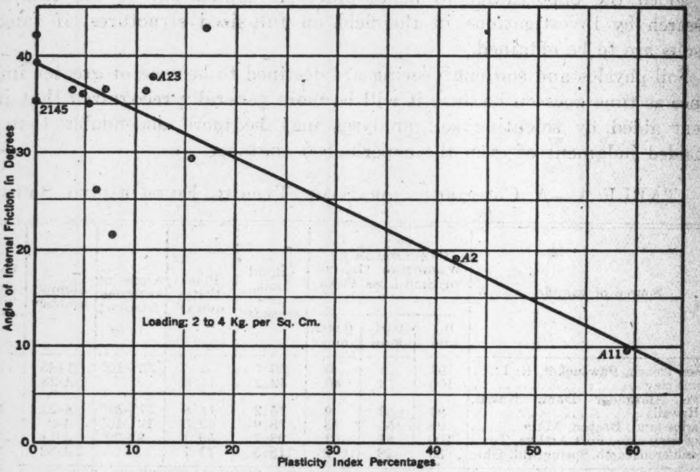

FIG 37.—TYPICAL RELATION BETWEEN ANGLE OF INTERNAL FRICTION AND PLASTICITY INDEX.

The Atterberg limits of consistency—liquid and plastic limits—are easily determined, and they furnish a valuable index to the plasticity of the soil. The liquid limit device has been used for some time and has been found to be superior to the hand method because more consistent results can be obtained and there is less variation due to the personal equation.

The interrelation of soil characteristics is such that it is difficult to select two characteristics and show that one is a function of the other. With a

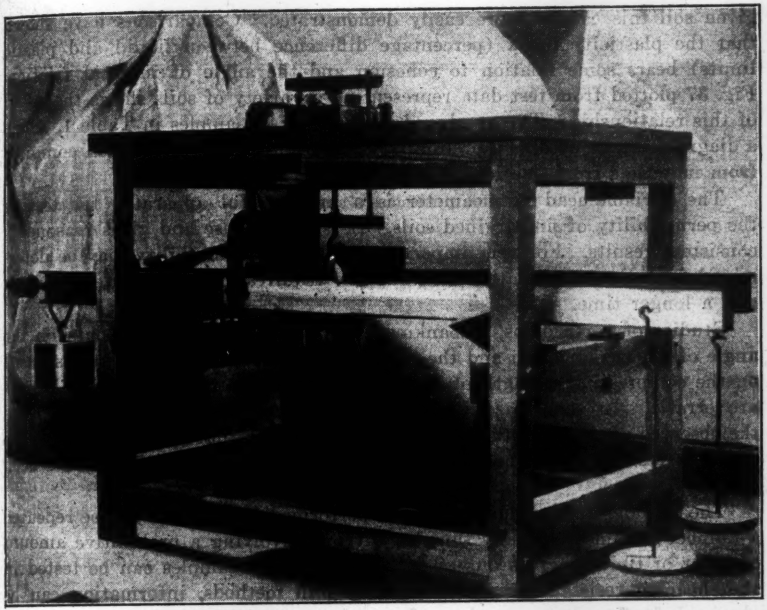

FIG. 38.—VIEW OF SHEARING MACHINE.

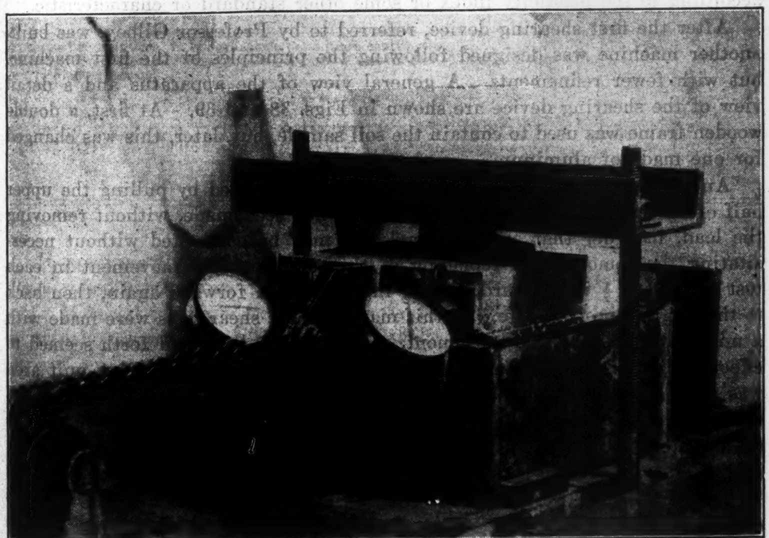

FIG. 39.—VIEW OF SHEARING UNIT.

given soil this can be more easily demonstrated. Comparisons have shown that the plasticity index (percentage difference between liquid and plastic limits) bears some relation to cohesion and the angle of internal friction. Fig. 37 plotted from test data representing a variety of soils shows the trend of this relationship. The numbered points refer to samples in Table 1. Such a diagram can be used as a preliminary rough guide especially when compiled from materials from one locality.

The variable-head permeameter is a most useful apparatus for testing the permeability of fine-grained soils. It is easy to use and gives reasonably consistent results. For very impervious soils, the permeability may be determined from the consolidation test, but this requires more elaborate apparatus and a longer time.

Studies of earth dams, embankments, and earth cuts require data on the angle of internal friction and the cohesion of the soil. Determinations based on the compressive strength of clay cylinders are interesting, but the results are erratic. In some cases the angle of internal friction computed from the observed angle of rupture agrees fairly well with that determined from the shearing resistance test and, in other cases, considerable variation has been found.

The cylinder rupture method can be performed quickly and can be repeated a number of times on many samples without involving a prohibitive amount of labor or time, whereas only a few representative samples can be tested in the shearing resistance machine. Using both methods, information can be obtained from a large number of samples, especially if they are grouped according to the plasticity index or some other standard or characteristic.

After the first shearing device, referred to by Professor Gilboy, was built, another machine was designed following the principles of the first machine, but with fewer refinements. A general view of the apparatus and a detail view of the shearing device are shown in Figs. 38 and 39. At first, a double wooden frame was used to contain the soil sample, but, later, this was changed for one made of aluminum.

An interesting series of experiments have been tried by pulling the upper half of the frame back, after one shear test has been made, without removing the load, in order that an additional test may be conducted without necessitating the removal and replacing of the sample. The movement in each test was about $\frac{1}{2}$ in. forward, then $\frac{1}{2}$ in. back, then forward again, then back to the original position, etc. In this manner three shear tests were made with a minimum of horizontal movement. The moving back and forth seemed to effect a slight consolidation of the material, because the shear per unit area was generally higher on the second and third tests than on the first, but not always so. Table 2 is typical of the results of such a procedure. The data are of interest as showing the prompt re-adjustment of the soil particles after a slip.

It is important that sufficient time be allowed after loading the soil for consolidation to take place. With a cohesive soil the time required may be from one to two days. After that, the change is comparatively small. What

happens over a period of months or years under constant load is not known, but it seems probable that some further consolidation or increase in cohesion takes place, resulting in increased shearing resistance. Table 3 shows the results of a shearing resistance test covering 26 days. There was very little change in resistance after 42 hours, and these differences may be within the limits of error of the test.

* Sample saturated with water during test.

In applying the methods described by Professor Gilboy to studies of soils for a rolled earth dam, it is not so necessary to use samples of undisturbed soil. Material in the borrow-pit is excavated and then deposited in the dam in thin layers which are thoroughly rolled. Much the same process can be carried out on a small scale in the laboratory. Undisturbed samples should be taken from the dam from time to time to check the degree of consolidation, moisture content, etc.

A helpful basis of study can be had by comparing the void-ratio of undisturbed samples of the embankment with the void-ratio of laboratory compacted samples. In general, the field-compacted samples are likely to have a little larger void-ratio than samples thoroughly rammed, kneaded into compact form, and similarly loaded in the laboratory.

GEORGE PAASWELL,[96] M. AM. SOC. C. E. (by letter).—This paper gives a sober account of the work done under the direction of Professor Gilboy, and it is primarily educational.

There can no longer be any doubt that the rule-of-thumb era in foundation work has passed. Foundation failures can no longer be ascribed to the perverse workings of a balky Nature. The proper design of a foundation is not simply a surface study of the loaded area. Bearing in mind that the loaded surface of the soil creates a certain stress distribution through a depth, comparable in extent with the area of surface loaded, it can easily be seen that an extensive soil exploration is required before a proper anticipation may be made of the distortion of the soil under load. Surface tests form merely one link, then, in a complete study of the foundation.

The vast amount of sub-surface construction in large cities has created a field for an extensive study of foundation problems. Not only must the foundation selected be of such character as to sustain safely the load to be placed upon it, but also the method of constructing this foundation must be such as not to endanger existing neighboring foundations. This has required a type of research that finds its conclusions from the applications of soil mechanics as given in the paper.

The writer was privileged to collaborate with both Professors Terzaghi and Gilboy on an extensive series of experiments in connection with the construction of the Houston Street Subway in New York City, mentioned by the author. On this work the sand extended in a deep layer down to rock which varied from 60 ft. to more than 100 ft. below the ground surface. The sand varied in texture from extremely coarse to extremely fine, distributed in irregular layers in so far as its texture was concerned. Its density bore no relation to the depth at which the density was ascertained so that the rule-of-thumb generally applied, which gives the bearing capacity as increasing with the depth, was entirely in error. The angle of internal friction as found by experiments on small samples of the sand was fairly constant, a fact which the writer believes has been justified by some later experiments conducted by Professor Gilboy, which show only small variations in the angle of internal friction in varying densities of sand. It was also found that for the small loads applied (none exceeded 5 tons per sq. ft.) the settlement was not a function of the area loaded.

This is an important conclusion, although it is one that has been frequently checked by experiment in sands, and it must be emphasized that it probably applies only to moderate loads. For very heavy loads, such as are carried by pile clusters with concentrated point loads, experiments seem to show that the settlement is a function of the area loaded. The writer hopes that this important topic will be a subject of future study and experiment, since it has been found that in clays the settlement is intimately related to the shape and area of the surface loaded.

The effect of surcharge was studied carefully in these experiments, and the settlement was noticeably decreased by the presence of a surcharge of sand around the loaded area; that is, the surface loading settles more rapidly under a given load than under the same load applied on the same area at a distance below the surface of the ground. When the load is applied at a depth below the surface equal approximately to the maximum diameter of the loaded area, the maximum effect of surcharge is obtained. This fact should be carefully noted in connection with the underpinning of buildings adjacent to a future excavation. The piers sustaining the existing building should be carried to a depth equal at least to the thickness of the pier below the depth of the future excavation.

[96] Engr., Corson Constr. Corporation, Brooklyn, N. Y.

The sum total result of the experiments gave quite a comprehensive picture of the behavior of sand of this character within the range of loads to be placed upon it, and was sufficiently substantiated by other observations and by the later behavior of the finished structure to vindicate the time and money spent on these experiments and to give striking proof that soil mechanics was able to answer decisively the questions of practical and immediate importance.

The design of a system of sheeting and bracing of unique character was governed primarily by the observations taken on the retaining-wall experiments quoted by the author. The various phases of movement in a retained bank of sand behind a yielding support (such as sheeting), were checked by observations during the construction of the subway. In some cases, the deflections of the sheeting were quite considerable, but no fracture occurred, showing the diminution in pressure as the retaining wall moved away from the applied load. It need hardly be mentioned here that a system of sheeting and bracing to sustain safely a deep bank of sand must be most carefully designed if the results of the quoted experiments are to be applied in a safe manner. Vast economies in subway construction have resulted to the City of New York because of the successful application of this type of sheeting and bracing, and it would not be "far fetched" to trace back this vast saving of money to the city to the series of experiments, starting in Constantinople, Turkey, and ending in Boston, Mass., as conducted in that brilliant series of studies made by Professor Terzaghi.

JOHN H. GRIFFITH,[97] M. AM. SOC. C. E. (by letter).—In regard to the question of stress distribution, Professor Gilboy states (see "Foundations"):

> "* * * while the classical theory of Boussinesq is the best available, it can yield only approximate results. The analysis of the stress-strain characteristics of soils thus far performed includes only the simplest cases. Most important of all, some assumption as to homogeneity of the underground must be made, and this is only approximately fulfilled, even under the most favorable circumstances."

Following this is the apparently contradictory statement that such analyses yield valuable information. He cites as proof the instance of a highly heterogeneous matter consisting of piles overlying an area of mud 120 ft. below the surface, and comments, as follows: "The results agreed remarkably well with the observed values, showing that such studies are of considerable practical importance, * * *."

---

[97] Prof. of Experimental Eng., Iowa State Coll., Ames, Iowa.

To understand the disparities of opinions which have originated with respect to earth analyses, or to use Professor Gilboy's term, "soils," it is well to consider that the theory of earth resistance has developed two schools; those who, like Professor Gilboy, take the physicist's, or molecular, point of view involving grain parameters, shapes of particles, true and apparent cohesions, intrinsic stresses, and structures of atoms; and those who adhere to the viewpoints of mathematicians, that such conceptions have no place in the systematic working formulations of science. It is important to consider the facts in this case.

Strictly speaking there are no systematic atomic or molecular theories formulated as such. They are unmanageable in science and much more so in applied physics, such as engineering and geology. A true molecular analysis is a problem in *n* body dynamics, with *n* very large, and involves a complex theory of numbers or a calculus of finite differences which the proponents of such methods do not seem to have at their command.

On the contrary the systematic theories of science involve molar matters the properties of which are defined by continuous functions except for discontinuities at particular points and boundaries. One may consider as examples among others the theories of electro-magnetism, thermodynamics, elasticity, hydrodynamics, meteorology, seismology, and relativity. They are fundamentally field theories. The field is the measurable entity, the only thing that can be measured. If an oscillator vibrates in mercury it immediately diffuses its effect into waves as in the case of a tuning fork. The tuning fork is a singularity or peculiarity of the wave field, the point or region where the lines of force converge, and the function may increase without limit.

Having the equation defining the field it is necessary to find the peculiarities the function may assume in limiting cases and at points and special boundaries.[98] In seismology the engineer seeks for the focus of disturbance, in electro-magnetism for the pole or electrode, in acoustics for the source, and their functional aspects, together with the types of existence theorems. The same type of problem arises in all branches of dynamics, for the different modes of energy.

The potential theory formulated for matter by George Green,[99] while strictly a molar theory, is really applicable to molecular systems composed of an immense number of mutually re-acting particles, as stated by its author, and without the necessity of multitudinous borings, and chemical and colloidal analyses, as the writer will proceed to show.

Several investigators have made tests[100] showing that the vertical distribution of pressure under a load appears to be in agreement with the mathematical distributions formulated by Boussinesq[101] and Michel.[102] The writer has suggested the availability of Boussinesq's formula,

treating the coefficient as an empirical constant in the usual manner illustrated in hydraulic formulas for orifices, which is entirely independent of physical constants, involving only the load, *P,* and the location of stress at the point distant *r* from *P.*

Anson Marston,[103] Past-President, Am. Soc. C. E., applied Boussinesq's theory to the problem of bridge rollers in 1894, and supplemented this by researches on large wheels in later years. In the Progress Report on Culvert Pipe Investigations covering 1915 to 1921, submitted to the U. S. Bureau of Public Roads and the various State Highway Departments, he showed by tests that Boussinesq's formula for a concentration (Equation (20)) applies to all levels of fill to within 2 ft. of the load "source" where the full concentration applies; the analytic function becomes infinite with the radius vector measured from the load reducing to zero. A little later, Messrs. Spangler, Mason, and Winfrey[104] demonstrated that the formula gave the upper limit of load and generally showed a close parallelism with Boussinesq's law. In 1920, at a lecture before a group of railroad officials, Dean Marston stated that the lines of force crowd into the culvert or pipe tending to break it, the weight sustained being more than the vertical surcharge over the extrados.

In the most recent researches of Dean Marston[105] the theory of potential based on molar matter analyses, where the integrations have been carried out for "concentrated super-loads" taken over the "conduit top horizontal plane projection," show excellent correlations according to a recent communication to the writer by Professor Robley Winfrey, of the Iowa Experiment Station. He has made a detailed study of the problem by comparing the results of summing Boussinesq's simpler formula under a concentration with the results obtained by integration and by dividing the stressed area into relatively small squares. The recent researches not only show that the potential formulas give the upper limits of the distributions, but actually apply when the load has close proximity with the extrados. As in the case of the simpler formula the results are independent of the moduli of the material applying to either gravel, sand, or clay, as long as the lattice structure of the medium is not too much deformed as would be the case in straining an ordinary bridge truss. If it experienced finite deflections, the panel shapes would change involving a suitable correction.

Researches of the kind mentioned are valuable epistemologically in showing inductively the sufficiency of the potential algorithm, as a complete physical method. One instance only will suffice to show the possibilities in the distribution of forces by railroad tracks.

The researches of Harold Medway Martin[106] show that the distribution over the track from the train load is a "witch-shaped" curve of the type originally deduced by Agnesi. Suppose a culvert is under the track, the stress may be obtained as given by the general formula (Equation (20)), with a load equal in amount to the ordinate of the track distribution of Martin, and summed or integrated for continuous distributions. In the case of the attractions of body upon body according to the Newtonian potential theory[107] the general potential of mass, m', with respect to the mass, m, is:

$$V = \int\int\int\int\int\int \frac{\rho\,\rho'\,dm\;dm'}{r} \quad \ldots\ldots\ldots\ldots(21)$$

in which, r is the distance between the mass elements of the bodies. Where there is an intervening medium, such as the earth matrix, it is necessary to introduce the direct and logarithmic potentials of Boussinesq in the manner shown in a previous paper.[108] In general, it is not possible to dispense with the elastic constants. This is the case in the instance of a retaining wall and for other elastic or semi-elastic distribution in which lateral pressures occur. The potential distributions hold very closely in the case of impact.[109]

The retaining wall problem is one of the oldest historically and is most difficult to formulate. The author's apparatus, designed with meticulous care, will doubtless throw new light on the problem. A solution by molecular dynamics will be of the greatest interest to the profession. In addition to his rational solution for the weir problem of hydraulics,[110] Boussinesq's theory of the retaining wall is perhaps the most important of his purely engineering analyses. He devotes more than 170 pages of his treatise on the subject[111] to this important case treating a molecular problem throughout by a strictly molar theory. He shows that it is a more general case than the theory of elasticity, and he arranges his parameters so that as a limiting aspect the theory reduces to the elastic case as a limit.[112]

The hangers, V_1 and V_2, of the retaining wall apparatus (Fig. 13) will balance Boussinesq's wall friction which he takes into account, except for infinitely smooth walls. It will be impossible to measure the maximum overturning moment because this is exerted when no energy has been expended in frictions and small displacements, and the author's apparatus will give some indeterminate equilibria and settlings in manipulations of the "wall" part as a result of the movements. The three-faced holder for the earth will act as a clamp on the specimen; under the wall friction there will be considerable restraint, making it impossible for the "retaining wall" to experience the maximum thrust. It was suggested to the writer by Dr. O. H. Basquin, of Northwestern University, that dental rubber placed on a wall would eliminate the friction since this material is nearly incompressible and has only a small modulus of rigidity. His theoretical reasons are sound, but the writer has never tried the material in this manner. It may eliminate the frictions of the side walls in the present case.

[112] *Loc. cit.*, p. 61.

In conclusion, the writer does not wish to be construed as asserting that atomic, molecular, colloidal, and crystalline researches are not valuable in themselves. On the contrary, they are of the highest scientific importance in developing correct philosophies of the nature of energy, ether, matter, and atomic and crystalline structures. The point emphasized in the discussion is that the systematic working theories of science are not molecular; they are and always have been essentially molar theories involving apparent continuous entities and transmission coefficients, and not discrete entities and grain parameters, except in isolated instances ultimately to be displaced as a wave theory displaces a discrete theory.

H. E. GRUNER,[113] M. AM. SOC. C. E. (by letter).—The interesting information contained in Professor Gilboy's paper prompts the writer to contribute a description of certain simplified methods of conducting similar experiments, so designed that the most important properties of soil can be measured right at the construction site.

After the general line of attack had been established by the pioneer work of Terzaghi and Krey, and testing apparatus had been developed at the Staatliche Versuchsanstalt für Wasserbau und Schiffbau, in Berlin, the writer undertook the construction of simplified devices for testing the soil used in the construction of the dam for the Albbruck-Dogern Power Station on the Rhine. The purpose of this research was twofold: First, to determine those soil constants required for calculations of the stability of the dam; and, second, to obtain continuous data on the properties of the material during the construction process.

On account of the wide variations in the properties of soils, it is necessary to have a definite basis for the selection of material suitable to a given purpose, and for the rejection of unsuitable material, such as soil containing a large proportion of colloids. It is the writer's opinion, therefore, that in the case of water-power projects involving large dams and canals a continuous series of soil tests is just as important as the continuous control tests customarily performed on cement and concrete.

Apparatus and Procedure.—A general view of the testing layout is shown in Fig. 41. Fig. 42 is a demonstration of the shear test, described subsequently. The devices are not intended to be as accurate as those used in research laboratories. They are well adapted, however, to the purpose for which they were designed, namely, to the rapid testing of a large number of samples, with a degree of accuracy sufficient for the analysis of dam construction materials. These instruments undoubtedly can be improved; in fact, the experiments to date have indicated the advisability of certain changes. The present description is intended merely to suggest one method of attacking the problem.

The tests thus far undertaken may be divided into five groups:

(1) Measurements of specific gravity, unit weight, and percentage of voids;

---

[113] Cons. Engr., Basel, Switzerland.

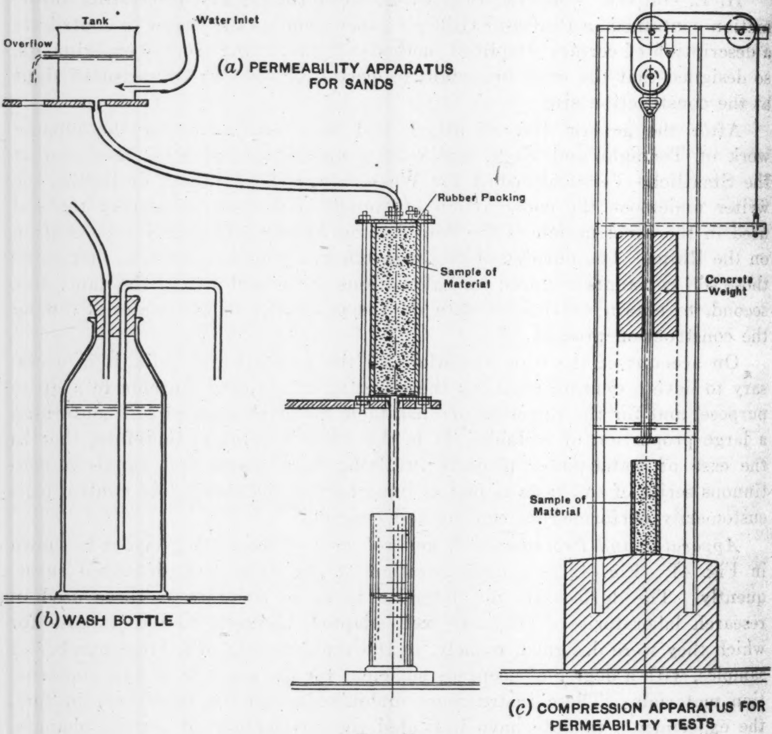
(2) Mechanical analyses, with the object of classifying the soil with regard to fineness;

(3) Permeability tests, to obtain data with which to determine the position of the line of saturation and the velocity of the seepage water;

(4) Measurements of shearing resistance, to determine those constants required in an analysis of the stability of the slopes; and,

(5) Tests of the compressibility, the variations in water content, and the lateral pressure of fine-grained materials.

The information in Group (5) is required for studies on the settlement of the dam, on the loss of water associated with consolidation, and on the possibility of compacting the earth by means of pressure.



(*a*) PERMEABILITY APPARATUS FOR SANDS

(*b*) WASH BOTTLE

(*c*) COMPRESSION APPARATUS FOR PERMEABILITY TESTS

FIG. 40.

Group (1).—These quantities enter into the determination of loading conditions in the dam. The specific gravity is determined by Schumann's volumenometer. The unit weight is obtained by the use of gauged capacity meters, different methods of filling being compared. In order to determine the change in unit weight produced by compression, the results of the consolidation test described under Group (5) are utilized.

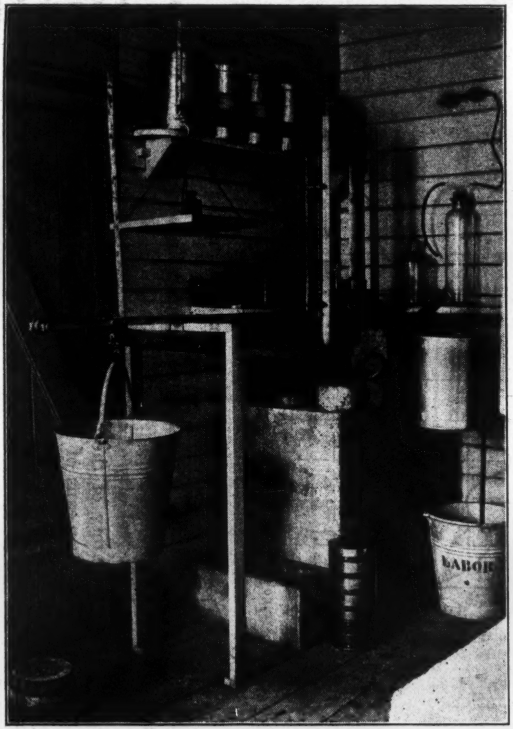


FIG. 41.—ARRANGEMENT OF APPARATUS.

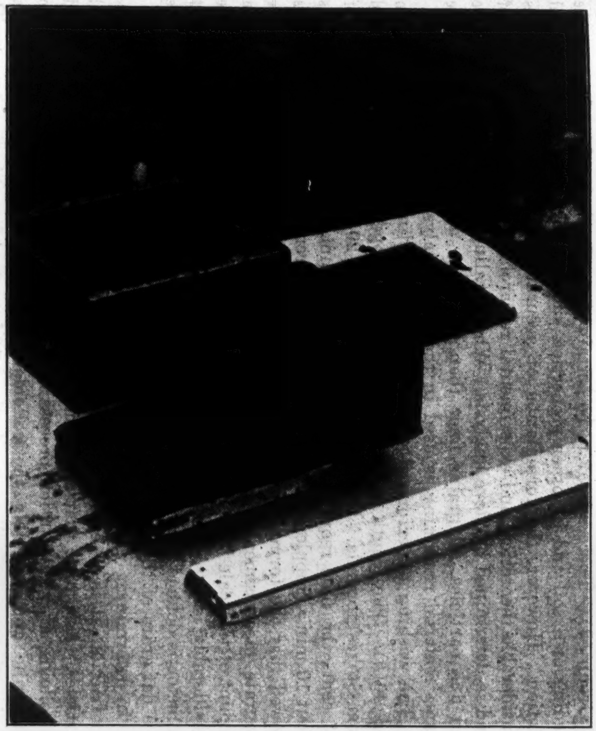

FIG. 42.—SAMPLE AFTER SHEAR TEST.

Group (2).—There appear to be certain general relationships between the grading of a soil and its other properties, such as permeability and internal friction. However, the formulation of accurate relationships still requires considerable theoretical and experimental research. The grain distribution of sand is determined by sieve analysis. When dealing with mixtures of coarse and fine particles, all grains finer than 0.02 mm. are washed out, and the coarse material remaining is used in the sieve analysis.

The washing is performed with the aid of a cylindrical bottle, shown in Fig. 40(*b*). The length of time required for the operation can be computed from Stokes' formula. Using a depth of water of 20 cm. at a temperature of 15° cent., the time required for a particle, 0.02 mm. in diameter, to settle is about 10 min. Supplementary microscopic measurement of the largest grains showed that the formula gives very satisfactory results. However, the more accurate measurements made by Atterberg and Terzaghi showed that on account of the scale-like character of the particles the actual grain diameters are considerably larger, possibly twice the equivalent diameters. The equivalent diameter is defined as the diameter of a sphere which settles at the same rate as a flat grain of the same specific gravity.[114]

In determining the shearing resistance as a measure of the angle of internal friction, it is of especial importance to know the percentage of colloidal particles. Assuming that all particles smaller than 0.002 mm. may be classed as colloids, a sedimentation process similar to the foregoing may be used to determine approximately the colloidal content. The settling time for a particle, 0.002 mm. in diameter, is about 16 hours. After this time has elapsed, the percentage of colloids is determined by optical measurements of the transparency of the turbid water.

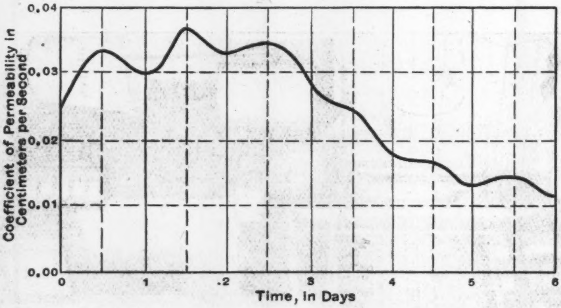

FIG. 43.—VARIATION OF PERMEABILITY WITH TIME.

Group (3).—The velocity of the seepage water is of particular importance in analyzing the safety of the dam against washouts. The permeability of sand is measured by means of a cylinder, obtained from the Versuchsanstalt für Wasserbau und Schiffbau in Berlin, and illustrated in Fig. 40(*a*). To ensure that the voids in the sample will be free of air, water is allowed to flow slowly into the cylinder from the bottom during the filling process, keeping the water level always slightly above the level of the sand. Thus, the sample is always completely immersed, and at the same time the washing out of very fine particles is avoided.

---

[114] "Erdbaumechanik," by Charles Terzaghi, M. Am. Soc. C. E., p. 40.

The influence of temperature on the coefficient of permeability may be determined from Justin's data.[115] In the test, measurements are first made on the value of the coefficient of permeability, k_0, which is defined as the apparent velocity of the water through the uncompressed soil under unit hydraulic gradient. Then, the sample is compressed under a pressure of 1 kg. per sq. cm. in the apparatus shown in Fig. 40(*c*), the change in volume is measured, and the permeability test is repeated on the compressed material, in order to determine the influence of the compression on the permeability.

The phenomenon of a partial sealing of the sample within itself during a period of continuous flow was investigated on several occasions. The permeability appeared to increase slightly during the first few days; but afterward it decreased rapidly and continuously, finally attaining a certain minimum value. A graph of this relation is shown in Fig. 43. In addition to the general tendency, it was observed that the permeability was subject to daily fluctuations of variable amplitude. The causes of these fluctuations could be studied only by performing accurate experiments in a scientific laboratory.

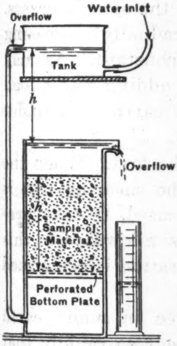

FIG. 44.—PROPOSED APPARATUS FOR MEASURING PERMEABILITY OF SAND-GRAVEL MIXTURES.

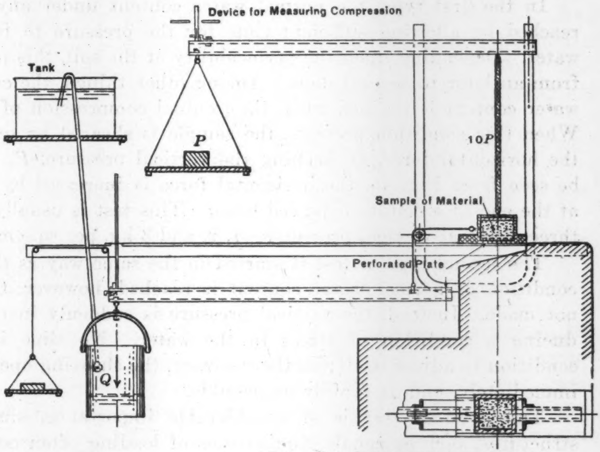

FIG. 45.—SHEARING APPARATUS.

In order to determine the permeability of sand-gravel mixtures, the sand fraction, consisting of all grains smaller than 7 mm. in diameter, was separated from the sample by sifting; this fraction was then subjected to permeability tests as outlined herein. By making certain theoretical assumptions it is possible to determine the permeability of the mixture from the permeability of the sand fraction and the proportion of sand to gravel, provided the latter is such that all the voids in the gravel are completely filled with sand. However, the assumptions that must be made are open to question. In order to eliminate them, and to arrive at a correct result without the necessity of determining the proportions of the constituents of the mixture, it seems preferable to obtain the permeability of the mixture by direct measurement in an apparatus such as that illustrated in Fig. 44. Parallel experiments on the mixture and on the sand fraction alone provide means for determining empirically the relations outlined herein.

---

[115] "The Design of Earth Dams," by Joel D. Justin, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 1.

Group (4).—The shearing resistance of fine-grained soils, as a measure of the angle of internal friction, is determined by means of the apparatus shown in Fig. 45. Fig. 42 shows the appearance of a sample after it has been tested to failure in shear.

Two different types of tests are made: (*a*) Normal tests, in which the water in the voids of the sample is under no excess pressure; and (*b*) rapid tests, in which the water carries part or all of the superimposed load.

In the first type, the normal water content under any given pressure is reached by allowing sufficient time for the pressure to force out all excess water. Depending upon the permeability of the soil, this process may require from an hour to several days. Among other things, the condition of normal water content is reached when the gradual compression of the sample ceases. When this condition prevails, the sample is sheared by gradually increasing the horizontal force, Q, keeping the vertical pressure, P, constant. As may be seen from Fig. 45, the horizontal force is increased by adding water load at the end of a counterbalanced beam. This test is usually carried out under three different vertical pressures—1, 2, and 3 kg. per sq. cm.

The second type of test is started in the same way as the first. When the condition of normal water content is reached, however, the shearing test is not made. Instead, the vertical pressure is suddenly increased, thereby producing a condition of stress in the water. No time is allowed for this condition to adjust itself; on the contrary, the shearing operation is performed immediately, and as rapidly as possible.

This type of test is of considerable importance, since in many earth structures, such as canals, fluctuations of loading often occur so rapidly that the stresses produced in the water within the voids of the soil have no time to adjust themselves. The results of rapid shear tests, therefore, serve as a basis for analyzing the most unfavorable loading conditions.

Comparisons between the friction angles determined from the two types of test offer interesting indications concerning the character of the soil. To provide a numerical basis for such comparisons, a coefficient, λ_2, is defined by the relation,

$$\lambda_2 = \frac{\tan \mu_{1+1}}{\tan \mu_2}$$

in which, μ_2 is the angle of internal friction determined from a normal test under a pressure of 2 kg. per sq. cm., and μ_{1+1} is the angle determined from a rapid test in which a pressure of 1 kg. per sq. cm. was applied; time was allowed for the stress in the water to adjust itself; then an additional load of 1 kg. per sq. cm. was applied, and the sample was sheared off immediately afterward.

The finer the grains of a soil, the smaller are the angles of internal friction, μ_{1+1} and μ_2, and the smaller is the coefficient, λ_2. For pure clays, λ_2 may attain very low values—perhaps in the neighborhood of 0.3—whereas for pure sands, or soils containing a large percentage of sand, it approaches unity.

Group (5).—The compressibility of the soil is measured by means of the apparatus shown in Fig. 46. The device is arranged so that the lateral pressure may be determined at the same time.

After the water content of the soil has been measured independently, the material is filled into the brass cylinder in a plastic condition, and the total weight is determined. Then a pressure of 1 kg. per sq. cm. is applied to the soil through a precisely machined piston. The compression, magnified ten times, is measured by the movement of the end of the load beam. Motion ceases when the water content is reduced to the normal value corresponding to the applied pressure. When this condition is reached a measurement of the lateral pressure is made. The horizontal force, H, is gradually diminished by siphoning water from a tank (not shown) until the index, Z, shows a small movement. The index is arranged to magnify the motion fifty times, because only a very small amount of movement is permissible if arching action and other disturbing effects are to be avoided.

Let σ_I and σ_{II} denote the vertical and horizontal pressures, respectively. Let β be their ratio, defined by $\beta = \frac{\sigma}{\sigma_I}$. From Mohr's diagram it is possible to determine the angle of internal friction, ϕ, as a function of β. The relation is $\tan \phi = \frac{1 - \beta}{2\sqrt{\beta}}$.

After several measurements of the lateral pressure have been made, the weight of the cylinder and sample is again determined. The difference between this weight and the original weight represents the quantity of water forced out by the applied pressure. Next, the load is suddenly increased from 1 kg. per sq. cm. to 2 kg. per sq. cm. A lateral pressure measurement is made immediately, that is, while the water in the voids is still in a state of stress. Then follows a period of gradual compression under the increased load. When the compression is complete, the lateral pressure is determined once more. This continuous process is especially advantageous in that a whole series of measurements is made on the same sample without disturbing it in any way. Thus, a clear understanding of the relations between the various properties of the material is readily obtained.

Both the shearing apparatus (Fig. 45) and the consolidation apparatus (Fig. 46) can be improved. The more favorable characteristics of both might be combined advantageously in a single device, such as that illustrated in Fig. 47.

Summary.—The foregoing description illustrates the possibility of making continuous tests, using relatively cheap and simple instruments right at the job, to measure the most important characteristics of the soils encountered in construction work. Without claiming that the results are highly accurate, the writer believes that field laboratories, designed to fulfill the needs of a single construction project, serve as a practical supplement to the investigations undertaken in scientific institutions. Such investigations should make it possible to improve upon the economy and safety of earth structures.

To illustrate the practical application of such studies, experience in connection with the power plant at Albbruck-Dogern, on the Rhine, and the Kockovce Ladce project, on the Waag, may be cited. In both cases the canals were lined with concrete to insure water-tightness (see Fig. 48). In both cases it was necessary to economize on gravel. Hence, the dikes had to be composed partly of silt. The question as to the best use of the available material was decided from the results of tests on the soil, and from statical computations based on the methods of Ehrenberg.[116]

Although the same factor of safety was applied to the slopes of both canals, the resulting cross-sections differed materially, as a comparison of Fig. 48(*a*) and Fig. 48(*b*) will show. In the case of the Waag project, the silt core had to be much smaller than that in the Albbruck-Dogern dikes, because the silt found in the Waag had a much smaller shearing resistance than the Rhine material.

---

[116] "Grundlagen der Berechnung von Staudämmen," *Wasserkraft und Wasserwirtschaft*, 1929, Heft 23.

The writer was assisted in all the tests by Mr. Robert Haefeli, who is in charge of the Albbruck-Dogern Laboratory and of similar laboratories on other projects with which the writer is associated.

PROF. DR.-ING. F. KÖGLER,[117] (by letter).—Under the heading, "Research in Soil Engineering (Foundations)," Professor Gilboy states that his studies have shown that the settlement under a given unit load not too near the ultimate is practically independent of the size of the loaded area.

An extended series of tests performed under the writer's direction in the Soils Laboratory of the Bergakademie, in Freiberg, Germany, yielded valuable information on the subject as early as 1924. Figs. 49 and 50 show the relations between settlement and diameter of loaded area as derived from these studies. The laboratory tests agreed, in the main, with tests performed in the field.[118]

The first part of this research program was devoted to careful measurements of the distribution of vertical stress under loaded areas.[119] Later, the settlement characteristics of areas of similar shapes but of different sizes were studied. The curves of Fig. 49 were obtained from the results of a series of such tests on seven different circular areas with diameters ranging from 8 cm. to 100 cm.[120] The researches were next extended to include studies of the settlement characteristics and ultimate bearing capacities of areas of equal size but of different shapes.[118]

The shape of the curves in Figs. 49 and 50 may at first appear rather peculiar; but it can easily be explained. The settlement of a loaded area is due to two factors: First, to the compression (elastic and non-elastic), of the soil; and, second, to the displacement of the soil sidewise and upward. The latter factor is especially marked in the case of loads applied to the surface of the soil over small areas; the smaller the area, the more marked is the influence of lateral displacement.

This relation is reflected in the appearance of the left branches of the curves in Fig. 49. An understanding of this action is essential to the proper interpretation of the results of loading tests on small areas. The larger the area and the greater its depth, the smaller becomes the influence of this factor. Even so, however, it may still be appreciable if the soil is of a character offering relatively low resistance to lateral displacement.

With regard to the direct compression of the soil, theoretical considerations lead to the conclusion that the settlement due to this factor is proportional to the diameter of the loaded area. The writer's tests confirm this relation, as indicated by the right branches of the curves in Fig. 49. Tests performed in the field by Dr.-Ing. Heinrich Press[121] and the tests by W. S. Housel, Assoc. M. Am. Soc. C. E., gave similar results. The relation appears to hold for sand as well as for clay. Therefore, it is not correct to state that the settlement is independent of the size of the loaded area; it increases with increasing size, and, in certain ranges, is approximately in direct proportion.

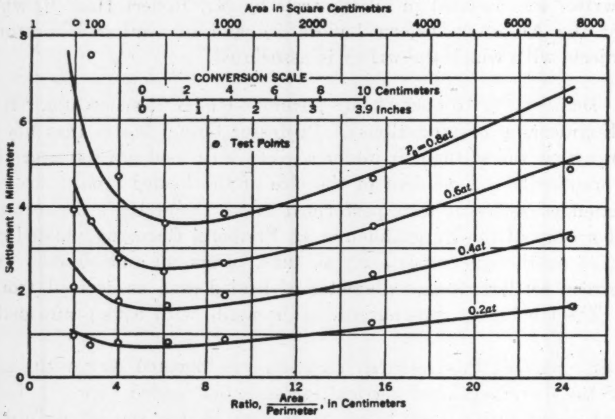

FIG. 49.—RELATION BETWEEN SETTLEMENT AND LOADED AREA, OF SAND.

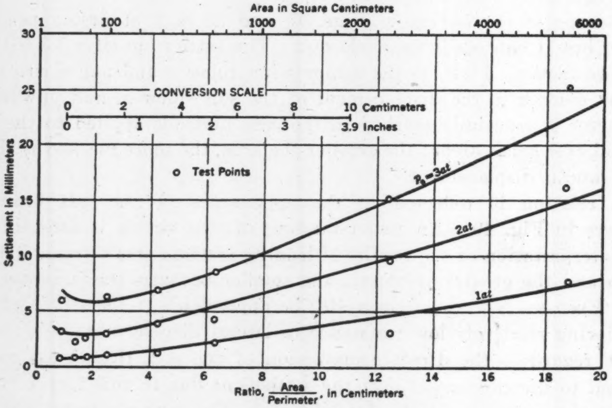

FIG. 50.—RELATION BETWEEN SETTLEMENT AND LOADED AREA, IN CLAY.

However, it is not justifiable to assume that this proportionality extends to very large areas. For such areas the settlement becomes correspondingly smaller. The reason is that the stresses produced in the soil by a large area extend to much greater depths than those under a small area, and at such depths the soil is denser and the lateral resistance is greater.[122] If it is assumed that the coefficient of compressibility (modulus of elasticity) of the soil increases in direct proportion with depth, theoretical analysis of the problem gives a curve of the type, shown at *B*,[123] Fig. 51. Even this assumption, however, leads to the results that under large areas the settlement will be large. It is unfortunate that there are not sufficient data on the behavior of large areas to permit a definite answer to the question.

---

[121] *Die Bautechnik*, September 26, 1930.

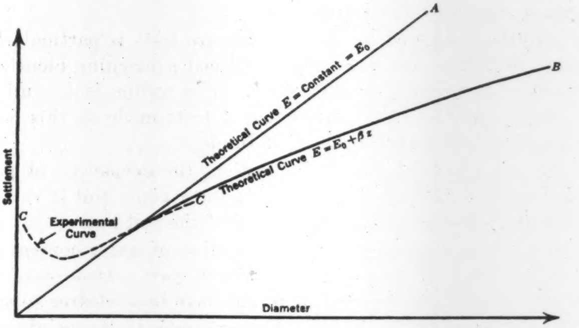

FIG. 51.

The fact that Professor Gilboy's studies appear to have yielded different results may possibly be explained by the consideration that the areas which he tested, if plotted on Fig. 49, would lie near the minimum points of the curves. An exact interpretation of his results would, under these circumstances, conform to the curves of Fig. 49. At all events, it is highly desirable to obtain settlement data on very large areas.

GLENNON GILBOY,[124] JUN. AM. SOC. C. E. (by letter).—The number of discussions contributed to this paper is indicative of the rather widespread interest now being taken in soil mechanics. In spite of the difficult nature of the problems involved, there appears to be a growing sentiment in favor of continuing the attack from all angles, thereby adding slowly but steadily to the somewhat meager fund of knowledge available. The information thus far accumulated affords a clearer understanding of the behavior of soil as a construction material than has hitherto been possible; and persevering study is certain to produce comparable results in the future.

Mr. Meem's idea that bearing values should be stated in terms of settlement is quite logical. However, the writer is not optimistic with regard to the possibility of reducing the problem of settlement to a relatively simple classification as outlined by Mr. Meem. Furthermore, there is not much hope that loading tests, even on the broad scale advised by Mr. Meem, will furnish adequate information. To mention only one difficulty, the time element involved in the settlement of foundations under-laid by clay makes it difficult, perhaps impossible, to predict the behavior of a large building over a long period of years from no other data than the results of a test on a limited area lasting a relatively short time.

[123] Aichhorn, "Ueber Zusammendrückung des Bodens infolge örtlicher Belastung," Dissertation, Freiberg, 1931, *Geologie und Bauwesen,* 1932, H. 1.

[124] Asst. Prof. of Soil Mechanics, Mass. Inst. Tech., Cambridge, Mass.

The apparatus suggested for lateral pressure tests is particularly interesting because, some time ago, the writer outlined a machine identical in principle, although on a much smaller scale. The writer is in full agreement with Mr. Meem regarding the importance of tests made on this basis. Their performance is impeded only by lack of funds.

In answer to Professor Parsons' question, the coefficient of permeability as used in Equation (2) is not a constant; for a given soil it varies not only with temperature, but also with the density of the soil mass.

Mr. Feld's misunderstanding of the definition of water content is probably due to a poor choice of terms on the writer's part. Instead of "weight of water per unit weight of dry soil," it might have been clearer to say, "weight of water per unit weight of solid." For example, if the original weight of a sample of soil is W, and the weight of the same sample "bone dry" is W_0, the water content of the original sample, w, is, $w = \frac{W - W_0}{W_0}$.

The objection by Mr. Feld to the lack of homogeneity of Equation (1) is sound. Here, again, a looseness in statement is apparent. To be strictly correct, the quantity, $V_1 - V_0$, should be multiplied by the weight of water per unit volume. Since, however, this is unity in the centimeter-gramme-seconds system, one easily falls into the habit of forgetting its existence in routine laboratory work.

There is still considerable controversy concerning the effect of the size of the loaded area on the magnitude of settlement. Although the tests with which the writer has had to deal justify no other conclusion than the one stated, it is possible that the range of areas involved was not sufficiently great to show the true situation. Extended series of tests performed in Freiberg under the direction of Professor Kögler indicate that the settlement on sand increases with the size of the area. On the other hand, this increase can scarcely be unlimited. If it were, large and heavy buildings founded on deep sand deposits should undergo considerable settlement; but this does not seem to be the case. A number of fairly heavy buildings on Lower Manhattan Island are founded on deposits of sand, frequently rather loose in structure, extending to depths of 100 ft. and more; yet if the writer's information is correct, settlements in this locality are relatively small.

To quote some figures, one series of the Freiberg tests on different areas under a pressure of 0.8 ton per sq. ft., gives a curve of which the asymptote may be represented approximately by the equation, $S = 0.026\,R$, in which, S is the settlement and R, the ratio of area to perimeter. This extension leads to the result that a building founded on a mat of 100 by 200 ft., with the very light load of less than 1 ton per sq. ft., should settle about 10 in.; or that a subway 50 ft. wide, with the same light load, should settle about 8 in. Such conclusions are manifestly absurd.

Just where the discrepancy lies, the writer is not at present prepared to state. It is evident, at any rate, that considerable work remains to be done in order to bring out the true relations between the results of loading tests and the behavior of actual structures, even when operating with a relatively simple material, such as cohesionless sand.

Mr. Jahn's pertinent comments on the hydrometer method illustrate the difficulties involved in working out a procedure for wet mechanical analysis. Certain of the faults enumerated can be minimized by the use of proper corrections. It is true, as Mr. Jahn intimates, that even with all possible corrections taken into account the method still remains approximate; but the margin of error is small enough so that the method fulfills the usual requirements of practice. Its many advantages, including the low cost of equipment, the ease of operation, and the short time consumed, make it a useful adjunct to routine laboratory work.

The writer was favorably impressed by Mr. Jahn's scheme of using a balanced immersion cylinder for this work, although it seems probable that the apparatus might be expensive. The scale-beam would have to be extremely sensitive, and the weights accurate, on account of the small changes in the uplift of the soil suspension. In addition, the temperature of the outfit would have to be kept constant, in order to eliminate changes in uplift due to changes in density of the water.

Mr. Eiffert's clear description of the field work at the Germantown Dam requires no comment. It may be useful, however, to clarify the meaning of the term, "percentage consolidation." To say that a soil is 25% consolidated means nothing, of itself, with regard to solidity. It merely means that of the total quantity of water that must eventually be forced out of the soil mass by the pressure to which it is subjected, one-fourth has already been forced out. In order to determine the solidity of the material, its angle of internal friction and the magnitude of the pressure acting upon it must also be known. For example, if a soil having the characteristics of the Germantown core material was subjected to a pressure of 1 ton per sq. ft., it would develop, if 100% consolidated, a compressive strength of about 1.7 tons per sq. ft. On the other hand, if the same soil were under a pressure of 4 tons per sq. ft., but only 25% consolidated, its strength would still be 1.7 tons per sq. ft. Thus, it is evident that the degree of consolidation alone is not sufficient to define the characteristics of the material.

With regard to the slow rate of consolidation of the Miami cores, it is the writer's opinion that this is a favorable feature, much to be preferred to the situation arising in a core which has been made coarser purposely to facilitate rapid consolidation. If the core is stable at a low degree of consolidation, additional hardening merely adds strength where it is not needed. Rapid and complete consolidation is, therefore, neither necessary nor desirable. Conversely, a core that consolidates slowly has, in addition to its high degree of water-tightness, the advantages that the re-adjustments of the entire dam accompanying consolidation are very gradual, and that there is no danger that drying and cracking of the core, in the manner described by Mr. Eiffert, will take place.

Mr. Eremin's remarks on colloids touch on one of the many effects that complicate the physical and chemical properties of soils. In fact, it is on account of these complications that direct methods of testing appear much more promising than attempts to infer the physical and mechanical properties from detailed technical analyses.

Professor Menefee has brought out some interesting points concerning the rupture of materials under compression. It is true that specimens of concrete and of soil frequently fail due to lateral tension, the failure being accompanied by vertical cracks; but this action is not the reason why true shear failures do not occur on planes making an angle of 45° with the principal planes. Rupture in shear takes place along a given plane when the obliquity of the resultant stress on that plane equals the angle of internal friction of the material. Therefore, if a specimen fails in shear, it will fail along planes upon which the obliquity of stress is a maximum. These planes are not necessarily planes of maximum shear intensity. In a material, such as steel, having a low angle of internal friction, the planes of maximum obliquity and the planes of maximum shear practically coincide; but this condition no longer prevails when the angle of internal friction has a value appreciably greater than zero. The greater the angle of internal friction, the greater is the angular displacement between these two sets of planes.

Referring again to Mohr's diagram in the original paper (Fig. 9), the positions of the planes of maximum obliquity are represented by the two radii drawn to the points of tangency. Suppose that the angle of internal friction of the soil specimen is 26°; then the angle, α, is 64 degrees. This is twice the angle between each plane of maximum obliquity and the plane of minor principal stress. Therefore, shear failure of the specimen will take place along planes making an angle of 32° with the vertical, in spite of the fact that the maximum intensity of shearing stress occurs on 45° planes. It is thus evident that Professor Menefee's observation in connection with Fig. 18 that "actual tests show that the failures in earth cylinders and concrete as well, are along planes of greater slope than 45°," substantiates theoretical concept.

Mr. Walker is correct in stating that the changes in consistency of clay as the water content decreases are not all marked by well-defined points of division. The shrinkage limit is an easily recognized boundary, but the plastic and liquid limits—especially the latter— are really transition states. It is precisely for this reason that standardized methods of determination of these limits are essential.

Mr. Walker suggests the correlation of moisture content with the force required to produce some agreed distortion of the sample. This is, in effect, the basis of the liquid limit determination. The agreed distortion is represented by the flowing together of the two halves of the sample over a specified distance. The force is measured by the number of impacts required to produce this distortion. When the number of impacts required equals an agreed number—say, 25—the water content of the sample is said to correspond to the liquid limit. To this extent the definition is arbitrary; but, as long as the adopted standard is adhered to, the results will be consistent, and the values will afford a definite measure of the character of the material.

It should also be noted that any elaborate method of determining the limits, or of setting up comparable standards, would defeat its own purpose. As the writer has pointed out, the chief advantage of the limit determinations is their simplicity. As soon as they become difficult to handle, their utility ceases.

Mr. Walker's unfavorable opinion of the shrinkage limit equation undoubtedly arises from the same difficulty that misled Mr. Feld. If Equation (1) is written:

$$S = \frac{(W_1 - W_0) - \rho\,(V_1 - V_0)}{W_0}$$

in which, ρ is the weight of water per unit volume, the obscurity disappears. The shrinkage limit is, by definition, the weight of water in the sample at the limit, divided by the dry weight of the sample. The quantity, $W_1 - W_0$, is the total weight of water in the saturated sample at the outset. The quantity, $\rho\,(V_1 - V_0)$, is the weight of water that disappeared from the sample as it dried from its original state to the shrinkage limit. The difference must be the weight of water that the sample contained at the shrinkage limit. Dividing this by the dry weight gives the desired value.

It is advisable, as Mr. Walker suggests, to calibrate the capillary permeameter before using it on an extended program of tests. However, the writer adheres to his original opinion that the apparently large variation in the coefficient, F, does not prevent the use of the uncalibrated apparatus for approximate measurements. If one could be absolutely certain of seepage calculations within 50% or even 100%, it would represent a fair degree of accuracy. For example, the permeability of the apparently homogeneous core of the Germantown Dam, determined from direct tests on undisturbed samples, varied from 20×10^{-7} to 400×10^{-7} cm. per min. In heterogeneous natural deposits the variations are many times greater. Hence, an approximate measurement that is within 50% of the truth is by no means worthless. In scientific research, a high degree of accuracy is essential; but in the practical field, the most elaborate computations frequently can do no more than define the general region within which the true solution lies.

The remark by Mr. Walker concerning the end effect in the retaining-wall apparatus brings out one of the main difficulties associated with devices of this type. The effect is not quite as marked as Mr. Walker states. Although the bin is 10 ft. deep, the model wall is only 7 ft. high, so that the ratio of depth to width of restrained earth is 1 to 2. In addition, the depths actually used in the tests were somewhat less than 7 ft., thus giving an even more favorable ratio. A further attempt was made to minimize the side friction by greasing the wall before placing the fill. Therefore, while certain end effects were always apparent, it is believed that they were not of sufficient magnitude to invalidate the results.

Professor Krynine's bibliography and synopsis of the investigations pursued by many scientists should be useful to those unfamiliar with the field of soil mechanics as an indication of the time and effort expended on the study of various important problems.

Mr. Crandall's remarks on the present unsatisfactory methods of soil classification are most pertinent. The writer did not touch on this subject because of the lack of anything concrete to offer. The problems involved in an attempt to arrive at a rational basis of classification are rather numerous. In the first place, the scheme of classification would have to be such as to meet the requirements of the particular purpose for which the standards are intended. A system satisfactory to an agronomist might be misleading to a foundation engineer. The sub-divisions should be based on variations in those physical properties of the soil that have a direct bearing on the behavior of the material from an engineering standpoint. There should be a sufficient number of sub-divisions so that any known soil would find a definite place, but not so many as to make the system cumbersome to use. The criteria of allocating soils to their proper sub-divisions should be definite, simple, and readily reproducible. Any tests required for applying these criteria should be of such an elementary nature as to be readily performed in the field, at least for a rough preliminary classification. The system as a whole should be of such a sensible and straightforward nature as to appeal immediately to the practical man. Finally would come the not inconsiderable task of educating engineers, architects, contractors, and drillmen in the essentials of the system, in order to make its use sufficiently widespread as to constitute a generally recognized and acceptable standard. The entire affair, therefore, represents a difficult and lengthy undertaking.

The sound ideas on the subject of pile foundations, mentioned briefly in Mr. Crandall's discussion, were presented in 1931 in a separate paper of greater length.[125] A valuable analysis of the effect of kneading on the properties of clay may be found in a paper published early in 1932 by Mr. Arthur Casagrande.[126]

Mr. Marston's brief discussion gives an insight into the careful studies which have been conducted under his supervision. The establishment of the Metcalf and Eddy laboratory represents a praiseworthy endeavor to apply the results of scientific analysis to practical problems, and to correlate laboratory findings with field observations.

The writer is indebted to Mr. Paaswell for the definite statement that the soil studies performed in connection with the subway construction in New York brought about a substantial saving of money. This is direct evidence of the fact that funds invested in such studies may be expected to pay good dividends. It is hoped that this idea will soon be grasped by the construction world in general, so that soil research will receive financial backing comparable to that accorded investigations on other engineering materials.

Professor Griffith apparently wishes to classify the writer as a member of a definite school of thought. To this the writer objects strenuously. He refuses allegiance to any particular school, believing that such an attitude is certain to result in a narrow field of view without adequate compensation in depth of perception.

It is quite true that the writer is interested in the physicist's concept of matter, and has been guilty of discoursing at some length on grain size and shape, intrinsic stresses, and soil structure, since he does not agree with Professor Griffith's idea that "such conceptions have no place in the systematic working formulations of science." On the other hand, the writer is equally interested in the methods of theoretical and applied mechanics, involving field equations subject to singularities and boundary conditions. Perhaps there was insufficient evidence in the original paper to make this clear to Professor Griffith. As an illustration, it may be interesting to elaborate a trifle upon the theory of consolidation. If a mass of saturated clay under pressure is taken as the field, it can be shown that the hydrodynamic conditions in the field are governed by the equation, $K \nabla^2 u = \frac{\partial u}{\partial t}$, in which, K is a constant of the material, and u is the hydrostatic excess at any given point in the mass at any given time, t. The solution of this equation in conformity with a given set of boundary conditions results in a theoretical expression determining the extent of consolidation as a function of space and time. A solution for the simplest case—a layer of clay infinite in horizontal extent, drained at the upper and lower faces, and subjected to uniform stress—was published by Professor Terzaghi in 1923.[127] The writer has since generalized the theory and has investigated a number of more complicated cases. This is, without doubt, exactly the kind of attack that Professor Griffith recommends.

In brief, the writer feels that it is not only possible but highly desirable to adopt a middle course, not relying exclusively on the methods of one or the other school, but investigating the favorable features of both.

Concerning the application of Boussinesq's theory to stress analysis in soils, the writer feels that his statements have been quite consistent. He merely pointed out that at best only an approximate solution is possible, but that in many cases an approximate solution comes close enough to actual conditions so that information of real value can be obtained therefrom.

Mr. Gruner's description of the field tests made under his supervision furnishes an interesting example of the manner in which properly conducted research can be used to aid in the solution of practical problems. Much still remains to be accomplished in this line; but it is encouraging to realize that the zone of uncertainty invariably associated with earthwork engineering can even now be narrowed appreciably by the use of physical measurements.

The proposed permeability apparatus shown in Fig. 44 would probably work better if it were arranged so that the water flowing through the sample were to travel downward instead of upward. An upward current tends to loosen the soil, and the results may be somewhat erratic for that reason.

---

[127] "Die Berechnung der Durchlässigkeitsziffer der Tone aus dem Verlauf der hydrodynamischen Spannungserscheinungen," *Sitzungsberichte* der Akademie der Wissenschaften in Wien, Mathem. Naturw. Klasse, Abt. 11-*a*, 1923.

The depth of the consolidation device illustrated in Fig. 46 appears to be rather large compared to the diameter. There is every reason to believe that a considerable part of the applied pressure is transferred to the walls, so that the pressure intensity at the bottom of the sample is only a fraction of that at the top. This means, of course, that the measurements will indicate a smaller compressibility than actually exists.

The proportions of the proposed device, Fig. 47, are much better. However, the writer is somewhat doubtful of the advisability of measuring the shearing resistance in the manner suggested. At first glance, it looks as if the withdrawal of the central section will produce pure shear along two horizontal surfaces, as indicated by the broken lines; but the actual situation is not so simple. The application of the horizontal force, *Q*, reduces the lateral stress on one side of the sample (on the left in Fig. 47) to zero, and produces an intense compression on the other side. This compression must be resisted by an equal and opposite comparison on the left side of the upper and lower elements of the sample. Consequently, the main compressive stresses within the sample will be transferred along curved paths from the right of the center element to the left of the two outer elements. This represents a rather complicated stress distribution which will not result in the desired condition of simple shear. For the present, at least, the writer believes that it is more satisfactory to use separate devices for consolidation and shearing tests.

Professor Kögler's remarks on the settlement of footings bring up the same question as that raised by Mr. Feld, and the writer's comments on Mr. Feld's discussion apply in both cases. As Professor Kögler suggests, it will be advisable, when circumstances permit, to execute a series of tests on a somewhat larger scale than usual, in order to bridge the gap that seems to exist between the behavior of model footings and the action of full-sized structures.

ENGINEERING FEATURES OF THE ILLINOIS WATERWAY[1]

By WALTER M. SMITH,[2] M. AM. SOC. C. E.

WITH DISCUSSIONS BY MESSRS. A. W. SARGENT, E. G. WALKER, DAVID A. MOLITOR, CHARLES A. D. YOUNG, AND WALTER M. SMITH

SYNOPSIS

Locks, dams, and power houses along the Illinois Waterway in the State of Illinois constitute the primary subjects of this paper. A general description of the structures at Lockport, Brandon Road, Dresden Island, Marseilles, and Starved Rock, is followed by a theoretical analysis of culvert valve chambers, operating machinery, etc., as designed for this project.

The steps in the design of miter-gates are reviewed briefly, including a description of a metal sealing-spring plate which permitted a more accurate and a lighter design. The gate anchorages were planned so as to make possible a fine adjustment of the rotation axis, similar to the arrangement for the locks at Sault Ste. Marie, Mich.

Interference with existing structures at Lockport, Ill., made necessary the installation of vertical lift-gates at this point. Furthermore, an emergency gate was necessary to take the place of movable gates that regulated water levels at the other dam sites in case of accidents. The physical features of all these units are treated herein.

An important part of the paper is an analysis of stresses in the side walls of the locks where the entry of the culverts complicates the design. The problem is solved by the Principle of Least Work, and one complete numerical example is given.

INTRODUCTION

The canal officially known as the Illinois Waterway, extends from the down-stream end of the Sanitary District Canal at Lockport, Ill., to Starved

FIG. 1.—GENERAL PLAN AND PROFILE ILLINOIS WATERWAY

Rock, a distance of about sixty miles. The plan and profile of the canal are shown in Fig. 1.

Locks have been located at Lockport, Brandon Road, Dresden Island, Bell's Island (about 2½ miles below Marseilles and known as the Marseilles Lock), and at Starved Rock. Dams and head-gate structures for power houses have been constructed at Brandon Road, Dresden Island, Marseilles, and Starved Rock. The Sanitary District of Chicago had a dam and power house in operation at Lockport before the beginning of work on the Illinois Waterway.

The head-gate structures of the power houses, except at Marseilles, were built first as a part of the dam, so that the power-house construction could be left for a later date. For a distance of 2½ miles up stream from Marseilles Lock, the Waterway consists of a canal entirely separate from the river. This is the case also for a distance of 2 miles down stream from Lockport Lock. Otherwise, the Waterway consists of a series of pools, dredged to a proper depth and width wherever necessary. The dimensions established were a minimum width of 200 ft. and a minimum depth of 9 ft.

DESCRIPTION OF STRUCTURES

Lockport Lock.—The structure a short distance southwest of Lockport consists of a lock with a maximum lift of 40 ft., which has miter-gates at the lower, and vertical lift-gates at the upper, end. An emergency dam has been constructed at the up-stream entrance to the lock.

Brandon Road Pool.—Des Plaines River enters the canal between Lockport and Brandon Road. Hence, there will be much greater flood flow at this site than at Lockport, and provision has been made to take care of a flood of 35 000 sec-ft. It is desired to hold this water at a very uniform level (Elevation 539.0) because this is the pool elevation through Joliet, Ill. A concrete retaining wall was built along the east side of the river through Joliet from the upper end of the city, southward 13 500 ft. to the dam, because the water level is much higher than the lower parts of the surrounding land. On the west side of the river a concrete wall was built from Jackson Street to the dam, a distance of 11 500 ft. As the retaining wall along the east side had to be built in any case, about 1 200 ft. of the lower end of it was constructed as a spillway weir. The crest of this weir is 2 ft. 3 in. below the water level as maintained by a series of twenty-one Taintor gates, 2 ft. 3 in. high by 50 ft. long. A gate has been constructed for passing ice, similar to the one at the Lockport Power Plant, of the Chicago Sanitary District.[3]

The crest of the long spillway weir is at Elevation 536.75, New York mean tide datum; the crest of the Taintor gates is at Elevation 539; and the crest of the ice-chute weir, at Elevation 534. A study was made to see if it would be better and more economical to construct several "Stickney" siphon spillways[4] rather than the long ogee weir. It was found that, in order to secure a considerable flow with very slight rise, the siphon spillways were slightly more economical; but there was a serious disadvantage in the fact that there is almost no increase in flow in these spillways as the water rises in the reservoir, whereas in the ogee type the capacity increases as the three-halves power of the head. For a 3-ft. head on the ogee weir, for example, the flow would be about 5.2 times as great as for a head of 1 ft. and, for a 4-ft. head, it would be 8 times as great. Because this great increase in discharge for a small increase in head was very desirable, it offset decidedly the slight economy of the siphon spillway. In addition, six sluice-gates with clear openings of 6 by 8 ft. were provided in the base of the dam. The normal lower-pool elevation is about 506.2, making the normal lift of the lock, 32.8 ft. The section of canal from Lockport to Brandon Road (see Fig. 1) is about 6 miles long.

---

[3] *Engineering News*, Vol. 60, 1908, p. 512.

[4] *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1098.

Intercepting sewers are constructed in the base of the retaining walls at Joliet, the one on the east intercepting all the sewage and storm-water run-off from that part of the city and discharging it below the dam. The west side of Joliet is much higher than the east side, except for a narrow strip along the back of the retaining wall. Therefore, most of the storm-water run-off is conveyed into the canal through submerged cast-iron pipes that pass through the wall. The sewage from the west side is conveyed into the intercepting sewer in the base of the wall. A 36-in. pipe has been placed across the river bed to convey this sewage to the larger intercepting sewer in the wall on the east side near its down-stream end.

Dresden Island Pool.—From Brandon Road to Dresden Island Dam is about 14 miles and two rivers of consequence enter this stretch, the Du Page from the north and the Kankakee, with a very large drainage area, from the south. According to the best data available the maximum flood flow that will occur at this site is 75 000 sec-ft. The dam consists of a concrete weir with nine Taintor gates, 60 ft. long—each sustaining a head of 14 ft. of water normally—and an ice chute, 30 ft. long, with a gate sustaining a head of only 5 ft. when closed. This gate is similar to the ice chute for the dam at Brandon Road.

The elevation of the normal upper pool and the Taintor gates is 505; the crest of the Taintor-gate weirs is at Elevation 491; the crest of the ice-chute weir is at Elevation 500; and the normal lower-pool elevation is 486.3.

Marseilles Pool.—From Dresden Island to Marseilles Dam is about 24.5 miles; but no rivers of consequence enter the canal between these two points so that the maximum flood flow for this site is 77 000 sec-ft. The Marseilles Lock is about 2½ miles below the dam and a canal has been excavated beside the river from the dam to the lock instead of using the river. A short distance down stream from the old dam, the new one, 970 ft. long, is planned to extend to the side of the canal entrance. It includes seven Taintor gates, each 60 ft. long and 14 ft. high. The tops of the Taintor gates were set at Elevation 483.25.

Marseilles Canal and Lock.—A canal separate from the river extends about 2½ miles from the Marseilles Dam to the Marseilles Lock. Since this canal is intended both for navigation and power purposes the power house is near the lock. The general plan and sections of the lock are shown in Fig. 2, while Fig. 3 shows the details at the upper gates.

FIG. 2.—GENERAL PLAN AND SECTIONS, MARSEILLES CANAL AND LOCK

All the locks on the Illinois Waterway have a usable length of 600 ft. and a width of 110 ft., with lifts varying from 15 to 40 ft. Miter-gates will be used at both up-stream and down-stream ends of locks, except at Lockport, where a different type of gate had to be used at the up-stream end for reasons to be given subsequently.

FIG. 3.—MITER-SILLS AND CULVERT CONNECTIONS AT UPPER END OF MARSEILLES LOCK

Starved Rock Pool.—The distance from Marseilles Dam to Starved Rock Lock and Dam is about 14 miles; one large river, the Fox, enters this stretch from the north side. The maximum flood flow will probably not be more than 85 000 sec-ft.

The dam consists of ten Taintor gates, each 60 ft. long, normally sustaining a head of 17 ft., and an ice chute, 30 ft. long, with a gate similar to the one for the Brandon Road ice chute. The elevation of the crest of the weirs carrying the Taintor gates is 442; the crest of the ice-chute weir is at Elevation 454; the top of the Taintor gates is at Elevation 459. The normal upper pool is at Elevation 459 and the lower pool at Elevation 441.

Filling and Emptying System.—The principal requirements of a lock-filling and emptying system, due regard being given to economy, are that it (1) shall permit equalization of levels in a reasonable time; (2) will not create dangerous water disturbances in the locks or approaches; and (3) will not allow excessive waste through leakage.

A large circular culvert in each lock-wall was adopted without further study because the economy of such design has been demonstrated by past experience. Studies showed that two culverts, 12 ft. in diameter, would ensure equalization of levels in from 7 to 12 min., depending on the location of the lock and subject to the limitation in equalization of 4 ft. vertically per min. A complete description of the filling and emptying system and lock valves has been written by L. D. Cornish, M. Am. Soc. C. E.,[5] and the operating machinery for the valves has been described by Mr. A. S. Grossberg,[6] Designing Engineer.

NOTATION

In the analytical parts of this paper the definitions of the various symbols are as follows:

b = length of culvert arch.

c = strength coefficient = Hs.

e = eccentricity, or the moment arm of a load, P.

f = unit stress, in pounds per square inch; f_u = stress in up-stream flange; f_d = stress in down-stream flange.

g = acceleration of gravity = 32.2 ft. per sec. per sec.

h = thickness of a culvert arch at any point.

i = a dimension, in feet (see Fig. 6(b)); i_1 = moment arm of the force, P_3; i_2 = horizontal distance along the neutral axis from the center of rotation of a gate to its center of gravity.

j = distance from line through contact points to point of application (air chambers), skin on up-stream side.

j' = distance from line through contact points to point of application (no air chambers), skin on down-stream side.

l = length of arch culvert measured along the axis.

e_n = distance of the point of application of P_n from the center of the section at any assumed joint.

$r = \dfrac{P_1}{2 \sin \alpha}$.

s = spacing of miter-gate girders, in feet.

---

[5] Manuals of Engineering Practice, Am. Soc. C. E., No. 3, p. 17.

[6] *Loc. cit.*, p. 21.

t = time required to fill a lock chamber, in seconds.

w = weight, in pounds; w_g = weight of miter-gate; w_w = weight of 1 cu. ft. of water.

x = transverse horizontal distance from the center of rotation of a gate to its center of gravity.

y = horizontal distance from the down-stream face of a gate to its center of gravity.

A = area, in square feet; A_c = combined area of the pair of culverts leading into a lock chamber; A_l = area of lock chamber; A_n = area of a culvert section at any assumed joint, acted upon by the force, P_n.

A_1 and A_2 = pull in the anchorages with gates closed.

C = a constant, varying from 0.75 to 1.15.

E = modulus of elasticity.

F = total stress, in pounds; F_u = stress in the up-stream flange; F_d = stress in the down-stream flange.

H = head, or lift, in feet.

I = moment of inertia of a section of any assumed joint that is acted upon by P_n.

K = resisting force, is equal and opposite to $\frac{P_1}{2}$.

L = distance from a culvert support, measured along the axis; dL = an infinitely small distance along the axis.

M = bending moment in a culvert section at any assumed joint.

N = resisting force, is equal and opposite to P_1.

P = direct pressure, in pounds; P_1 = total water pressure perpendicular to flange on one girder; P_2 = total water pressure against ends of one girder; P_3 = total pull exerted on anchors, A_1 and A_2, at the top of a miter-gate $= \frac{W_g i^2}{i_1}$; P_n = total pressure normal to a section at any assumed joint of a culvert.

r = radius, in feet.

$T = P_1 + P_2$.

V = velocity, in feet per second, in up-stream approach; and V_t = velocity of water at the throat section of a Venturi meter.

W = total work of resistance in a culvert wall.

α = angle of miter-gate with a line perpendicular to the lock-walls.

Culvert Valve Chambers and Operating Machinery

The culvert valve chambers were designed according to the principles of the Venturi meter as developed[7] by the late Clemens Herschel, Past-President, and Hon. M. Am. Soc. C. E., the culverts being circular (12 ft. in diameter), and the valve openings, 9 ft. square.

For some reason it has been the practice of canal engineers to design culvert valves with a considerably larger opening than the area of the culvert. On the other hand it has been the practice of water supply engineers to put gates in a conduit or pipe line of considerably less area than that of the conduit or pipe, knowing that if the reduction is not very great the loss of head is negligible and the smaller gates are much more economical.

Herschel took advantage of this fact in his development of the Venturi meter. In 1887, he performed many experiments with two meters of different sizes. The first was with a tube 1 ft. in diameter and a throat diameter of $\frac{1}{3}$ ft., so that the throat area was one-ninth the area of the tube. In the second set the tube was 9 ft. in diameter, with a throat diameter of 3 ft., making the throat area one-ninth the area of the tube, the same as in the other case.

---

[7] *Transactions*, Am. Soc. C. E., Vol. XVII (1887), p. 228, and Vol. XVIII (1888), p. 133.

The loss of head of the water passing from the inlet to the throat may be expressed in two ways: First, in terms of velocity at the throat, V_t; and, second, in terms of increase in velocity at the throat, $V_t - V$.

In the experiments with the small meter, with velocities at the throat varying from 10 to 35 ft. per sec., the loss of head in terms of the velocity at the throat was $0.00172\ V^2_t$ and in terms of the increased velocity at the throat, $0.00218\ (V_t - V)^2$.

In the case of the large meter the loss of head was slightly higher, probably due to the fact that it was not so well made; also, there was a greater variation in values, the loss of head being about $0.00230 V^2_t$, or $0.00290\ (V_t - V)^2$. In the case of the small meter a very uniform coefficient of 3.0 was obtained, but in the larger size the coefficient was about 2.5 and varied considerably more than in the small one. In these experiments the velocity at the throat of the meter was nine times as great as that in the tube.

In designing the inlet gates in the main gate-house at the Ashokan Dam, of the Catskill Water Supply System for New York City, advantage was taken of the Venturi principle by the Engineers of the Board of Water Supply. The valve, which is the throat of the meter, is 5 ft. in diameter, with an area of 19.6 sq. ft.

The sides flare on the down-stream side at an angle of 2° 30′, the same as in the Herschel meters, to a diameter of 7 ft. 4¼ in. and an area of 42.6 ft. at a distance of about 29 ft. from the valve. This gives an increase of 117% in area over the throat area. In testing these valves a coefficient of 1.18 was obtained before the Venturi action was broken.

In the filling and emptying system of the locks of the Illinois Waterway the culverts are circular, 12 ft. in diameter, with an area of 113 sq. ft. The valves are 9 ft. square. A transition section down stream becomes a circle 12 ft. in diameter in a distance of 19 ft. from the valve, or an increase in area of 40 per cent. For the same distance, the increase in area of the tail-tube in the Ashokan valve is 72 per cent. It is hoped that as high a coefficient will be obtained in the valves as that obtained in the Ashokan tests.

The formula for finding the time required for filling a lock chamber is,

$$t = \frac{2\ A_l\ \sqrt{H}}{C\ A_c\ \sqrt{2g}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

and it has been the practice to take $C = 75$. It was found in testing the Panama Canal locks after completion that when the valve area was much greater than the culvert area, $C = 0.83$. Using this value in Equation (1) the time required to fill the Marseilles Lock, if the rise is unlimited and $H = 21.6$ ft., is: $t = \frac{2 \times 74\,910\ \sqrt{21.6}}{0.83 \times 226\ \sqrt{64.4}} = 464$ sec., or 7 min. 44 sec.

Assuming that a coefficient of $C = 1.15$ will be obtained in the valve constructed in this manner and substituting this coefficient and the area of the valves, $A_c = 162$, for the area of the culverts in Equation (1), the time required will be 467 sec., or an increase of 3 sec. in the time of filling the lock due to using the smaller size of valves. This shows that with this size and type of valve the time of filling and the time required for a vessel to pass through the locks will not be materially increased by using the smaller valves unless the coefficient falls below 1.15 which is not at all likely.

If a coefficient of 1.10 only should be obtained in the valves, the increase required in filling one lock is only 25 sec.; the increase in time of the boat going through the five locks is less than 3 min.

The gate-valves are raised 10 ft. in about 1 min. The machinery is driven by a 10-h.p. electric motor, at 900 rev. per min., through a worm-wheel drive, and a train of gears revolving a drum, to lock the gate in any position of opening or closing. A close-link chain, attached to the gate, is deflected from a vertical direction by an idler sheave near the top of the coping. It runs a short distance horizontally through a hawse pipe and winds around the scored drum. The machinery can be operated by hand from the top of the masonry by a windlass with a sliding bevel-gear pinion that can be engaged very quickly by means of a detachable collar on the shaft. For a more complete description of the culvert valves see Lock Valve Manual No. 3, previously mentioned.[8]

MITER LOCK-GATES

With the exception of the upper gates for the structure at Lockport all lock-gates are of the mitering type. There will be thirteen miter-gates of two leaves each, the total weight of which will be about 3 000 tons. The leaves are 65 ft. long, 7 ft. wide, and vary in height from 20 to 59 ft., and in weight from 90 to 320 tons.

Structurally, each leaf consists of several horizontal girders rigidly connected to a miter post on the free end and a heel post on the hinge end. The leaf is stiffened vertically by five sets of diaphragms between all girders, and has diagonal tension rods with turnbuckles on the up-stream side to provide means of adjusting the miter-posts to a vertical position. The miter and quoin-posts are built of structural steel shapes as shown in Fig. 4, the web-plate being in sections which extend well in between the girder flanges as vertical diaphragms which transfer the thrust of the leaves along the quoin and miter-posts to the web-plates in the horizontals. The sheathing or skin-plates are on the down-stream side. Buckle-plates were utilized where possible and they will be in tension except where a double skin was used to form air chambers. Intercostals are not necessary with buckle-plates; hence, this type of sheathing costs less than flat plates.

No other type of gate was considered because mitering gates have long been the standard form for canals and have given excellent satisfaction in operation and maintenance. Estimates based on actual designs have shown that usually, for the lock as a whole, the most economical rise of mitered gates is approximately one-fourth the lock width and that, for a leaf 65 ft. long, the economical width of the horizontal girder is about 7 ft. The flanges should be straight except for a short curved length near each end of the up-stream flange.

---

[8] Manuals of Engineering Practice, Am. Soc. C. E. No. 3, p. 18.

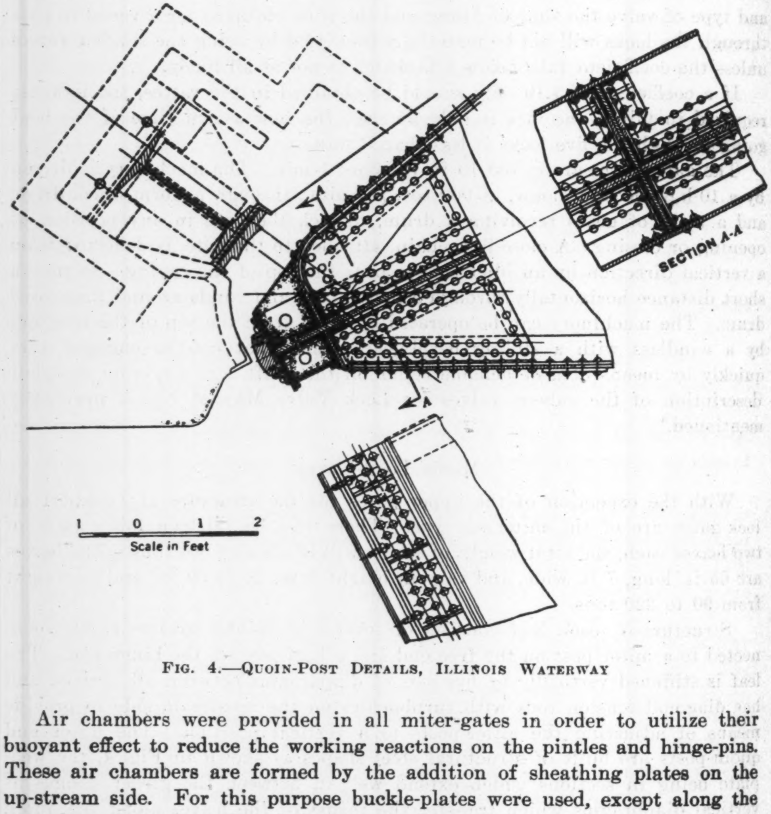

Fig. 4.—Quoin-Post Details, Illinois Waterway

Air chambers were provided in all miter-gates in order to utilize their buoyant effect to reduce the working reactions on the pintles and hinge-pins. These air chambers are formed by the addition of sheathing plates on the up-stream side. For this purpose buckle-plates were used, except along the curved portion, where flat plates supported by intercostals were necessary.

The bearing plates along the quoin and miter-posts are of steel with convex curved surfaces. The bearing plates in the hollow quoin or reaction post are also of steel, but with a concave surface, the radius of which is slightly greater than the convexity radius of the quoin-post. The bearing plates are accurately adjusted with set screws after which melted lead-antimony alloy is poured into the spaces left for that purpose behind the plates.

The determination of the stresses in the gate and gate anchorage is not described at length in this paper because it would involve merely a repetition of what has been written before on this subject.

It was originally thought that air chambers would not be needed in any of the miter-gates except those previously mentioned, but after both the upper and lower gates at Marseilles Lock had been completed according to the original designs, and after making operating tests, it was found desirable to construct air chambers in all the gates to relieve the heavy load on the pintles. Fig. 5 shows the various details.

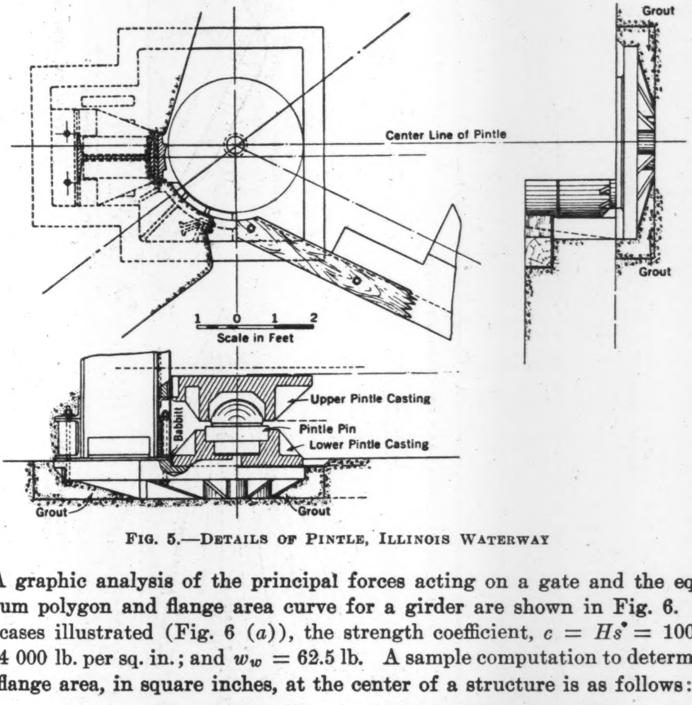

FIG. 5.—DETAILS OF PINTLE, ILLINOIS WATERWAY

A graphic analysis of the principal forces acting on a gate and the equilibrium polygon and flange area curve for a girder are shown in Fig. 6. In the cases illustrated (Fig. 6 (*a*)), the strength coefficient, $c = Hs^* = 100$; $f = 14\,000$ lb. per sq. in.; and $w_w = 62.5$ lb. A sample computation to determine the flange area, in square inches, at the center of a structure is as follows:

$$\text{Flange area} = \frac{Tj}{7f} = \frac{71.8\,w_w H\,s \times j}{7f} = \frac{71.8 \times 100 \times 62.5 \times 7.78}{7 \times 14\,000} = 35.6, \text{ in}$$

which, 71.8 was measured from Fig. 6(*c*); and $w_w H = c = 100$. To determine the value of $j = 7.78$ ft., refer to Fig. 6(*d*). Taking moments about O:

$$j - x = \frac{0.112\,N + 3.55\,P_2 + 32.456\,K - 16.228 \times 0.5\,P_1}{P_1 + P_2} = 7.78$$

and, similarly,

$$j' = \frac{0.112\,N + 32.456\,K - 16.228 \times 0.5\,P_1}{P_1} = 8.226$$

The total stresses, in pounds, in the flanges then are equal to:

$$F_u = \frac{Tj}{7} \text{ and } F_d = \frac{T(j-7)}{7}$$

FIG. 6.—DESIGN DATA FOR MITER-GATES, ILLINOIS WATERWAY

Fig. 6(*b*) shows that the maximum pull on one anchor is, for gate closed, $-0.84\,P_s$ and, for gate open, $+0.12\,P_s$, and for the other anchor, $1.03\,P_s$ maximum with gate nearly open.

On the diagrammatic cross-sections of the various gates for the waterway are shown the girder spacing and the coefficient, *c*, of each girder. The water pressure diagrams in Fig. 7 show the actual or assumed head acting on each leaf and the coefficients, $c = Hs$, for each girder. The load per linear foot on any girder equals $w_w\,c$. As the required cross-sections of girders are directly proportional to their coefficient (Fig. 6(*c*)), a correct determination of flange areas for a girder the coefficient of which is, say, 100, solves the flange-area requirements of all girders. It should be noted that the total flange stresses

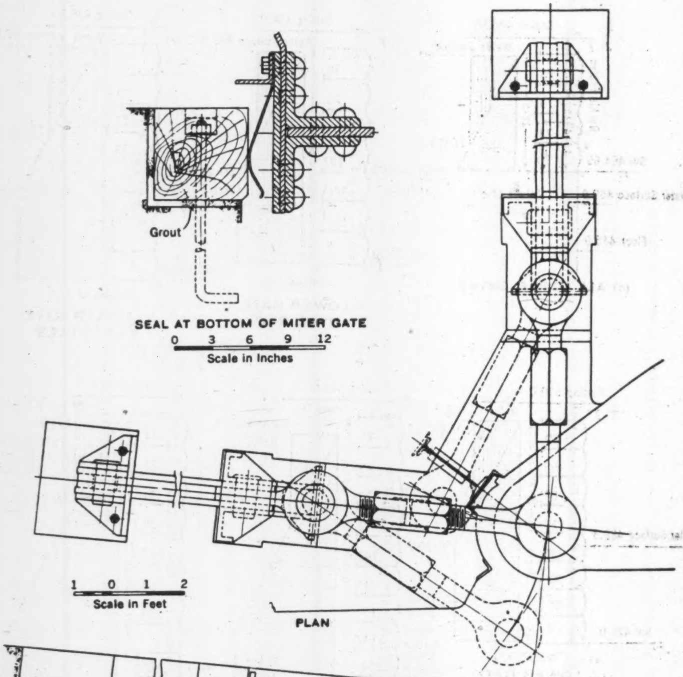
are less when the skin is on the down-stream side than when it is on the up-stream side. The difference is due to the elimination of the force, P_2, shown for the left-hand leaf in the analysis of "Principal Forces (Fig. (*6d*))."

Figs. 6 and 7 were devised by L. D. Cornish, M. Am. Soc. C. E., Chief Engineer of the Division of Waterways, State of Illinois, and were of great value in the designing of all miter-gates.



SEAL AT BOTTOM OF MITER GATE

PLAN

SECTIONAL ELEVATION

FIG. 8.—ANCHORAGE OF MITER-GATE, ILLINOIS WATERWAY

Contact at Miter-Sill.—In the design of mitering gates it has been the practice heretofore to permit close contact and heavy bearing between the lower gate girders and the miter-sill. The result does not permit an accurate and scientific design of either the lock-gate or the miter-wall. Both must be designed unnecessarily strong to withstand the unknown and indeterminate pressures, which are assumed to be heavy. This indeterminate condition has been remedied by placing a metal sealing-spring plate on the gate, which alone will be in contact with the miter-sill when the gate is closed, and which cannot transmit to the sill more than a part of the pressure due to the water in contact with the spring itself. This permits a more accurate and lighter design of both gate and miter-wall and results in decidedly lower costs (see Fig. 8).

The gate anchorage designs for these locks differ in many respects from any other designs of which the writer has knowledge. (See Fig. 8.) Large gate anchorages usually are extended deep into the massive concrete against which the gate abuts and are made of eye-bars or built-up structural members. Such anchorages are difficult to set and hold accurately while the concrete is poured. To secure the same results, that is, to carry the pull of the gate when hanging free, well down into the concrete mass, the gate-reaction monoliths of these locks are reinforced by a network of reinforcing bars and only straight eye-bar anchors are used, the anchor ends of which are about 4 ft. below the coping level of the concrete. Troughs are left in the concrete so that the bars may be accurately set at leisure and subsequently embedded in concrete. A rather fine adjustment of the rotation axis of a gate is necessary and this is provided for by adjustable double eye-bars which connect the hinge pin of the gate and the fixed anchor. The adjustment is accomplished by means of sleeve nuts with threads of slightly different pitch and size at each end, but in the same direction. This design is the same as that used in the new locks at Sault Ste. Marie, Mich. The advantage of this design over the ordinary turnbuckle is a much finer adjustment per turn and, therefore, less force is required, which is an important item as adjustments must be made when the anchor is under maximum stress.

The quoin-post which is embedded in the concrete to distribute the thrust of the gate is made up of I-beams with pressure-distributing angles riveted on the back and a channel section on the front to which the hollow quoin plates are fixed. A cross-section of the quoin-post is shown in Fig. 5. The posts are in one piece and the bottom end is bolted to a projection of the pintle bed-plate casting so as to facilitate holding the quoin-post in an exact position during concreting operations.

MITER-GATE OPERATING MACHINERY

The so-called bull-wheel type of operating machinery devised for the Panama Canal is used to open and close the miter-gates (see Fig. 9). It has been described in detail in a paper by Edward Schildhauer, M. Am. Soc. C. E.[*]

This machine, under constant motor speed, imparts an ideal motion to the gate, that is, slow speed at the ends of travel and high speed at the mid-point. The force required mainly depends upon the vertical area which is submerged during operation as the movement causes a difference in water level on the two sides of the gate, which is very marked near the recess and mitered position and during acceleration. As the depth of submergence of the Illinois Waterway gates in no case exceeds 16 ft. when operated, or less than one-half the submergence of the Panama gates, the forces are much less and the machinery is lightened accordingly. Several other changes have been made in the design, among which may be mentioned the omission of the spring-center spur gear to reduce the starting torque of the motor. Experience has shown that the value of the spring center is not commensurate with its cost.

FIG. 9.—PLAN OF STRUT ARM AND BULL WHEEL FOR OPERATING MITER-GATES, ILLINOIS WATERWAY

LIFT-GATES AND OPERATING MACHINERY

At Lockport there exists a small modern lock built by the Sanitary District of Chicago to connect the Drainage Canal with the old Illinois and Michigan Canal. The necessity of retaining this lock so restricted the remaining available lock site in width that, adjoining the small lock, there was not sufficient area for the mass of concrete required for the thrust of a mitering gate. Hence, for these upper gates, a vertical-lift, horizontal, truss-type of gate was adopted (see Fig. 10).

Two gates similar in construction and operation have been installed. One acts as an emergency gate and will be used only if it becomes necessary to remove the other for repairs. The structure consists of a movable gate, counterweighted, with a tower at each end, which is connected at the top by a service bridge placed at a clear elevation of 50 ft. above the high-water level. These gates have been described previously in a paper by the writer.[10]

The lock chamber is 110 ft. wide, and is provided at the upper end with recesses in the side walls about 5 ft. wide and 14 ft. long, that extend the full depth of the lock, and the gate operates within these recesses. The vertical travel is 23 ft. 8½ in. and is accomplished in 2 min. by a 50-h.p. electric motor, placed at the center of the service bridge, and acting through the necessary reductions on internal gears integral with the sprocket drums. Two link chains at each end of the gate pass over these sprocket drums at the top of the towers and connect to a steel-skeleton counterweight box, filled with sufficient concrete to balance the weight of the gate when immersed.

PLAN

FIG. 10.—LIFT-GATE OPERATING DIAGRAM, LOCKPORT LOCK

The lift-gate consists of five horizontal trusses, hereinafter designated as Trusses Nos. 1, 2, 3, 4, and 5, and placed one below the other, Truss No. 1 being uppermost. Trusses Nos. 1, 2, and 3 are spaced 6 ft. 8 in., center to center; Trusses Nos. 3, 4, and 5 are spaced 5 ft. 1 in., center to center. Each truss is of the ordinary Pratt type, with a single web system. The web members and posts are composed of angles, and the down-stream or tension chord of 15-in. channels is reinforced with 12-in. side-plates where necessary. The up-stream or compression chord is built up of four angles spaced 20 in. back to back, two 19 by $\frac{11}{16}$-in. web-plates, a 13-in. cover-plate outside the skin-plates, and reinforcing side plates where required. In addition to the direct compression, this chord was designed to carry the bending moments resulting from the uniformly applied water-pressure load transferred to it from the skin-plates.

---

[10] *Engineering News-Record*, Vol. I, 1926, p. 722.

Each truss is 11 ft. 9 in., center to center of chords, and consists of ten panels of 11 ft. 9 in. each, making a distance of 117 ft. 6 in., center to center of end bearings. A continuous sheet of $\frac{1}{4}$-in. buckle-plates connects to the outside flange angles of the up-stream chord. A set of vertical bracing, extending between Trusses Nos. 1 and 3, is provided in the plane of the inside flange angles of the up-stream chord, as well as in the plane of both flanges of the down-stream chord, to carry the dead load stresses to the ends of the structure. Trusses Nos. 4 and 5 are suspended from this bracing by hangers at the respective panel points. The dead loads carried by this bracing are delivered to a vertical girder at each end of the gate, and thence to the two sets of link chains.

At each end of each truss, on the down-stream side, there is a cast-steel bearing block with a finished cylindrical bearing surface 20 in. long, bolted to the gate, which transmits the water pressure to a continuous vertical finished steel casting, bolted to 24-in. Bethlehem I-beams embedded in the masonry walls.

Guide rollers, bolted near the top and bottom of the gate at each end on the up-stream side, act against vertical T-guides bolted to the masonry, and limit movement in a direction parallel with the lock chamber. In a similar manner rollers near the top and bottom at each end, and placed on a line coincident with the center of gravity of the gate, limit movement in a direction at right angles with the lock chamber.

Water seals along the bottom and ends of the gate on the up-stream side prevent serious leakage of water when the gate is raised and the water level in the lock chamber is lowered. The bottom seal consists of a continuous line of $4\frac{1}{2}$-in. standard wrought-iron pipe, connected together by screw plugs and resting on a horizontal curb angle just below the top of the breast wall. This pipe terminates at each end in the side of a casting, resting on, but not bolted to the masonry, and the top of this casting serves as a support for another $4\frac{1}{2}$-in. pipe forming the vertical seal. This vertical pipe also terminates in a casting bolted to the masonry at the upper end. Screw plugs are provided at each end of the vertical pipe and enter recesses in the castings. These recesses allow the necessary movement for the pipe to come in contact with the gate. The horizontal pipe forms a contact between the curb angle on the masonry and the cover-plate on Truss No. 5. Rivets coming in contact with all pipes are countersunk. A series of T-headed bolts, spaced 3 ft. 6 in., center to center, throughout the length of the horizontal pipe and anchored to the masonry (the heads being inserted through slotted holes in the pipe and then turned 90°) prevent this pipe from falling out of position when the gate is raised for repairs. At the same time this arrangement allows freedom of movement for the pipe to assume a curve corresponding to the deflection of the gate under maximum pressure. The vertical seal acts in a similar manner to the horizontal, forming a contact between a vertical curb angle embedded in the masonry and vertical plates riveted to the ends of the gate.

Owing to the great quantity of sludge in the drainage-canal water a flushing system for the bottom seal and recess is necessary. A flushing pipe is placed in the breast-wall masonry just back of the recess with smaller pipes leading from it into the recess at frequent intervals. This pipe is connected with a tank placed on one of the towers of the operating bridge so that water can be discharged into the recess under a 60-ft. head.

The operating machinery of the lift-gate is at the center of a tower bridge, 50 ft. above the upper pool water level. Sprocket drums are mounted on the top of the towers and by specially constructed link chains suspend the lift-gates and the counterweights at each corner, equilibrium being established when the gate is in its middle position (see Fig. 10). A 50-h.p. electric motor, at 600 rev. per min., was agreed upon as the basis of calculations for the moving machinery, the time of operation to be 2 min. for a lift of 25 ft. Internal gears cast *en bloc* with the sprocket drums are meshed with operating pinions mounted on a shaft between them and are revolved by a large gear at the center through a gear train ending in a set of miter gears. A line shaft running the entire length of the tower bridge rigidly connects the two systems of gears and drums at each end, a small gear being coupled at the center. A short counter-shaft is driven by the motor pinion at one end, while at the other a sprocket-wheel and roller chain facilitate hand operation.

Lockport Emergency Dam

A lock-gate may be damaged or wrecked by boats going in either direction. The most common accident occurs from a misunderstanding of signals on an upbound boat approaching the lock when it is filled. In case of accidents to the lock-gates at Starved Rock, Marseilles, Dresden Island, or Brandon Road, the water can be drawn down almost to the level of the upper miter-sill by opening the movable dams.

At the summit level at Lockport it is not possible to draw the pool down in this manner. An emergency gate has been designed therefore to be installed up-stream from the upper lock-gate. In case any of the gates at this lock are carried away the emergency dam can be raised and the flow of water reduced.

An outline of this emergency dam is shown in Fig. 11. It consists of an immense steel shutter swiveling on a horizontal axis operated by valves in manholes in the side walls. Ordinarily, this shutter rests in a horizontal position in a recess in the floor. Beneath the up-stream half of this shutter there is a recess in which this part of the gate swings. This recess can be connected with either the upper or lower pool by manipulating the proper valves in the side walls. When the recess is connected with the upper pool the pressure on both sides of this half of the shutter is equalized and, as the other leg of the shutter is longer, it will maintain a horizontal position. When it is desired to raise the shutter to an upright position the valves connecting the up-stream recess to the upper pool are closed and those connecting it to the lower pool are opened. The pressure from the upper pool on the up-stream leg of the shutter, being then unbalanced, will force this part of the shutter down.

FIG. 11.—PLAN AND PROFILE, EMERGENCY DAM, AT LOCKPORT, ILL.

It may be noted from the diagram that a large pipe has been provided in each side wall connecting the upper pool with the recess under the down-stream leg of the gate. This is done to supply water and equalize the pressure on the face and back of the gate when it begins to rise and prevents the tendency for a partial vacuum in this recess to hold the shutter down. There is a pipe in the concrete beneath the recess, below the down-stream half of the shutter. At intervals there are smaller pipes, connecting the recess with this pipe, which blow out sludge and other deposits that may form in the recess from time to time. This can be done by connecting the pipe with the lower pool. It is very necessary on account of the large quantity of sludge carried by the Sanitary Canal.

When the dam has been lifted, the flow is cut down sufficiently for the water surface to take the elevations shown in Fig. 11. As all the water will then be going through the culverts the upper lock-gate, or the emergency gate, whichever is uninjured, can be raised. After this has been done and before the valves are closed, the emergency dam can be lowered by closing the valve connecting the space below the up-stream leg of the shutter to the lower pool and opening the one connecting it to the upper pool. The dam will then revolve into the recess in the floor.

SIDE-WALL ANALYSIS

As the culverts in the locks are circular, the stress in the wall at the culvert cannot be found by the method used when they are rectangular. It is believed in this case that the most accurate method of determining the stresses in the masonry around the culvert is that of the "Principle of Least Work."

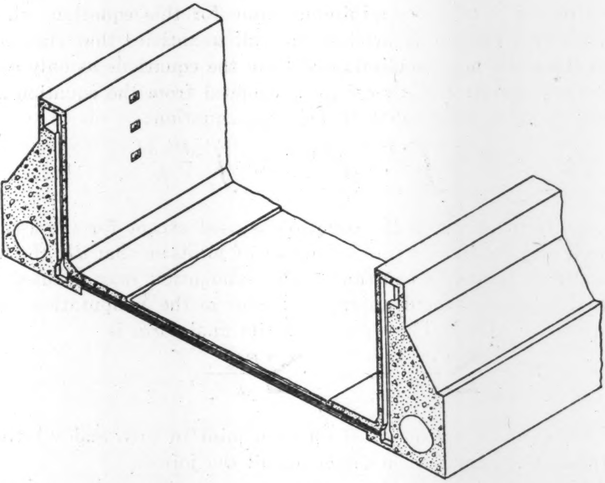

FIG. 12.—ISOMETRIC VIEW OF SECTION OF LOCK, ILLINOIS WATERWAY

In this analysis the assumption is made that the arch will do the least amount of work necessary to support the load upon it. Hence, if an expression can be found for the work done by each pressure line, the pressure line giving the least amount of work is the true one, and the stresses in the joints can then be computed.

The formula for the work of resistance in an arch (see Fig. 12) is:

$$W = \int_0^l \frac{M^2\,dL}{2\,EI} + \int_0^l \frac{P^2_n\,dL}{2\,EA_n} \quad \ldots\ldots\ldots\ldots\ldots\ldots \text{(2)}$$

in which,

W = total work of resistance in the structure.
M = bending moment at any assumed joint.
P_n = total pressure normal to section at any assumed joint.
L = distance from support measured along axis.
dL = an infinitesimally small distance along the axis of the arch.
l = length of arch measured along axis.
E = modulus of elasticity of material of arch.
A_n = area of section at any assumed joint where P_n acts.
I = moment of inertia of section of any assumed joint where P_n acts.
e_n = distance of point of application of P_n from center of section at any assumed joint.

Substituting h for the thickness of the arch at any joint and making the length of the arch considered equal to $b = 1$ ft., $A_n = hb = h$. The equation then becomes:

$$W = \int_0^1 \frac{M^2 dL}{2E\frac{h^3}{12}} + \int_0^1 \frac{P^2_n dL}{2Eh} \quad \ldots\ldots\ldots\ldots\ldots\ldots(3)$$

The next object is to get a minimum value for this equation, which can only be done by trial. It is evident that all quantities that stay constant throughout the trials may be eliminated from the equations as only comparative values are wanted; 2 E, therefore, is dropped from the equation and for M its value, $P_n e_n$, is substituted, making the equation:

$$W = \int_0^1 \frac{P^2_n e^2_n dL}{\frac{h^3}{12}} + \int_0^1 \frac{P^2_n dL}{h} \quad \ldots\ldots\ldots\ldots\ldots(4)$$

This is the form in which the equation is used except for the assumption that the arch may be divided into a number of joints so that dL, the distance between assumed joints, is constant. The summation may be used instead of the actual integral without appreciable error in the computations to determine comparative value. The equation in its final form is:

$$W = \sum \frac{P^2_n e^2_n}{\frac{h^3}{12}} + \sum \frac{P^2_n}{h} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(5)$$

in which, h, P_n, and e are obtained for each joint in turn and substituted in the equation. The sum is then taken for all the joints.

After the arch has been divided and the forces acting on the various blocks have been found, a force polygon can be drawn and the resultants obtained from it in direction and magnitude. The point of application of each resultant can then be found by taking the sum of the moments of all the forces acting on one-half the arch about any point and dividing this moment by the resultant. This will give the lever arm of the resultant about the center of moments, and the resultant can then be drawn in position on the arch.

There are three unknown quantities to be obtained, the horizontal and vertical components and the point of application of the crown thrust, and all are determined very easily by this process. Any point on the springing line and crown joint may be taken and the horizontal crown thrust is obtained that will pass a pressure line through the point on the crown joint and the springing line. This is accomplished by taking moments of all the forces acting on that half of the arch about the point on the springing line and dividing the sum by the distance to the line of action of the crown thrust. This thrust can then be applied at various points on the crown joint, the pressure line can be drawn, and the work computed for each.

It is generally desirable to apply the thrust at about five points on the crown joint at equal distances apart. Then it is only necessary to draw the two outer pressure lines because the distance between these lines can be measured at each joint and divided by four in getting the values of e_n for each line. After the work has been obtained for the set of pressure lines for this crown thrust, assume a thrust a little larger or smaller, pass pressure lines through the same points on the crown joint and through a minimum, and compute as before.

After computations have been made for five or six different crown thrusts the value of the work for each thrust at each different point of application should be plotted on a cross-section diagram with the work as ordinates and the point of application at the crown as abscissas. By connecting the points thus plotted for the same crown thrust in each case, a series of curves is obtained. Next, draw a curve passing through the lowest point on each of these curves. The lowest point on the resulting curve gives the point of application of the true crown thrust. Then on another cross-section diagram, with work as ordinates and horizontal component of crown thrust as abscissas, plot the lowest point on the curve for each of the trial horizontal components of the crown thrust. Draw a curve through these points. The lowest point will give the true horizontal component of the crown thrust. This leaves only the true vertical component of the crown thrust to be obtained.

As the true horizontal component and point of application of the crown thrust are now known, try several different vertical components using the same horizontal component and point of application in each case. Of course, for each vertical component it is only necessary to draw one pressure line since the point of application is already known. When a sufficient number of different vertical components have been tried in an effort to obtain a minimum, the results are plotted on a cross-section diagram as before, with the work as ordinates and the vertical components as abscissas. Passing a curve through these points and taking the lowest point on that curve, the true vertical component is obtained. Having the true vertical and horizontal components and point of application, the true pressure line may be drawn and stresses in the various joints computed.

The wall of the Marseilles Lock (see Fig. 13) is being built up to the level of the shoulder after which a wait occurs until the concrete sets sufficiently to erect the forms for the back of the wall upon it. This results in a well-defined joint on this line. The wall above this line is designed so that for the most adverse conditions possible there will be no tension at the heel. The stress diagram for this joint is then drawn as shown in Fig. 13(*a*) and the upper wall is assumed to be replaced by this pressure on the top of the arch. The arch is then divided into sections by imaginary joints and by the forces found acting on each of these blocks. A force diagram is then drawn, and the resultants acting on the two halves are obtained in direction, magnitude, and point of application, as previously explained. With the moments of all the forces on each half of the arch determined, it is very easy to obtain the horizontal component of crown thrust to pass a pressure line through any point on the springing line. It will be noticed from Fig. 13 that the trial crown thrusts used are not horizontal, but very much inclined. It is not necessary to use a horizontal crown thrust, but in the first set of computations to find the true horizontal component and point of application, the vertical component must be the same for each trial.

A trial computation for a horizontal component of 12 000 lb. is shown by Fig. 13 and the computations are given in Table 1. In drawing the pressure lines on the arch it is well first to prolong the crown thrusts at the extremes out to the resultants and then draw lines from their intersections on the resultants, parallel with the line in the force diagram representing the resultant of the crown thrust and all the forces on one-half the arch. These lines are $A1$ and $A23$ in the force diagram, Fig. 13(a). This will give points on the springing line to which the pressure lines drawn from joint to joint must come if correct. Only the two outside pressure lines are drawn although there are five used in the computation. The intermediate values of e_n can be obtained very easily, as they are all an equal distance apart. The values of P_n are the same on each joint for all the lines. It will be noticed in Table 1 that they are divided by 1 000, so that the numbers in the computations will not be too large.

FIG. 13.—ANALYSIS OF STRESSES IN CULVERT WALL, MARSEILLES LOCK

After completing this computation another value of crown thrust is taken and a similar table is computed for it. Four different values of crown thrust were used in this case, the horizontal components being 13 000, 12 000, 11 000, and 9 000 lb. The values of work for each of these crown thrusts for each

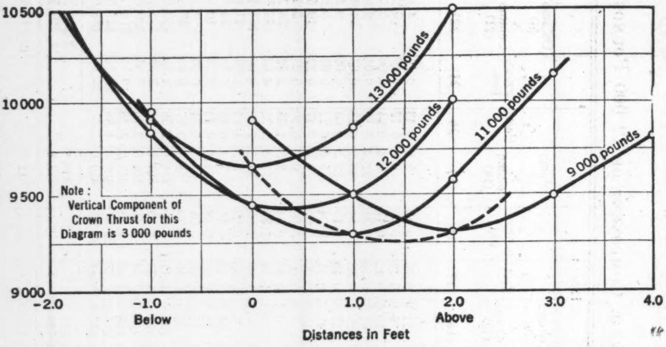

FIG. 14.—DISTANCE OF POINT OF APPLICATION FROM CENTER OF CROWN JOINT

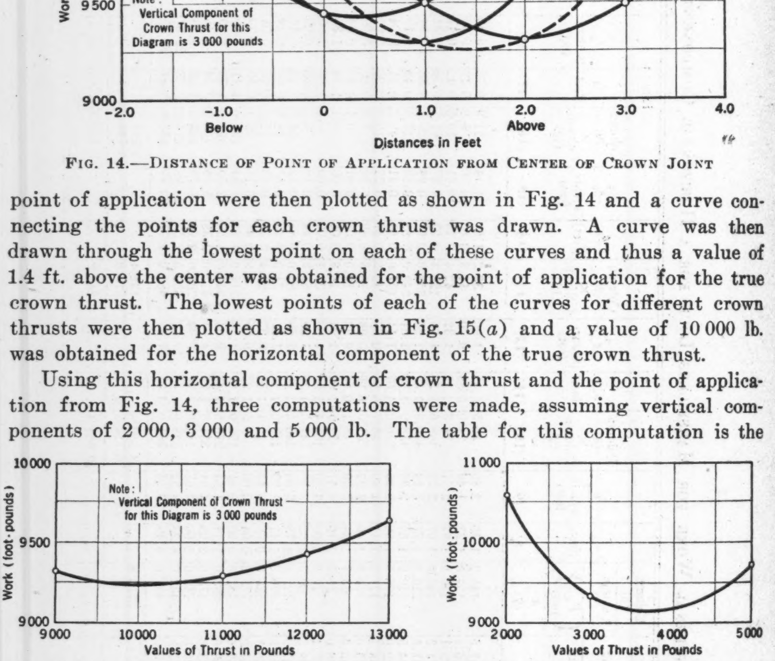
point of application were then plotted as shown in Fig. 14 and a curve connecting the points for each crown thrust was drawn. A curve was then drawn through the lowest point on each of these curves and thus a value of 1.4 ft. above the center was obtained for the point of application for the true crown thrust. The lowest points of each of the curves for different crown thrusts were then plotted as shown in Fig. 15(*a*) and a value of 10 000 lb. was obtained for the horizontal component of the true crown thrust.

Using this horizontal component of crown thrust and the point of application from Fig. 14, three computations were made, assuming vertical components of 2 000, 3 000 and 5 000 lb. The table for this computation is the



(*a*) HORIZONTAL COMPONENT

(*b*) VERTICAL COMPONENT

FIG. 15.—COMPONENTS OF THRUST AT THE CROWN

same as that used for obtaining the horizontal component, except that for each vertical component assumed only one pressure line is drawn, as the point of application is known. The values obtained for the different vertical components are then plotted as illustrated in Fig. 15(*b*), and a curve is drawn through these points. The lowest point on this curve gives a value of 3 700 lb. as the true vertical component.

Having now obtained the true vertical and horizontal components and point of application of the crown thrust it is a simple matter to draw the true pressure line and compute the stresses in the various joints. The pressure line and stresses obtained for the section in question are shown in Fig. 13.

It is not claimed that this method will give exact results, but it is believed to give results nearer the truth in a case of this kind than any other method. The computation would be rigidly true if the arch were divided so that $\frac{dL}{l}$ is constant for the first term of the formula. Perform this part of the computation, then divide the arch so that $\frac{dL}{A_c}$ is constant and use this division for the second term of Equation (2).

In designing the arched conduits through the dams for the Miami Conservancy District, at Dayton, Ohio, this was done as a check for one of the arches after the true pressure line had been obtained by the method described herein. It was found that the pressure lines obtained by the two methods were practically identical; the crown thrust differed only 0.17% and the point of application was practically the same.

TAINTOR GATE DAMS AND OPERATING MACHINERY

The dams at all the sites except Brandon Road consist of a concrete weir of moderate height, with piers at certain intervals. A movable gate that may be opened during flood periods is placed between each two piers. At one end of each of the dams the height of the gate is different from the others, similar to the sector gate at Lockport. This is for the purpose of taking care of the ice (see Section *B-B*, Fig. 16).

Three types of gates were studied for the movable parts of these dams. The first consisted of a shutter, hinged along the up-stream edge, which is at the level of the crest of the permanent masonry portion of the dam. At the two down-stream corners chains from heavy counterweights are attached, the counterweights sliding along the backs of the piers.

The second consisted of the well-known "Stoney gate" type, consisting of a large, counterweighted shutter traveling vertically in grooves. Instead of having a train of rollers for each end bearing traveling with the gate at half speed, as is the custom in this type, fixed wheels with roller bearings were substituted.

The third type is a "Taintor gate" and consists of a part of a cylindrical surface braced to and revolving about a horizontal axis. It is counterweighted so that the operating machinery will have only friction to overcome. This gate can be counterweighted accurately much more cheaply and simply than either of the others. The operating machinery is carried by a light steel footbridge spanning from pier to pier.

The first type was quickly discarded because of the great difficulty of counterweighting due to the extreme variation of the load for different positions of the gate. This would make the cost of operating machinery and power very heavy.

In studying the second and third types the cost was found to be about the same, but there were several disadvantages of the second, or "Stoney" type. A heavy operating car with powerful machinery would have to be provided for installing the gates and removing them when necessary, and a heavy

FIG. 16.—PART PLAN AND SECTIONS OF METAL WORK AT STARVED ROCK DAM

overhead bridge would be necessary to carry this car and the suspended gate. This bridge would have to be on high piers with its floor far above the tops of the lock walls, thus necessitating a stairway at each end and making it difficult to install or take out either the operating car or the gates. To offset this cost, the piers in the second type were much lighter than those in the third type, the weir being the same in each. This saving in concrete practically balanced the extra cost of the operating car and heavy bridge, but on account of the difficulty in installing and operating the Stoney type the "Taintor" gate type was adopted. Fig. 16 shows the layout of metal work at Starved Rock Dam.

A method has been provided to close any one Taintor gate-opening so that a gate may be inspected, repaired, and, if necessary, taken out and replaced without loss of water. Notches are provided on each side of each pier at the water surface into which a steel coffer (the bottom of which is a very strong horizontal beam) can be floated. Steel needles are inserted with the lower ends resting in a groove in the concrete apron and the upper ends against the bottom girder of the coffer. After the needles are placed, cocks in the bottom of the coffer are opened, and the water is drained out. These cocks are provided so that the coffer can be made to float at the proper level to fit into the notches in the piers.

All Taintor gates are operated by machinery placed on the piers. An alternative hand and motor operation is provided as indicated in Section *C-C*, Fig. 16. A shaft operated by a worm-wheel at the pier extends to the center of the operating bridge. A pinion on the end of this shaft, at the center of the bridge, engages a spur gear on a shaft that extends the entire length of the bridge. On the ends of this shaft are pinions that engage in the operating struts attached to the end struts of the gates, which extend beyond the center of rotation and carry the counterweight. The purpose of this method of operation is to insure the same amount of torsion at both ends of the operating shaft and thus prevent twisting in the gate.

Adjustable Crest-Sector Dam at Each Site

This dam (Section *C-C*, Fig. 16) is built of structural steel and is a part of a cylinder rotating about a horizontal axis. The curved surface is faced up stream so that the pressure of the water is exerted through the center of rotation. The weir is 30 ft. long, with an adjustable crest of 7 ft. maximum variation. It is constructed to facilitate the movement of ice. The curved sheet of the sector has a radius of 10 ft. A weir tube controlling the water level under the dam can be manipulated to regulate the amount of pressure head within the movable dam. The hinge consists of steel castings bolted together in sections. The upper, being part of the gate, is held by four pins to the lower castings embedded in the masonry and anchored. The castings run the entire length of the dam. A seal is obtained by arranging a curved overlapping apron of the upper casting so that it is in rubbing contact with a movable strip of metal secured to the lower stationary casting by set screws. Steam pipes prevent ice from forming about the hinges. The sides of the movable structure are sealed by pipes pressed against steel plates attached to the walls of the flanking masonry piers. The gate can be locked in the elevated position by bolts keyed to a shaft on the breast-wall which holds the gate in position, while the water pressure inside can be released. A suitable manhole gives access to the interior of the chamber for cleaning or repairs. This dam is like that of the Sanitary District of Chicago at Lockport.[11]

BRIDGES

Twelve highway and street bridges that crossed the river channel either had to be rebuilt entirely or a draw span had to be constructed. Five of these bridges are in the City of Joliet and the others at various points along the Waterway. The five in Joliet and one at Brandon Road are rolling-lift bascule structures of the Scherzer type. The others are ordinary fixed bridges built at a high level.

In addition, there are draw spans in five railroad bridges that cross the river. One of these located in Joliet was entirely rebuilt.

WATER-PIPE TUNNEL

The Illinois Waterway interfered with the water pipes that crossed on existing bridges. The law authorizing construction required the State to provide a means of conveying the water across the canal before the existing mains could be disturbed. As the bridges at Joliet are of the rolling-lift bascule type, it was impossible to place any water mains on them and, therefore, a tunnel in which water mains could be placed had to be constructed under the river. The Electric Light and Power Company, the Telephone Company, and the Gas Company, also desired to use the tunnel, so they each paid their proportional part of the cost of the structure.

The section of the tunnel is oval, the longer diameter being horizontal. It has a maximum height of 9 ft. and a maximum width of 10 ft. The shafts are the same size as the tunnel. Conduits for electric light and power wires are provided in the side wall of the tunnel and in shafts on one side, with a manhole at the top of each shaft. Similar conduits are provided on the other side for telephone wires, also with manholes at the top of each shaft. Two 16-in. water mains and three gas pipes occupy the open space of the tunnel and shafts.

The center line of the tunnel is about 38.5 ft. below the bed of the stream and is in first-class limestone. There is a working chamber at the head of each shaft. Ordinarily, the tunnel and shafts will be kept flooded to within a few feet of the working chamber floors as this makes it safe to place gas mains, and electric light, power, and telephone wires in the same chamber. A sump is provided at the bottom of one of the shafts, in which a rotary pump is placed with a shaft running up to a motor in the working chamber and a discharge pipe running up to and entering an intercepting sewer in the wall along the side of the canal. When it is desired to inspect the tunnel this pump will clear the tunnel of water in about seven hours. A blower is provided in the same working chamber to force air down the shaft, through the tunnel and up the shaft on the far side of the canal, before any one enters.

---

[11] *Engineering News*, Vol. II, 1908, p. 512.

DISCUSSION

A. W. Sargent,[12] M. Am. Soc. C. E. (by letter).—Some new and interesting features in lock design have been brought out in this paper. The use of the Venturi principle in the design of lock culverts has resulted in a saving in the cost of valves and valve-operating machinery with little loss in efficiency. The valves, which apparently are designed to be lowered by their dead weight, without strut or stem to force them to the closed position, would operate satisfactorily in quiet water and under a small head, but it is the writer's opinion that some mechanism should have been provided to force them to their seats under a head equal to the maximum lift of the lock. It will be interesting to know whether in actual practice the valve-operating mechanism, which is quite simple and inexpensive compared with many other types now in use, has proved entirely satisfactory; and, also, it would be interesting to know the maximum head under which a valve can be lowered to its seat.

The design of the gates, with air chambers in the lower part, single skin on the upper part on the tension or down-stream side, and buckle-plates for sheathing, has no doubt resulted in economy, but the additional protection afforded by a complete double skin would be beneficial. It would prevent the accumulation of driftage on the girders and the painted surfaces would be better protected. The interior surfaces of the double-skin gates of the Lake Washington Ship Canal, which is between salt water and fresh water, require little attention. A coating of bituminous solution and enamel applied about 1916 is still (1931) in excellent condition, while the exterior surfaces have required extensive repairs annually when the lock is unwatered for general overhauling of all under-water equipment.

The design of the part in contact with the miter-sill is new, and the writer believes it will be uniformly satisfactory when the strut-arm method of operating the gates is used (Fig. 9). This method does not allow the leaf to swing beyond the proper mitering position. The motion is eccentric at the heel and does not contact with the quoin-post except when mitered (Fig. 4). Where gates are operated by wire cables a stop should be provided to prevent a leaf from swinging too far and injuring the sealing strip as well as stressing the hinge-pins and anchorage. The writer had this in mind when he designed the water-seals for the lower guard-gates of the Lake Washington Ship Canal.[13]

To insure the successful operation of an emergency dam when an emergency arises, all parts should be easily accessible for inspection and repair. A structure of this kind which is continually submerged is not considered the best type. This condition could possibly have been avoided by placing the guard-gate up stream from the emergency dam. All parts of the dam would then be accessible after unwatering the lock. The spar bull-wheel type of gate-operating machinery which is now generally used for mitering lock-gates, has proved very satisfactory.

---

[12] Civ. Engr., U. S. Engr. Office, Govt. Locks, Seattle, Wash.

[13] *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 1008.

The Lockport Lock, which has a lift of 40 ft., is one of the highest in the United States. The Wilson Dam Lock has a lift of 45.5 ft., and the Keokuk Lock, one of 41.0 ft. The locks of the Welland Ship Canal, in Canada, have a maximum lift of 46.5 ft. The difficulty of handling vessels in high-lift locks, while the water is being raised and lowered, is quite apparent. At the Welland Ship Canal mooring passages are provided in the lock-walls to facilitate the mooring of vessels at lower pool levels.[14] This method possibly has some drawbacks as the passages no doubt become slippery making it dangerous for the men handling the lines.

The writer believes that it would be practicable to equip high-lift locks with movable mooring devices which could be held in vertical recesses in the lock-walls, and raised or lowered with the water, either mechanically or by floats. A mechanism equipped with roller-bearings would facilitate the raising or lowering when a ship's lines are taut. A ship entering a lock which has been equipped with these devices, would have the eye on the mooring lines attached to two or more as desired and this should be secured to the ship's cleats or windlass. Lengthening and shortening of lines, as is usual when lowering or raising a vessel, would not be necessary. The ship's crew would do the principal work now required of the linesmen on the lock-wall, and the safety of the vessel in the lock would be dependent upon the vessel's crew and its own lines. With workable mooring devices which would be held a certain distance above the water in a lock while the water is being raised or lowered, the operation of locks of extreme lift would be feasible and much of the difficulty of providing lockage facilities at high dams would be overcome, and the time of passage between pools would be reduced.

E. G. Walker,[15] M. Am. Soc. C. E. (by letter).—The arrangement of the sluices on the culverts of the locks along the Illinois Waterway is certainly unusual, and it would be interesting to learn whether the advantages claimed for the reduction of the size of the valve, relative to the cross-section of the culvert, are fully justified in practice. In order to obtain efficiency, the principle of the convergent and divergent mouthpiece which was used by the late Clemens Herschel, Past-President and Hon. M. Am. Soc. C. E., in the development of the Venturi meter, presumes a gradual convergence to the smallest cross-section and subsequent divergence of the stream line without varying the general shape of the stream, except possibly by such gradual changes of curvature as will prevent the formation of eddies and turbulence.

In the design which the author describes, a circular culvert, 12 ft. in diameter, is reduced at the valve face to an opening 9 ft. square. In practice, any transition from the circular to the square must introduce a certain amount of eddying, however gradual it may be, and, therefore, the full benefit of the contraction of sections cannot be obtained. The type of sluice-valve described by L. D. Cornish, M. Am. Soc. C. E., as being used on the Illinois Waterway,[16] could not readily be adapted to suit a circular opening, and this accounts for the change in cross-section of the water passage. The principal benefit that is obtained by using a smaller sluice-valve is that the cost of the valve is thereby reduced. It does not seem likely that there can be much practical value in the theoretical hydrodynamical advantage of increased rate of flow, when the practical circumstances of the problem are considered. The author calculates a theoretical advantage of only 25 sec., and it seems doubtful whether even this could be fully justified if a practical comparison could be made between the larger and smaller valves.

---

[14] *Proceedings*, Am. Soc. C. E., October, 1929, Papers and Discussions, p. 2066.

[15] (Maxted & Knott), London, England.

[16] Manuals of Engineering Practice, Am. Soc. C. E., No. 3, on Lock Valves, Appendix 3, p. 17.

The proportion, 1 to 4, of rise to span for the lock-gates seems high. It is stated that it was adopted as the result of estimates based on actual designs. Is it to be assumed that these were designs prepared in connection with the job, or is it the author's generalization of an examination of previous practice? If the latter it would seem that he has examined only the more abnormal cases. The writer knows of many instances of mitered gates in which the rise is as little as one-sixth of the width between the centers of the quoin-posts, and he believes that although cases can be found, especially on small locks, of rises of one-fourth and even one-third of the width, an average would probably be considerably less than one-fourth.

It would be of interest if the author would enlarge a little upon his reasons for stating, as he does under "Miter Lock-Gates," that mitering lock-gates should be of the parallel type. It is common practice in America for this to be so, but in many other places the cylindical-backed gate has been found to be suitable, and there are definite features in favor of it. The parallel gate has the advantage of taking up considerably less space in the lock-wall when open, and may enable a reduction to be made in the over-all width of the lock between the backs of the walls of the gate recesses (usually the widest part of the structure). In many instances, particularly when two locks or entrances have to be constructed side by side in a limited width, this may be a great advantage in enabling the works to be arranged so as to give the most economical utilization of the available space. On the other hand, the cylindrical-backed gate does not present any difficulties of construction; the plates have only to be rolled to a relatively simple curvature in one plane and this applies to all the structural details involved. Therefore, it does not present any construction difficulties as compared with the parallel gate. At the same time, it has the advantage that the line of thrust can usually be kept well inside the thickness of the gate at all points, and thus enable better distribution of metal to be arranged with smaller variation of stress from point to point of the structure. It is noted that in Fig. 6 (*a*), the value of *j* (the distance of the line of thrust from the chord of the gate) reaches a maximum of 8.226 ft., as compared with a gate width of 7 ft.

The writer was interested to learn of the use of buckle-plates on the gates, a feature which would not be feasible with cylindrical-backed gates. This appears to be somewhat of a new departure in lock-gate construction and it is of value to learn that a saving of cost was effected thereby. If such saving can be effected in the general case it is a strong feature in favor of the use of parallel gates.

The statement in the paragraph introducing Fig. 5 is peculiar. It seems to the writer that in all lock-gates there is a self-evident benefit in endeavoring to balance as much of the weight of the gate by buoyancy as is suitable to the average circumstances under which the gate is to operate. This applies whether the gate is small or large. If the weight of the gate can be balanced by flotation there must be a self-evident advantage in equalizing the distribution of pressure on quoins, miters, and sills, and, therefore, of enabling more water-tight joints to be made and maintained. All the gates on the Illinois Waterway are certainly large enough to have made the provision of buoyancy chambers worth while and it seems remarkable, therefore, that any attempt to design gates without buoyancy chambers should have been made at all.

The writer would suggest the desirability of adding to the paper the detail of the miter-post, similar to the clear detail of the quoin-post shown in Fig. 4. He suggests that this, in company with the other details of the gates given in the other diagrams in the paper, would complete the author's clear description of the gates as a whole.

The design of the pintle, as shown in Fig. 5, while it is in accordance with American practice, seems to be rather more complicated than is necessary. With properly supported gates in which, under most of the conditions of operation, the weight is balanced by the buoyancy of the air chambers, there should not be a large load upon the pintle and, therefore, a plain steel casting with a corresponding plain cast-steel cup on the heel of the gate, should be sufficient and would appear to be a cheaper solution.

The design of the sill on the miter-gate is an interesting attempt to overcome the disadvantages inherent upon the older methods of attempting to make a tight joint by means of timber or metal clapping sills. Provided no obstruction gets between the lock-sill and the spring-plate, there should be every possibility of making a tight joint, if the spring-plate has been properly adjusted in the first place. There are, however, one or two points upon which the writer would like information. It would be interesting to learn the amount of deflection allowed in the design. It is possible that small obstructions might easily cause inordinate leakage. With a solid clapping sill the introduction of such obstruction would be sufficient to prevent the gate from closing properly and so most likely the existence of the obstruction would be made known. With the spring-plate, however, it seems quite conceivable that the obstruction might force the plate back, but yet not be sufficient to prevent the gate from mitering, and in this way a permanent opening would be formed along the sill of the gate after the lock had ostensibly been closed, and considerable leakage would thus result. There is also the possibility of damage to the plate by obstructions, such that the damage could only be discovered by under-water inspection and yet not be of such a nature as would prevent the gates closing properly.

The design of anchorage shown in Fig. 8 is good. The writer agrees strongly with the author's complaint as to the common design of anchorages, which frequently consist of huge tie-bars carried back into enormous masses of concrete out of all proportion to the load which the anchorage is called upon to carry. The writer has known of cases in which it was simple to demonstrate that—entirely apart from the resistances of anchorage of old rails and large washer-plates at the ends of the ties—if the adhesion of the concrete to the tie-bar could be relied upon, it would be possible to break the anchor-bars by tension before reaching an admissible working adhesion between the steel and the concrete. The gate anchorages shown in Figs. 3 and 8 prove that, by rational design, it is possible to construct anchorages of reasonable dimensions which will stand up fully to the requirements of the job. The differentially threaded turn-buckle is ingenious and should enable closer adjustments of the quoin-post to be made relative to the quoin.

The gate-operating machinery shown in Fig. 9 seems well adapted for its purpose, in that it enables a maximum of force to be exerted in the operating arm at the beginning and the end of the stroke, the times when extra effort is most likely to be required. It has the disadvantage, however, that the effort is applied to the gate at a short radius relative to the radius of the center of water pressure on the gate, thereby inducing greater dynamic stresses in the structure of the gate than would otherwise be the case. At the same time, except by the use of the old method of attaching chains at the center of pressure, it is not possible to eliminate entirely the dynamic stress in gates during opening and closing, and the only designs that the writer has seen for substituting an arm for the chain for this purpose had a number of features which were obviously detrimental. It appears necessary to accept the fact, therefore, that compact and convenient gate-operating mechanism can only be obtained at the expense of a certain amount of dynamical stressing of the gate structure.

The writer was interested to note the relatively high degree of elaboration which it has been thought necessary to adopt in designing the structure of the lock-wall where it is intersected by culverts. He questions its value on the generally accepted principle that no structure can be safer than the foundations upon which it stands. The author of this comparatively elaborate graphical and analytical method of designing the wall gives no indication of why he assumes that all of the regular cross-section of the lock-wall acts as an arch. As far as can be followed from the paper, the lock-walls are simply plain mass concrete structures, and it is impossible, without making assumptions of the most arbitrary kind, to know how the pressures on the back and front of the wall are transmitted through the monolithic mass. It is surely going very far to assume that a rectangular wall section with a toe and a circular opening through it, as shown in Fig. 13(*b*), acts as a pure arch composed of a number of independent voussoirs each of special and arbitrary shape. The writer has strong belief in the application of scientific principles to design whenever benefit can be obtained thereby, but he does not think that this particular instance is one suited to extremes of mathematical analysis.

DAVID A. MOLITOR,[17] M. AM. SOC. C. E. (by letter).—In this paper, the author has attempted to describe briefly a work comprising a variety of

---

[17] U. S. Constr. Engr. for Superv. Archt., Treasury Dept., Lansing, Mich.

structures entering into the construction of the Illinois Waterway, and he gives special consideration to the stress analysis of the lock-walls with large culvert openings, which he claims to have solved by applying the principle of least work. Several of the subjects mentioned, since they are not adequately treated in books, might properly cover more space than was allotted to the entire paper.

***Mitering Lock-Gates.*—In designing horizontal girders of mitering lock-gates, the chief difficulty is in determining appropriate flange areas for the case of direct stress and bending, where the direct stress, the bending moment, and the moment of inertia, all change at each girder section, as shown on the author's Fig. 6(*a*).**

The writer has found the following formulas very useful in avoiding the customary trial-and-error method of proportioning the required girder flanges.

In addition to the notation used by the author, the following are introduced (see Fig. 17):

$F =$ area of flanges in Fig. 17; F_1 refers to Flange No. 1 and F_2 refers to Flange No. 2.
$f =$ unit stress; f_1 refers to extreme fiber of Flange No. 1 and f_2 refers to extreme fiber of Flange No. 2.
$d =$ depth of web-plate.
$t =$ thickness of web-plate.
$j =$ lever arm of resultant, T.
$T =$ resultant force acting on the girder section, A-A.

***Case I.*—To find the theoretical areas, F_1 and F_2, required for each flange, when the maximum allowable unit stresses are assigned, positive for tension and negative for compression. When T, j, d, t, f_1, and f_2, are given:**

$$F_1 = -\frac{1}{df_1}\left[Tj + \frac{d^2 t}{6}(2f_1 + f_2) \right] \ldots\ldots\ldots\ldots (6)$$

and,

$$F_2 = -\frac{1}{df_2}\left[T(d - j) + \frac{d^2 t}{6}(f_1 + 2f_2) \right] \ldots\ldots\ldots (7)$$

***Case II.*—To find the required area, F_1, for one flange, when the allowable unit stress, f_1, in that flange and the area, F_2, of the other flange, are given,**

but the unit stress in the given flange is not assigned. When T, j, d, t, f_1, and F_2 are given:

$$F_1 = -\frac{T\left(\frac{6\,j\,F_2}{d^2\,t} + \frac{3j}{d} - 1\right) + \frac{f_1}{2}\left(d\,t + 4\,F_2\right)}{2\,f_1\left(\frac{3\,F_2}{d\,t} + 1\right)} \quad \ldots\ldots\ldots(8)$$

and,

$$f_2 = -\left[\frac{6\,f_1\,F_1}{d\,t} + \frac{6\;T\,j}{d^2\,t} + 2\,f_1\right] \quad \ldots\ldots\ldots\ldots\ldots(9)$$

Case III.—The areas, F_1 and F_2, for the flanges, when the eccentricity of the axial thrust, T, varies between equal limits on both sides of the gravity axis of the section, are given by the formula:

$$F_1 = F_2 = -\frac{1}{6\,f_1\,d}\left[3\,Tj + 2\,f_1 d^2 t + \sqrt{(3\,Tj)^2 + f_1\,d^2 t\,[f_1 d^2 t - 6\,T(j-d)]}\right]. (10)$$

Equations (6), (7), (8), (9), and (10) look rather lengthy, but will be found very serviceable in designing columns and girders subject to direct stress and bending. The important subject of deflection of lock-gates is not mentioned in this discussion because it has been comprehensively treated elsewhere.[18]

FIG. 19.—MITER-SILL BUFFER

---

[18] "Kinetic Theory of Engineering Structures," by David A. Molitor, Chapter 14.

Contact at Miter-Sill.—The indeterminate conditions introduced by sill contact can be entirely eliminated in the manner described by the author, but when this is done, there should be provision for forcing centric mitering of the two gate-leaves at the instant contact is made on the miter-sill. With only a spring bearing at the sill, the chances for eccentric mitering are very great, and would lead to excessive stresses in the horizontal girders, besides causing delays in operation.

In January, 1912, the writer prepared a design for the lower lock-gate for the Mississippi River Power Company, at Keokuk, Iowa, which embodied several novel features not previously used in mitering gates. Among these was a spring-sill bearing having wooden contact surfaces with guards, and a miter-sill buffer, which forces simultaneous centric bearing of the miter-posts, prior to making spring contacts along the sill. The water pressure, as it gradually increases after closing the gate, forces all contact surfaces along the sill and miter-posts into tight bearing.

The Keokuk gate consisted of two leaves, 49 ft. high and 64.9 ft. wide, for a lock, 110 ft. wide, and a maximum lift of 34 ft. Figs. 18 and 19 show the miter-sill sealing edge and the miter-sill buffer designed for this gate. Hydraulic hand operation was first considered, but preference was given the automatic spring device for the buffer.

Other details may be mentioned only in a general way as the drawings are too extensive for the present discussion. The quoin and miter-post castings were designed to carry renewable metal bearing surfaces, the convex half being of steel and the concave half of lead-copper alloy cast in place, thus ensuring a good fit and saving much machine work.

The anchorage and pintle support were supplied with positive wedge adjustments for "take-up" of wear, and the wearing surfaces consisted of bronze bushings which could be replaced when the "take-up" was eventually exhausted after many years of service.

Side-Wall Analysis.—A side-wall with a large culvert opening, is analyzed as an arch with a superimposed load due to the wall above a certain plane, and acted upon by lateral earth pressure as shown on Fig. 20. All forces in this diagram are in kips (thousands of pounds), for a 1-ft. length of wall.

The solution of the arch portion may proceed according to the theory of elasticity, or by the line-of-thrust method, although when all the features of this problem are considered, the latter method has many advantages. When the arch is thick in comparison with the span, with sections irregular, and the loads diagonal non-parallel forces, the theory of elasticity becomes complicated, and the results are no more reliable than those obtainable by the simpler line-of-thrust method, which is based on the same fundamental principles. Hence, the laborious process is not justifiable.

The author's analysis is not an application of the method of least work, but represents an attempt to show that the most probable line of thrust actually corresponds to a condition of minimum internal work, a fact already well established. The following outline for a solution according to the theory of elasticity will clarify these matters and will establish the criteria for locating the most probable line-of-thrust.

FIG. 20

For a fixed arch, there are three redundant conditions, X_a, X_b, and X_c. Neglecting the effect of axial thrust (which is always small for semi-circular arches), the relations of these redundants, to the external loads, are expressed by the three following elasticity equations:

$$\frac{X_a}{EI}\int M^2_a\,du + \frac{X_b}{EI}\int M_a M_b\,du + \frac{X_c}{EI}\int M_a M_c\,du = \frac{1}{EI}\int M_o M_a\,du. \quad (11a)$$

$$\frac{X_a}{EI}\int M_b M_a\,du + \frac{X_b}{EI}\int M^2_b\,du + \frac{X_c}{EI}\int M_b M_c\,du = \frac{1}{EI}\int M_o M_b\,du \quad .(11b)$$

and,

$$\frac{X_a}{EI}\int M_c M_a\,du + \frac{X_b}{EI}\int M_c M_b\,du + \frac{X_c}{EI}\int M^2_c\,du = \frac{1}{EI}\int M_o M_c\,du \quad .(11c)$$

The three redundants, when found from Equations (11), for a given case of simultaneous loads, p, will determine the bending moment for any axial point, m, of the arch, by the following equation:

$$M_m = M_o - M_a X_a - M_b X_b - M_c X_c \ldots\ldots\ldots\ldots\ldots (12)$$

The expression for total internal work, due to bending and neglecting axial thrust, is,

$$W = \int_0^l \frac{M^2_m\,du}{2\,EI} = \int_0^l \frac{N^2_m e^2\,du}{2\,EI} \ldots\ldots\ldots\ldots\ldots (13)$$

in which, $M_m = N_m e$ represents the actual moment of the external forces by Equation (12), about successive axial points, m, and the integral extends over all points of the arch axis from 0 to l, with M_m and I as variables. The eccentricity, e, of the point of application of N_m, if treated as the only variable in Equation (13), will reduce the value of W to a minimum when $\int e^2\,du$ is minimum. This is the important conclusion in determining the most probable line-of-thrust as described subsequently.

In the present analysis, the three redundant conditions, X, are defined as follows, assuming the principal system to be a simple curved beam, A-B, without restraint: X_a = moment of restraint at the support, A, external to the simple beam; X_b = moment of restraint at the support, B, external to the simple beam; X_c = arch thrust acting along A-B; and, M_o = moment of the external forces, p, about any axial point, m, of a simple curved beam, A-B, when X_a, X_b, and X_c are not acting. M_a, M_b, and M_c are moments about the same axial points, m, for respective conventional loads, $X_a = 1$, $X_b = 1$, and $X_c = 1$, acting separately on the principal system, when the loads, p, are absent. The values of X_a, X_b, and X_c, if found from Equations (11) and inserted into Equation (12), are precisely those which give the minimum value to W in Equation (13), and, hence, the problem is solvable without using Equation (13), or resorting to trial-and-error methods.

However, when the external loads, p, are not parallel and are otherwise unrelated, then all functions involving M_o must be evaluated by some process of graphic summation which complicates matters to a point where the method becomes impracticable as in the present case; but even if a solution were carried through in this manner, the results would be no more accurate or reliable than those obtainable by the "line-of-thrust method" which is the method devised by the writer in 1907, for analyzing the walls of the Gatun Locks of the Panama Canal, as shown on Fig. 20.

The Line-of-Thrust Method.—The portion of wall, *ABCD* (Fig. 20), is treated as an arch, with the wall above acting as a superimposed load as shown. The external earth pressures acting between *A* and *C*, and the weights of the several voussoir stones (separated by assumed voussoir joints), constitute the system of external loads on this arch. These loads are combined graphically into Loads p_1 to p_{10}, acting on the respective voussoir stones. Owing to the unsymmetric shape and loading of this arch, the joint at *c* is chosen as the crown joint, while the springing joints are on the line, *A-B*.

First, the resultants, P_1 and P_2, of all external forces each side of the crown section, *c*, are found. This is done with the aid of a force polygon, by adding graphically the several loads, p_1 to p_{10}, in their proper order, true directions, and magnitudes. Then, the resultant, P_1, of the loads, p_1 to p_4, and the resultant, P_2, of the loads, p_5 to p_{10}, are found in direction and magnitude in the force polygon. A point on the line of action of each is found by drawing an equilibrium polygon, using any convenient pole, O_1, with pole distance, *t*. The intersections, d_1 and d_2, of the end rays, r_1 and r_2, with the pole ray, *t*, of the trial polygon, are the desired points, so that P_1 and P_2 are now fully determined. This much of the line drawing, including the dotted arch axis, should be drawn in ink so that the next steps, which are first drawn in pencil, may be erased after the final line of thrust is located by trial.

The foregoing really constitutes the preparatory work, and drawing the most probable line-of-thrust completes the analysis, giving the data for stress calculations for all voussoir joints.

The line-of-thrust in an arch ring, is a polygon found by joining, successively, the points of application of the resultant thrusts of the several assumed voussoir joints, as determined by an equilibrium polygon drawn for the given forces. Since any number of equilibrium polygons can be drawn through an arch ring, it becomes necessary to select the most probable one, for which the line-of-thrust satisfies the criterion: That the internal work of deformation, due to the actual loads, *p*, shall be a minimum. The terms, "equilibrium polygon," and, "resultant polygon," are synonymous, but distinct from the line-of-thrust.

The most probable line-of-thrust, according to the theory of elasticity, is that which reduces to a minimum, the residual departures from the arch center line according to the method of least squares. This is equivalent to making Σe^2 minimum, which is in agreement with Equation (13) for the condition producing the minimum internal work, *W*.

Hence, if a certain line-of-thrust can be made to coincide with the arch center line, then this particular thrust line will be the most probable one of all the possible lines for the given case of loads, making $\Sigma e^2 = 0$. For any other line-of-thrust, $\Sigma e^2 > 0$. Since values of e may be plus or minus, the sum of the squares can never become zero unless all values of e are zero.

As a first trial, draw a resultant polygon through three points *a, b,* and *c,* chosen on the axis of each section. This line, when obtained, will indicate how to shift the three points first assumed, so as to bring the resultant polygon into the closest possible coincidence with the arch axis. After two or three trials the line-of-thrust, *a c b,* was located as best satisfying the requirement, $\Sigma e^2 = 0_{\min}$.

There is a further condition which must be satisfied as follows: The line of thrust must intersect the arch axis in at least three points, and when the arch and its loading are both symmetrical, there must be at least four such intersections. Fig. 20 shows three intersections as required for unsymmetric cases.

The method of drawing a resultant polygon through three points, *a, c,* and *b,* is described as follows: Draw the two lines, K_2 and K_3, through the three given points and continue to the intersections, n_1 and n_2, with the resultants, P_1 and P_2. Then, draw the lines, K_1 and K_4. Now draw four lines, K_1, K_2, K_3, and K_4, in the force polygon, respectively, parallel to the lines just drawn and complete the parallelogram with the diagonal, $Oc' = T$, thus locating the pole, O, and determining the crown thrust, T, in direction and magnitude. This thrust acts at c, and the line, $m_1 m_2$ parallel to T, determines the final reactions, $m_1a = R_1$, and $m_2b = R_2$. The vertical component of R_1 is N_1, and the vertical component of R_2 is N_2, from which the stresses on the sections, *AB,* are found.

The stresses on any other voussoir joint are obtained from the line of thrust, by completing the resultant polygon for the correct pole, O. The rays, drawn from O to the several corners of the load line of the force polygon, represent the resultants on the several voussoir joints, measured to the scale of forces. The normal components, N, with the eccentricities, e, all scaled from the diagram, determine the stresses on the sections.

The stresses on any voussoir joint are now found from Navier's law for direct stress and bending, as follows:

When $e < \frac{D}{6}$,

$$f = -\frac{N}{D}\left(1 \pm \frac{6e}{D}\right) \dots\dots\dots\dots\dots\dots (14)$$

and, when $e > \frac{D}{6}$, allowing no tension,

$$f = -\frac{2N}{3\left(\frac{D}{2} - e\right)} \dots\dots\dots\dots\dots\dots (15)$$

In Equations (14) and (15), N represents the normal component of the resultant acting on the joint of width, D, and unit thickness, and e is the eccentricity of the point of application of N, as shown for the base sections on *A-B* (Fig. 20).

It is easily seen from Equation (14) that when the line-of-thrust remains everywhere within the middle-third, there will be no tensile stresses.

This completes the analysis, on a theoretically sound basis and with sufficient accuracy for all practical purposes. Had the author applied the criteria as here presented, for identifying the most probable one of all possible lines-of-thrust, all his involved calculations would have been avoided.

In Table 1 the sum of Column (7), representing the internal work due to axial thrust, and treated as a constant, contributes nothing of value, for which reason the author should have neglected axial thrust. If the sums are taken for Columns (9), (12), (15), (18), and (21), it will be found that Column (18) gives $\Sigma e^2 =$ minimum, which is the only conclusion of any value. These sums are not a true measure for minimum Σe^2, because the voussoirs were not taken at constant distances apart on the axis; hence, $d\,l$ should have been taken in as a variable factor.

The author further states, following Equation (5):

> "There are three unknown quantities to be obtained, the horizontal and vertical components, and the point of application of the crown thrust, and all are determined very easily by this process."

If he means by this that these three unknowns constitute the three redundant conditions involved in the arch problem, then he is seriously in error, because the three unknowns of which he speaks, merely determine one of the three redundants. He has thus solved a threefold statically indeterminate problem by considering only one.

All methods for the evaluation of the three redundant conditions in arches of the kind here treated, are more or less speculative; but they yield results which are within knowable limits, especially when the heterogeneous character of building materials is considered. Whether the resultant polygon and line-of-thrust are located correctly by the method of least work, by the elastic theory, or by a few trials observing the criteria stated herein, makes very little difference except in the labor involved, and certainly the least laborious solution is the most acceptable. If the problem dealt with large flat arch ribs, having thin rings and carrying vertical loads, then the theory of elasticity would be applicable and would afford the best and most accurate method of arch analysis.[19]

Charles A. D. Young,[20] M. Am. Soc. C. E. (by letter).—The author has presented a thorough description of the many interesting problems which arise in the design of navigable waterways and the accompanying locks and dams. The adaptation of the principles of the Venturi meter to the design of the culvert valve chambers is a valuable contribution to the art, and the results will be watched with interest by all concerned with the design of locks. If the results obtained in operation are as anticipated, this design, no doubt, will be adopted wherever applicable because it will afford a material saving in the cost of the valves and their operating machinery.

---

[19] "Kinetic Theory of Engineering Structures," by David A. Molitor, Chapter 15.

[20] Senior Engr., U. S. Reclamation Bureau, Denver, Colo.

It is only within comparatively recent years that the scientific design of lock-gates has been given much consideration, and as yet no method has been devised for determining the stress transferred to the upper girders by the vertical framing when the gate is in contact with the sill. It has been the custom to compensate for these indeterminate stresses by adding to the water load a certain amount of static head at the upper part of the gate; but by eliminating the cause of the indeterminate stresses as the author does, the design of a lock-gate becomes a comparatively simple problem and this excess head may be omitted.

In the design of the gates, as described by Mr. Smith, there is no contact at the sill and hence no indeterminate stress; but it is noted that an allowance of a 15-ft. head at the upper part of the gate was made to compensate for shock.

Standard specifications for structural steel construction provide that no steel less than $\frac{5}{16}$ in. thick shall be used. Due to the fact that lock-gates are particularly susceptible to corrosion, it is considered good practice to limit this thickness to $\frac{3}{8}$ in. When the girders are equally spaced and of equal depth, it is found that the upper ones will be much stronger than required to resist the static head.

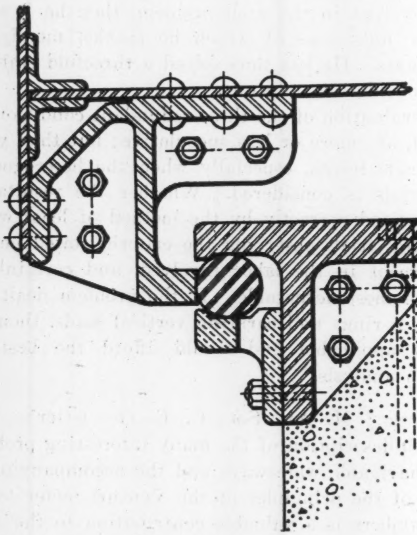

FIG. 21.—SECTION THROUGH SEAL; LOCK-GATE AT WILSON DAM

No doubt the spring seal, described by the author and designed to eliminate pressure between gate and sill, will provide an efficient seal, but experience with similar seals on the Stoney culvert valves at Panama, and at the Lake Washington Canal Lock, at Seattle, Wash., indicates that it may be short-lived. In the cases cited, after operation for a short time, the spring broke near the point of attachment to the valve, presumably due to vibration caused by slight leakage. The springs were replaced by heavy rubber belting and no further difficulty was experienced.

The first attempt to eliminate pressure at the sill that has come to the writer's attention, was in the design of the lock-gates for the double-lift lock at Wilson Dam (Muscle Shoals) on the Tennessee River (see Fig. 21). As the head is increased behind the gate, the water pressure acts through the holes in the lower support and forces the solid rubber bar against the gate. This same method was used by the writer on the gates for Lock and Dam No. 1, Tennessee River, at Florence, Ala., and in both cases was very successful in operation.

Adjustable bearing-plates backed by Babbitt metal, similar to those described by the author, were used on the lock-gates of the Lake Washington Canal. In this case the gates were swung to the closed position, the plates were forced out by set screws until they were in perfect contact, and the molten metal was poured in from the top. In order to insure that the space was completely filled with the Babbitt metal, the plates were removed, and large cavities were found due to the molten metal congealing on the sides near the top and clogging the opening. This difficulty was eliminated by drilling holes about 4 ft. apart and pouring in 4-ft. lifts.

It is interesting to note the effect on the stresses, of placing the sheathing plates on the down-stream side of the gate. Such placing of skin-plate has been considered an advantage in single-skin gates in order to reduce the uplift on the bottom when the gate was closed; but as this puts tension in the rivets that hold the skin-plate, it has seldom been done. One case only has come to the writer's attention and that was in the Tennessee River Lock, at Riverton, Ala. In this case, the girders were I-beams, and it is doubtful whether the designer had any other object in mind than the reduction of uplift. From an operation standpoint such an arrangement is objectionable because in a silt-bearing stream, such as the Tennessee, the girders fill with mud and débris which is difficult to clean out for painting.

The writer agrees with the author that gate anchorages made of eye-bars are difficult to set, but it is his experience that those built of structural members in the shape of a triangle are easily set and held in position, since they are rigid and may be held in place by anchor-bolts. This type of anchorage was used on the Lake Washington Canal Lock. The type described by the author has the advantage perhaps that it does not extend deeply into the concrete and can be placed after the concrete has been poured.

The method of adjusting the rotation axis of the gate as described by the author, was used on Davis Lock at Sault Ste. Marie, Mich., in order to secure the fine adjustment required and, at the same time, to provide the necessary strength of threads, and it has been used on other locks. Observation of the difficulties encountered in removing a gate-leaf of the Poe Lock at Sault Ste. Marie, prompted the writer to introduce the two eye-bars which can be swung out of the way and permit the gate to be lifted off its pintle without changing the adjustment.

Since the change in temperature of a lock-gate may materially change its location when mitered, a spring has been introduced in the spar, in some cases where the bull-wheel is used, to allow full stroke for all conditions. This spring also acts as a cushion to relieve the machinery of undue strain in starting and stopping the gate.

The addition of air chambers to lock-gates is of questionable value since the anchorages and pintle must be made of sufficient size to carry the load of the gate when swinging in air, which is necessary during construction for the purpose of making adjustments and, at other times, when the lock is unwatered for painting or repairs. It is true that the amount of swinging done under these conditions is small compared to the operation conditions, but if the pintle and gudgeon pin are conservatively designed to carry the full load of the gate in air, the wear on these parts will be kept at a minimum.

WALTER M. SMITH,[21] M. AM. SOC. C. E. (by letter).—Since the publication of this paper the Illinois Waterway has been practically finished, except for the completion of some of the bridges.

Owing to the tremendous increase in costs from the time the bond issue was voted for the construction and the time of construction, it was realized, in 1929, that the funds provided by the bond issue would not be sufficient. There were two possible ways to complete the Waterway. The first was for the State of Illinois to vote an additional bond issue. As the Illinois Constitution prohibits the State from lending its credit to the construction of railways or waterways, this would require an amendment. The Illinois Constitution also prohibits more than one amendment being voted on at any election, and there is always some important amendment to be voted on at each election. It was evident that this method would take years for completion, if successful, and there was a strong probability that it would not be successful.

The second method was to ask the Federal Government to furnish the money and complete the Waterway. It was impossible to turn the Waterway over to the possession of the United States Government because it belongs to the people of Illinois and can only be surrendered by a popular vote and very probably it would require another amendment to the Constitution to allow this vote to be taken. However, the President recommended, and Congress provided, the funds to complete the Waterway, except the bridges crossing it. The State, therefore, stopped work in 1930 to retain sufficient funds to construct the bridges.

The United States War Department began work on the project in February, 1931, the State concentrating its work on the bridges. At this time the lock and dam at Starved Rock, the Marseilles Lock, and the Lockport Lock were practically completed, except for the installation of equipment for electrical operation of lock-gates and valves. Brandon Road Lock was finished, except the installation of operating machinery, and the dam and walls through Joliet were about 75% completed. Marseilles Canal was about 90% completed. Dresden Island Lock was about 30% completed, but only a portion of the excavation had been done for the dam.

---

[21] Asst. Chf. Engr., Div. of Waterways, State of Illinois, Chicago, Ill.

Marseilles Dam had been designed but work had not been started on it. All metal work had been provided for Dresden Island Lock and Dam as well as the machinery for operating the gates and valves at Dresden Island and Brandon Road Locks.

The Des Plaines and Illinois River Valleys have abundant banks of gravel of a fine quality for concrete. In many of them the gravel does not need to be washed or screened to size. Concrete, with bank-run gravel, was used in all the structures built by the State, because it had been found satisfactory for massive works and was much cheaper than the washed and screened material. The Engineers of the War Department were not accustomed to the use of bank-run gravel in concrete so when they took over the Waterway, they very naturally wished to satisfy themselves as to the quality of the concrete in the structures built by the State Engineers. Therefore, they had many cores, 6 in. in diameter, cut to a depth of 10 ft in the Lockport, Brandon Road, Marseilles, and Starved Rock Locks. Sample pieces, 12 in. long, were then cut from these cores and tested, generally from two to four test specimens from each core. Wherever there were places in the cores that appeared bad, they were included in the test specimens because the Engineers wished to know the worst. In many places one stone would occupy more than one-half the area of the test cylinder. The results are given in Table 2. It is to be noted that from one to five test pieces were cut from each core.

TABLE 2.—Summary of Core Tests of Concrete

Lock	Number of cores	Number of specimens	Breaking Strength, in Pounds per Square Inch		
			Minimum	Mean	Maximum
Lockport	5	19	3 117	5 746	7 874
Brandon Road	4	15	3 915	5 228	6 913
Marseilles	3	11	2 779	4 975	7 666
Starved Rock	4	15	3 510	5 038	7 689
All tests	16	60	2 779	5 306	7 874

This concrete generally contained from 4½ to 5 bags of cement per cu yd, except for the upper part of the lock-walls where the water rises and falls. In this part of the work generally about 6 bags of cement were used per cu yd of concrete, in order to obtain greater density and to prevent spalling of the face from frost action.

Before turning the Waterway over to the War Department Engineers, tests were made on the operation of the gates and valves at Lockport, Marseilles, and Starved Rock Locks.

The specifications called for operating each pair of miter-gates through fifty complete cycles continuously, allowing 2 min each for opening and closing and a ½-min allowance at each end of each swing. This would require each pair of gates to be operated fifty times in 4 hr and 10 min. The lower gates operated under service conditions, but the upper gates had to be operated "in the dry." The lock-gates at Starved Rock and Lockport were swung only five times in order to avoid injuring the pintles. At Lockport, the upper gates were required to open or close in 2 min. No specific test was prescribed. These units are vertical lift-gates, only the lower gates being of the miter type. The leaves are 59 ft high and weigh about 320 tons each. The results of the tests of the miter-gates are shown in Table 3.

TABLE 3.—TESTS OF MITER-GATES

Location	LOWER GATES (150 CYCLES)					UPPER GATES		
	Average time of opening, in seconds	Average time of closing, in seconds	Average time lost, in seconds	Total time elapsed, in hours	Total time allowed, in hours	Average time of opening, in seconds	Average time of closing, in seconds	Average time lost, in seconds

Taintor Gates at Starved Rock.—The Taintor gates at the Starved Rock Dam were all completed and tested before the Waterway was turned over to the Government. The War Department Engineers made some tests of the flow through these gates partly open, varying from a small fraction of a foot to about 9 ft. With the water in the reservoir averaging about 4 to 5 in. below the level of the tops of the gates when closed, runs were made with the results shown in Table 4. Confidence can be felt in the reliability of the coefficients obtained.

TABLE 4.—COEFFICIENTS OF FLOW THROUGH TAINTOR GATES AT STARVED ROCK DAM

Item	Number of gates open	Height of opening, in feet	Coefficient
1	9	0.797	0.996
3	8	1.066	0.964
2	7	0.931	0.931
4	6	1.268	0.982
5	1	9.000	0.737

The openings under the gates were entirely submerged, except in the case of Item 5 where the lower edge of the gate was about 7.06 ft above the level of the lower pool.

There is a large pool up stream from the Starved Rock Lock, but the deep water is on the opposite side of the valley where it has just the depth necessary for navigation. Down stream, the water is carried away in the standard channel of the waterway 200 ft wide by 10 ft deep.

The consequence of this is that when the upper valves are opened to fill the lock, the up-stream water drops and does not regain the full head for about 5 min; therefore, for two-thirds of the time of filling, the flow is not under full head. Furthermore, when the lower valves are opened to empty the lock, the first rush of water lowers the down-stream flow for a few seconds. It then surges back and rises higher than normal, decreasing the head for emptying materially; this excess head down stream gradually lowers as the flow from the lock decreases.

In the past, trouble has been caused by surging of water in locks during filling or emptying, making it necessary to limit the rate of rise or fall in the lock. A careful study was made of this subject by Mr. Cornish, and he came to the conclusion, that there should be more ports from the culverts into the up-stream half of the lock than into the down-stream half. He developed a formula for the spacing of the ports.

By referring to Fig. 2 in the paper, it will be seen that there are six ports from each culvert in the up-stream half of the lock, while there are only four in the down-stream half. It will also be noticed that these ports are not equal distances apart, there being a long distance near the center of the lock with no ports.

On account of Mr. Cornish's study, the tests were made to find not only the time of filling and emptying and the corresponding coefficients, but to see whether objectionable surging had been eliminated. The latter is much more important than a small difference in the coefficient of filling and emptying, as it generally takes considerable time to moor a vessel securely if the surging is great. In the tests, therefore, an attempt was made to determine the exact time of fall or rise of each foot at each end of the lock during each filling or emptying. An observer was stationed at each end of the lock with a tape line attached to a float. During the operation each observer would read the time on a stop-watch for each foot of rise or fall. The method was rather crude as the floats were not protected from the rough water in the lock during filling.

In Fig. 22 is shown some typical curves of flow for emptying and filling the lock. Curve 1 is for emptying the upper end and Curve 2 for emptying the lower end. Comparing these two curves, it will be seen that there is a slight surging, but not more than 1 in. from the normal at either end, because of a maximum difference in level of from $1\frac{1}{2}$ to $1\frac{3}{4}$ in. between the water at the up-stream and down-stream ends. The following flow coefficients were determined, from the time the valves were fully open, on the basis of difference in head:

	Emptying lock	Filling lock
Culverts, upper end, $C =$	0.76	0.77
Valves, upper end, $C =$	1.06	1.05
Culverts, lower end, $C =$	0.73	0.78
Valves, upper end, $C =$	1.03	1.06

It is seen that a coefficient of from 0.73 to 0.75 was obtained for the culverts and from 1.03 to 1.06 for the valves.

It was observed that at the beginning of the opening of the valves the water in the canal below the lower gates was first shoved away down stream and the level was lowered about 0.7 ft. It surged back quickly until it rose to 1.5 ft above the level of beginning of flow and then very slowly lowered

so that for almost the entire time of emptying the lock the actual head causing the flow was materially less than the theoretical head used in the computations. Therefore, the actual coefficient should be considerably greater than the one shown.

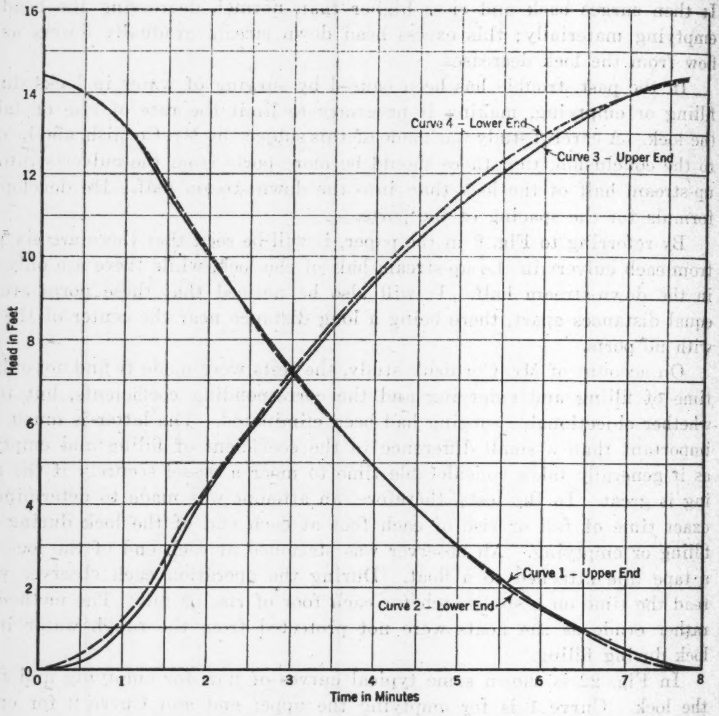

FIG. 22.—STARVED ROCK LOCK OPERATING TEST

Curves 3 and 4 in Fig. 22 are typical of flow for filling the lock, observation being made at both the up-stream and the down-stream ends of the lock the same as in the emptying test.

It will be noticed from these curves that the surface at the up-stream end is consistently from 2 or 3 in. above the surface at the lower end until just before the lock is full, when they practically coincide. It will also be noticed that coefficients of 0.77 and 0.78 are obtained for the culverts and 1.05 and 1.06

for the valves. In this case, also, the actual head causing the flow is considerably less than the head used in the computations from the fact that upon opening the valves the head-water falls 0.8 ft in the canal above the gates before the valves are fully opened, and does not regain its level for 5 min; therefore, the lock is filling under a smaller head than that used in the computations.

When the valves and culverts were designed by the writer, it was hoped to obtain, as a possible maximum coefficient, 0.83 for culverts and 1.15 for the valves. It was realized, however, that seldom is a coefficient of more than 0.75 obtained for the culverts in a lock of this type, and as the valves did not reduce the flow in the culverts below this coefficient, it seems conclusive that they are working as well as larger valves, which answers Mr. Sargent's question about the operation of the valves.

A tow consisting of a large towboat, dredge barge, and derrick barge, coupled end to end and occupying about 300 ft, was locked through between two of the tests. To show how little surging there is during filling at full speed, this tow had out only one stern line and one bow line for the entire tow, and neither of these lines were taut at any time during the filling. Furthermore, the vessels did not move more than a foot away from the lock-wall during filling. The entire time from passing the lower gate going in to passing the upper gate going out was 20 min, and a part of this time was used in taking on water after the upper gate had been opened.

TABLE 5.—COMPARISON OF FLOW COEFFICIENTS THROUGH CULVERTS AND VALVES

Description	Pedro Miguel Lock, Panama Canal	Starved Rock Lock, Illinois Waterway
Flow Coefficients:		
Filling chamber with two culverts	0.65	0.775*
Emptying chamber with two culverts	0.67	0.745*
Filling chamber with side culvert only	0.82	....
Emptying chamber with side culvert only	0.73	....
Filling chamber with center wall only	0.52	....
Emptying chamber with center wall only	0.66	....
Filling lock-chamber with two culverts (for valves)	....	1.055
Emptying lock-chamber with two culverts (for valves)	....	1.045
Areas of Cross-Section, in Square Feet:		
Valves	576	162
Culverts	510	226
Ports	1 285	350
Proportions:		
Valves	1.00	1.00
Culverts	0.88	1.40
Ports	2.23	2.16

* For culverts.

The coefficients obtained in filling and emptying the Pedro Miguel Lock[22] of the Panama Canal are compared with those of the Starved Rock Lock in Table 5, as are also the comparative areas of valves, culverts, and ports in the two structures. It will be noticed that the Panama locks have a culvert area 2.25 times, a port area 3.68 times, and a valve area 3.6 times, as great as the locks of the Illinois Waterway. The Panama locks have a ratio of valve area to culvert area of 1 to 0.88, whereas the Illinois Waterway locks have a ratio of 1 to 1.4, and the Waterway has as high a coefficient of flow as the Panama Canal.

---

[22] "Hydraulics of the Locks of Panama Canal," by R. H. Whitehead, Vol. II, p. 200, of "The Panama Canal," by the late George W. Goethals, Hon. M. Am. Soc. C. E.

The spring sealing strips along the lower edge of the miter-gates to form contact with the miter-sill have given some trouble at the up-stream gates at Starved Rock Lock. When filling the lock a slight noise and vibration starts in the gates when the water in the lock has risen to within about 5 ft of the level of the water in the canal above the up-stream gate. This noise and vibration increases slightly for the next 2 ft of rise; then it gradually dies down and stops when the difference of level is somewhat less than 1 ft. Apparently, this vibration is caused by the pressure not being sufficient to keep the spring in close contact with the sill when there is a moderate difference in head. The same noise and vibration between these same levels occurs while emptying the lock. Some of the bolts attaching the spring seal to the gate have been broken by the vibration. It is singular that no noise or vibration occurs in the lower gates.

Bridges.—As stated in the paper, the State was required to replace twelve bridges across the Waterway. It was decided to have two of these bridges constructed by the State Division of Highways and the other ten by the Division of Waterways.

In Joliet, Ill., it was decided to construct four bridges of the rolling-lift bascule type. The fifth bridge in Joliet will be of the trunion bascule type similar to the Brandon Road Bridge. The Brandon Road Bridge was finished and thrown open to traffic in the latter part of 1932.

The cheapest type of bridge that could be used is the simple through-truss fixed bridge and whenever conditions would allow, this type was used. There are two bridges of this type. The fourth type used is a cantilever at Ottawa, Ill. This bridge, while costing slightly more than a simple through truss, was much better suited to this location on account of the long center span, as the Fox River enters the Illinois River immediately above the bridge. Furthermore, the elimination of falsework under the main span is a very desirable feature in the construction of the bridge.

Mr. Sargent has raised various points in discussion. The question as to the success of the future method of valve construction has already been answered. The valves operating under their own weight only, in closing, work with thorough satisfaction as the friction in the roller bearings is very slight.

A skin is used only on one side of the gates and is solely for economy. The reason for putting it on the down-stream side was to make it possible to put the miter-sill along the down-stream side of the gate instead of back beneath the gate.

The emergency dam at Lockport is so simple that there is little prospect of its giving trouble, and it has been operated and thoroughly adjusted. The recess under the up-stream leg is protected so that nothing can get in it but sediment, and this can be sluiced out at any time by connecting the recess with the down-stream pool at one end and the up-stream pool at the other. This will wash the chamber out thoroughly.

Lines of mooring posts have been provided at various levels in recesses in the side-walls of the locks so that lines can be changed as the barges rise or fall. As stated, all appreciable surging has apparently been eliminated in these locks so that very little mooring is needed.

Mr. Walker inquires about the success of the Venturi principle in the valves. He also inquires about the reasons for the adoption of the miter-gates with a rise of 1 to 2 in the sills and with parallel faces.

A very thorough study was made in the design of the gates for the Panama Canal Locks, and actual designs were made upon which prices were obtained. The result was that the type of gate adopted is the one that was shown to be most economical in that investigation. Inasmuch as the Illinois Waterway Locks are the same width as those at Panama, it is evident that the same condition obtains here. A complete account[23] of the investigations pertaining to the Panama Locks was published by Henry Goldmark, M. Am. Soc. C. E.

The detail of the miter-post is exactly the same as the quoin-post, except that the adjustable bearing pieces are alike in both miter-posts and that the convexity of the abutting surfaces are of a much longer radius.

Both Mr. Walker and Mr. Molitor criticize, severely, the method of analyzing the stresses in the side-walls in the part surrounding the culverts. Attention is called to the original paper under "Side-Wall Analysis," where the writer states, "it is not claimed that this method will give exact results, but it is believed to give results nearer the truth in a case of this kind than any other method." He is still of that opinion. Contrary to opinions expressed by Messrs. Walker and Molitor it is believed to be well worth the time spent upon it even if the results are approximations. Engineering structures are designed and built every day under assumptions just as uncertain as any made in this case.

CONSTRUCTION WORK ON A FEDERAL RECLAMATION PROJECT

BY MORRIS MASON,[1] JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. JOHN SANFORD PECK, EDWARD W. BUSH, ORRIN H. PILKEY, CLIFFORD A. BETTS, GEORGE C. IMRIE, ARTHUR RUETTGERS, AND MORRIS MASON

SYNOPSIS

This paper deals specifically with the Kittitas Division of the Yakima Project, in the State of Washington, constructed by the United States Bureau of Reclamation. All irrigation projects undertaken by the Bureau are similar in character, although new ideas of design and new methods of construction are introduced in each new structure. Most of the structures on any one project are small in size, but generally the topography of the ground and the type of structure are such that the method of constructing each unit must be different from any other. There is a great variety in size and type of structures. The choice of a method of construction is placed in the hands of the contractors, subject to the approval of the engineers. In the case of small units, it is uneconomical to install elaborate and expensive set-ups of machinery.

It is the purpose of this paper to give the history and general description of the Kittitas Division of the Yakima Project as a whole, with an enumeration and description of the various structures, and the more common methods of construction. The large quantity of concrete involved (150 000 cu. yd.), varying in strength from mass concrete in the diversion dam to the extremely high-strength concrete in the high-head siphons (all of which must be of high impermeability), made necessary a very strict supervision of the proportioning and mixing of the aggregate. The method by which a concrete of known and uniform quality was attained, will also be of interest to engineers engaged in this class of work.

NOTE.—Published in October, 1931, *Proceedings*.

[1] Engr., Standard Oil Co. (Indiana), Wood River Refinery, Wood River, Ill.

HISTORY

The history of irrigation in the Kittitas Valley, situated in the central part of the State of Washington, dates back to before the appearance of white men in that region. As farming developed in a larger way and more land was put under cultivation, there was more demand for water. Private and community low-level canals were then put in to serve a few farms along the Yakima River and its tributaries. As early as 1889 active survey work was in progress for the construction of a high-line canal to serve the farms on the higher benches and to provide more water for the low farms. Actual construction was begun on some of these canals, but it resulted in failure because of lack of funds. Stretches of the canals are still in evidence. Some survey work was done by the Government on the high-line canal prior to 1910. The Kittitas Reclamation District entered into a contract with the United States for water from Government reservoirs in 1921. In 1923 a board of engineers appointed by the United States Bureau of Reclamation decided that the Kittitas Unit should be selected for first construction, four divisions of the Yakima Project being considered. These were:

1.—Kittitas Division, covering approximately 72 000 acres of irrigable land, near Ellensburg, Wash.
2.—Moxee Division, covering about 35 000 acres of irrigable land, just east of Yakima, Wash.
3.—Rosa Division, covering about 60 000 acres of irrigable land, above the present Main Sunnyside Canal and lying north of the Towns of Sunnyside and Grandview, Wash.
4.—Kennewick Division, covering about 35 000 acres of irrigable land, west of the Columbia River at its confluence with the Yakima River near the Town of Kennewick, Wash.

Surveys were begun in 1924. General authority for the construction of the Kittitas Division was contained in a contract dated December 19, 1925, between the United States and the Kittitas Reclamation District. The active construction period began in April, 1926. Prior to this time the feasibility of the project from an engineering and economic standpoint had been thoroughly investigated. Topographic and soil surveys of the entire area were made, and the value of each 40 acres, or less (according to the legal subdivision lines, and including improvements), had been determined by a Board of Appraisers appointed jointly by the Government and the Reclamation District.

GENERAL DESCRIPTION

The Kittitas Division of the Yakima Project includes the arable lands of the Kittitas Valley in the State of Washington, with the exception of the bottom-lands which have been irrigated from the Yakima River for many years. Figs. 1 and 2 show the part of the Kittitas Valley to be embraced in the District. The main body of the land includes ranges in elevation from 1 700 to 2 100 ft., and surrounds the older irrigated lands in the form of an ellipse, with the Yakima River as the major axis and the City of Ellensburg near the center. FIG. 2.—MAIN BODY OF LAND INCLUDED IN THE KITTITAS PROJECT FARTHER EAST OF, AND OVERLAPPING, FIG. 1.

The area included within the limits of the Division is approximately 96 000 acres. The estimated irrigable area is 72 000 acres, of which 58 250 acres are in private hands; 6 750 acres are owned by the Northern Pacific Railway Company and by its subsidiary, the Northwestern Improvement Company; 5 400 acres are public land; and 1 600 acres belong to the State. Two impounding reservoirs are in use in connection with the Lower Yakima Project, surrounding Yakima, Wash. These reservoirs are situated at Lake Keechelus and Lake Kachess. (See Fig. 1(*a*).) From these points, water is fed into and supplements the natural flow of the Yakima River. Diversion into the Kittitas Main Canal is affected at the foot of the Cascade Mountains through the construction of a dam north of Easton, Wash. The Main Canal is parallel to the Yakima River for approximately 25 miles. The water is then divided at the South Branch Head-Works (Fig. 1(*b*)). Most of the water is carried in the North Branch Canal about a mile to the Yakima River Crossing, from which point the canal extends around the north and east sides of the Kittitas Valley, about 36 miles to the Whipple Pumping Plant (Fig. 2). Here, a portion of the water is lifted to a higher level by a direct-connected turbine pump. The gravity canal, pump canal, and drop canal extend around Badger Pocket. These laterals end at the mouth of the Yakima River Canyon about 6 miles southeast of Ellensburg. At the South Branch Head-Works 250 sec-ft. of water is diverted from the Main Canal. From there, it is carried in the South Branch Canal down the south side of the Kittitas Valley about 14½ miles to Manastash Creek, from which point delivery is made as far as the Yakima River Canyon by a main lateral.

PERSONNEL ORGANIZATION

All work is done under the supervision of the Construction Engineer. The Office Engineer and the Principal Field Engineer have headquarters in the Project Office in Ellensburg. The location engineers, designers, draftsmen, bookkeepers, and clerks are under the supervision of these men. Minor designs, including the preparation of steel bending and cutting lists, are made in the Project Office, where, also, purchasing and material accounts are kept. Division engineers are in direct charge of construction, each having charge of a separate division of the Project. Each Division Engineer has an office engineer, clerk, field parties, and inspectors. There were four Division Offices in operation on the Project, but only three at any one time. The work on the First Division was completed in sufficient time for the engineer in charge of that office to direct the work in the office of the Fourth Division also. All monthly estimates for contract payments are made in the office of the Division Engineers.

Structures of major importance are designed in the office of the Chief Engineer in Denver, Colo., who has general supervision of all irrigation work. The Commissioner of the Bureau of Reclamation, in Washington, D. C., is in charge of all work done by the Bureau.

DIVERSION DAM

The diversion dam is on the Yakima River just above the Town of Easton and a mile down stream from the junction of the Kachess and Yakima Rivers. It is situated in a timbered country on the eastern slope of the Cascade Mountains in a region subject to heavy snowfall during the winter months. The dam is a straight, gravity-type, concrete structure with an over-all length of 248 ft.; and it raises the water surface approximately 43 ft. above the low-water level in the river. Fig. 3 shows the plan and elevation of the dam. The reservoir has an area of about 240 acres and impounds about 4 000 acre-ft. of water. The lake formed is about 1½ miles long by ½ mile wide. The level of the water in the lake must be held practically constant in order to keep the water in the canal at the designed height. Any appreciable rise in the lake level will damage both of the railway tracks that border the lake on the south

SECTION THROUGH SPILLWAY

FIG. 4.—SECTIONS THROUGH DIVERSION DAM

The spillway section is 64 ft. long, and is provided with a 64 by $14\frac{1}{2}$-ft. structural steel, floating drum-gate. The automatic control of the gate is accomplished through a float which operates a 16-in. balanced valve which, in turn, controls the water pressure in the drum-gate float chamber beneath the gate and raises and lowers the gate. The automatic operating mechanism holds the water level in the reservoir at a constant elevation of 2 180.3 ft., the drum-gate automatically rising and lowering to accommodate a change in elevation of water level in the reservoir. The spillway capacity with gate lowered is 13 000 sec-ft. while the maximum recorded flow of the river at this point is 6 000 sec-ft. The automatic control mechanism of the drum-gate is contained in the gallery in the right pier, adjacent to the spillway section. The emergency valve for controlling the drum-gate by hand operation is in the left pier. Two 4.8 by 6.0-ft. sluicegates are provided at the river level of the dam. These gates are used for sluicing out the sand which accumulates during the irrigation season, and to pass the low flow of the river during the non-irrigation season. Conforming with the regulations of the Department of Fisheries of the State of Washington a fishway is provided in the north side of the river, having twenty bays and a rise of 2 ft. 1 in. between bays. The canal head-works are located on the extreme right of the dam and adjacent to the Northern Pacific Railway tracks. Two 12 by 11-ft. radial gates, motor-operated, control the flow of water into the Main Canal.

A full description of the diversion dam has been presented by Messrs. G. C. Imrie and A. A. Whitmore.[2]

THE CANALS

The canal system is composed of a single primary canal and two branch canals, as shown in Fig. 1(*b*).

---

[2] *New Reclamation Era,* March, 1931, p. 54.

Location.—From the diversion dam to the South Branch Head-Works, about a mile west of the Yakima River Crossing, the Main Canal of this project extends for a distance of about 25 miles. Its capacity at the point of diversion is 1 320 sec-ft. The variation in dimensions and hydraulic properties of the regular sections of the Main Canal is shown in Table 1. The side slopes in the regular sections of all canals were 1 on 1½ in the unlined sections and 1 on 1¼ in the lined sections. There were a number of special sections. All the reinforced concrete lining in the regular sections was 3 in. thick. About 50% of the Main Canal is concrete-lined although this lining is not all 3 in. thick and reinforced. Due to the topography of the ground, the canal follows along the side-hill slopes. In some places on account of very steep slopes it was impossible to build or to hold the lower banks. In these places combination sections of canal lining and bench flume were constructed. This section has a regular canal section on the inside and a vertical retaining wall on the outside. (See Fig. 5.) About 140 ft. of bench flume was also used. The walls of the bench flume and the outside wall of the combination sections were 11 ft. above the inside of the canal. These walls were 6 in. thick at the top and 14 in. at the bottom, reinforced on the inside and outside. The inside wall on the combination section was 6 in. of plain concrete and was poured against the trimmed rock face of the bluff. The hand-placed rock on the bluff side is shown in Fig. 5. There were also four canal sections termed "lined rock sections," which were excavated in shattered basalt formation, with side slopes of 1 on ½. These sections were lined with an average thickness of 6-in. plain concrete with a minimum thickness of 2 in.

The earth sub-grade of the lined sections of canal is trimmed and tamped to accurate dimensions. The operation of trimming canal sections to prepare for lining (see Fig. 6) is paid for as a separate unit at so much per square yard.

The South Branch Canal has a capacity of 250 sec-ft. at the head-works and the flow is controlled at this point by electric, hoist-operated, radial gates. The Main Canal gate is 15 ft. long and 8 ft. high, and the South Branch gate is 8 ft. long and 8 ft. high. The South Branch Canal is about 14½ miles long and its capacity at the end is 32 sec-ft. and, from that point, the total flow is taken in a main lateral which extends to the Yakima River Canyon (see Fig. 2). About 1¼ miles of the South Branch Canal is lined with 3-in. reinforced concrete slab; the remainder is unlined. The variation in dimensions and hydraulic properties of the regular canal sections is shown in Table 1.

The North Branch Canal is 36 miles long, 3¼ miles of which are ordinary, or combination, section. The variation in dimensions and hydraulic properties of the regular sections of the North Branch Canal is shown in Table 1. A part of the regular lined section is 4-in. reinforced concrete; the remainder of the regular lining is 3-in. reinforced concrete. There is a stretch of combination section between the South Branch Head-Works and the Yakima River Crossing. It has a vertical wall on the outside, 9 ft. high, 6 in. thick at the top, and 11 in. thick at the base, with reinforcement on the inside.

TABLE 1.—DIMENSIONS AND HYDRAULIC PROPERTIES OF REGULAR SECTIONS USED IN ALL CANALS

Dimension	MAIN CANAL		NORTH BRANCH CANAL		SOUTH BRANCH CANAL	
	Unlined sections	Lined sections	Unlined sections	Lined sections	Unlined sections	Lined sections
Number of sections	5	9	19	6	15	4

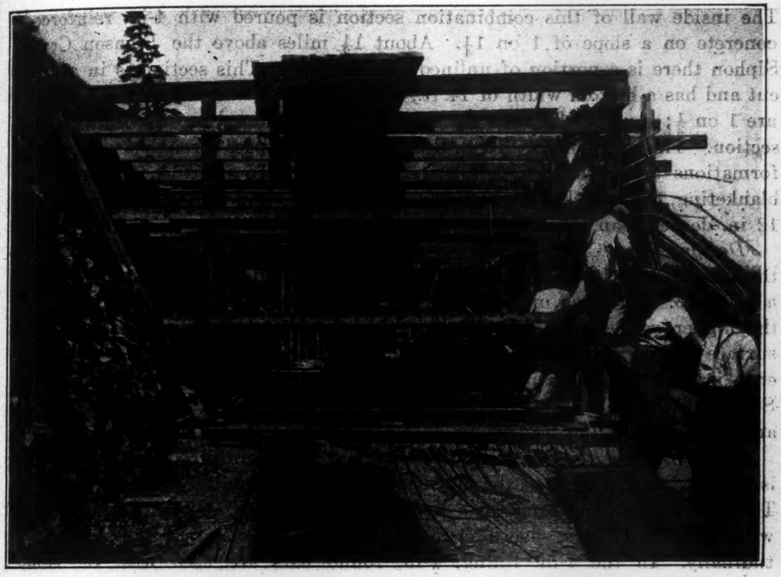

FIG. 5.—PLACING OF FORMS FOR COMBINATION SECTION

FIG. 6.—TRIMMING CANAL SECTION FOR LINING

The inside wall of this combination section is poured with 4-in. reinforced concrete on a slope of 1 on $1\frac{1}{4}$. About $1\frac{1}{2}$ miles above the Johnson Creek Siphon there is a portion of unlined rock section. This section is in a deep cut and has a bottom width of 14 ft., with 4.75 ft. of water. The side slopes are 1 on $\frac{1}{2}$; a value of Kutter's n equal to 0.030 was used in the design of this section. The parts of the North Branch Canal that pass through porous gravel formations are covered with an earth blanket. To provide for the earth blanketing, the gravel is excavated from the bottom and sides to approximately 12 in. deeper than the limits of the normal canal section.

Design.—The Chezy-Kutter formula was used in design throughout. In the lined sections a value of $n = 0.014$ is used; and in the unlined sections $n = 0.0225$. In some unlined sections this was increased to 0.025 and 0.03, the higher values being used in some parts of the canals when the inside surface was very rough due to the presence of cement, gravel, and rock. Reference is made to the paper[3] entitled "The Hydraulic Design of Flume and Siphon Transitions," by Julian Hinds, M. Am. Soc. C. E., which gives plans and elevations of the transitions used by the Bureau of Reclamation.

Canal Lining Reinforcement.—The 3 and 4-in. reinforced concrete lining is provided with a berm at the top that extends horizontally with a 5-in. width. This creates an appearance of a 5-in. lining. The 3-in. lining is reinforced with $\frac{3}{8}$-in. round bars, spaced 24 in. apart transversely and 12 in. apart longitudinally. In the 4-in. lining, $\frac{1}{2}$-in. round bars are used with the same spacing. The $\frac{3}{8}$-in. bars are lapped 18 in. and the $\frac{1}{2}$-in. bars are lapped 24 in. In all other reinforced concrete work the length of splices is 40 diameters. Vertical construction joints extend across the base and up the slopes at about 14-ft. intervals. All longitudinal steel is continued through these joints without providing for expansion.

Canal Sub-Drainage.—All the lined sections of the canals are designed with a system of under-drains. The longitudinal drains are 4 to 10-in. vitrified clay or concrete sewer pipe laid in gravel-filled trenches in the center of the canal base. When side drains, or "finger drains," were used the longitudinal drains were near the upper side and parallel to it. The longitudinal drain-tile was laid with open joints. In Fig. 7 it has been covered with tar paper. The trenches have a minimum depth of 10 in. and drain from 200 to 800 ft. from two directions into the lateral drains, which are 4 to 12-in. vitrified clay or concrete sewer pipe laid with cemented joints. The laterals drain the water from the longitudinal drains and extend beyond the canal prism and the waste banks. These lines have concrete cut-off and head-walls. (See Fig. 8.) The side drains or finger drains were spaced from 5 to 10 ft. These are trenches filled with gravel which extend from the longitudinal drains up the side slopes on the upper side of the canal. When completed they are covered with a thin layer of mortar to hold the gravel in place on the 1 on $1\frac{1}{4}$ slopes until the lining is poured.

Canal Side Banks.—A 14-ft. roadway on one side bank along the entire length of the Main Canal is intended for operation and maintenance purposes

---

[3] *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 1423.

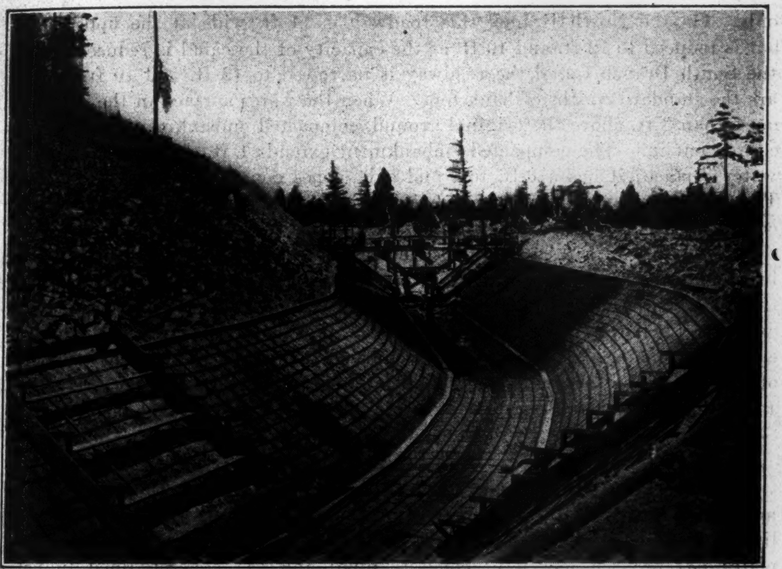

FIG. 7.—REINFORCING STEEL IN PLACE FOR CANAL LINING, SHOWING THE SCAFFOLDS USED IN PLACING STEEL

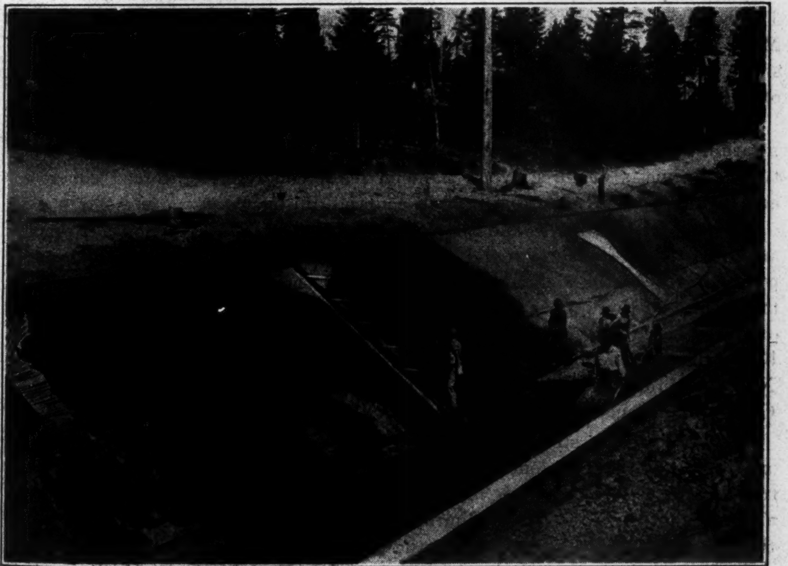

FIG. 8.—SIDE DRAINS, OR FINGER DRAINS, SHOWING LONGITUDINAL DRAINS NEAR BASE OF UPPER SLOPE

only. On the North Branch this roadway is 14 ft. wide at the upper end, but is reduced to 12 ft. and 10 ft. as the capacity of the canal is reduced. On the South Branch Canal the roadway is narrowed to 12 ft. and 10 ft. which are the standard widths of bank tops. When the water surface in the canal is more than 3 ft. above the original ground, compacted embankment or puddled core is put in. The compacted embankment extends 1 ft. above the proposed water surface; it has a 6-ft. top, and side slopes generally equal to 1 on 1½. The compacted embankment is placed adjacent to the canal prism in successive horizontal layers, not thicker than 6 in. A roller weighing not less than 2 000 lb. per lin. ft. does the compacting. These banks are usually built in advance of the regular side bank. Puddled core is placed vertically not less than 3 ft. in width, in the center of the canal bank. This core must extend 1 ft. above the proposed water level and about 3 ft. into undisturbed earth. All material is deposited and churned in water. In the lined portion of the canal the compacted embankment and puddled core are constructed to the top of the lining.

INVERTED SIPHONS

The very rough topography made necessary the construction of a large number of siphons all of which may be classified in four types: (1) Monolithic reinforced concrete; (2) combination reinforced concrete and steel plate; (3) pre-cast lock-joint concrete pipe; and (4) concrete-lined tunnel siphons with both circular and horseshoe barrel. Taneum Siphon on the South Branch (Fig. 1(*b*) and Fig. 9) is one of the siphons constructed of lock-joint pipe; the siphons at Horseshoe and Morrison Canyons on the Main Canal (Fig. 1(*b*)) have steel pipe for the lower part where the hydrostatic head is relatively high; Dry Creek Siphon on the North Branch is one of the monolithic reinforced concrete structures.

The pressure tunnel siphon under the Yakima River passes through a stratum of basalt at an average depth of about 150 ft. below the ground. The tunnel lining is of three types, namely, plain concrete, reinforced concrete, and segmented steel plates with plain concrete lining.

Tucker Creek Siphon and the siphon at Station 275+50, South Branch, are square; the others are round. Table 2 gives the dimensions and hydraulic properties of all the siphons. In Column (3) the maximum head is the distance between the water surface in the inlet and the lowest point of the invert of the siphon. The horizontal distance in Column (4) is measured from the beginning of the inlet transition to the end of the outlet transition. Items Nos. 1 to 9 refer to the Main Canal; Items Nos. 10 to 16, to the South Branch Canal; and Items Nos. 17 to 22, to the North Branch Canal.

The reinforcing steel in the round cast-in-place siphons consists of from one to three layers, depending on the hydraulic head on the siphons. The transverse steel for one layer is bent in the form of an ellipse with the major axis horizontal, and is placed a minimum distance of 3 in. from the inside at the top and bottom and 3 in. from the outside on the horizontal axis. When more than one layer is used, the rings are circular. Each bar is a half ellipse with

the 40-diameter laps staggered and placed on opposite diagonal quarter-points of the barrel. The 40-diameter laps of the longitudinal steel are staggered by spiraling the joints around the barrel.

Each of the siphon inlets is made up of two transitions, the first from the canal section to a square barrel entrance, and the second from the square entrance to a round barrel. (See Fig. 9.) The outlets reverse the order of the transitions. When the velocity is great enough to carry gravel in suspension, the entrances to siphons on lined canal sections are provided with gravel traps. These traps are 2 to 3-ft. depressions in the canal base, extending 40 to 80 ft. in an up-stream direction.

Construction joints with 3 by 4-in. keyways, are spaced about 32 ft. apart. These joints are furnished with 4-in., 5-in., or 6-in. copper strips which are cast around the entire circumference of the barrel. The strip has a V-shaped crimp, $\frac{5}{16}$ in. deep, in the center, which allows for expansion and contraction of the barrel, without permitting leaks. When steel pipe is used in the lower part of the siphon, expansion is provided for by a sliding joint at each end of the pipe where it meets the concrete part.

The inside forms are supported on 1-in. square reinforcing bars bent in the form of a cradle and embedded at each end in a 1 ft. by 5 by 1.5-ft. concrete pier. As concrete is poured in the barrel section and around these supports they become a part of the structure, acting as anchors. The inside form supports are spaced on 8-ft. centers.

All monolithic siphons are furnished with an 8-in. blow-off valve at the lowest possible point for gravity drainage. The siphons with steel pipe are also furnished with a manhole near the bottom.

WASTEWAYS

On all the canals provision is made for wasting the water during operation, or in case of emergency. In the Main Canal the water is controlled by standard radial gates, one in the canal and one in the wasteway chute. These gates are lifted by motor-driven hoists. The gates in the wasteways of the South Branch Canal are operated by hand. In the Main Canal there are wasteways at Peterson Creek Siphon, at Station 1146+30, and at Morrison Canyon Siphon. In the South Branch Canal, wasteways are located at Taneum Creek Siphon and Manastash Creek Siphon. Ten on the North Branch Canal are located at the following places: Yakima River Crossing, Naneum Creek, Johnson Creek, Cook Creek, Caribou Creek, Whipple Pumping Plant, one on each of the three laterals where they cross Badger Creek, and the wasteway to the Yakima River at the end of the lateral system.

Peterson Creek Wasteway is a 12 by 8-ft. flume, 280 ft. in length. The head-works are located in the inlet transition to the siphon. The flow of water is controlled by a 16-ft. radial gate in the wasteway and a 12-ft. gate in the canal.

The wasteway at Station 1146+30 consists of an 8 by 7-ft. concrete flume, 1 231 ft. long, with a drop in elevation of 340.5 ft. The slopes were 0.1800 for the upper part, and 0.6536 for the lower. The flume extends to the inlet

FIG. 10.—PLAN AND PROFILE OF WASTEWAY HEADING AT STATION 1146+30

Morrison Canyon Wasteway consists of two structures, the head-works connected to the inlet transition of Morrison Canyon Siphon, and the culvert under the railway tracks about ½ mile down the canyon (see Fig. 1(*b*)). A 100-ft. chute at the head-works ends at the top of a nearly vertical bluff about 125 ft. high. The water is allowed to drop over this bluff and then to follow the natural channel to the culvert. Flow is regulated with standard radial gates operated by electricity. A 20-ft. gate controls the wasteway and a 16-ft. gate controls the Main Canal.

Taneum Creek Wasteway on the South Branch, is 2 821 ft. long, of which 1 326 ft. is lined with concrete and has a drop in elevation of 202.8 ft. The chute is a lined canal section with a bottom width of 4 ft, a depth of 3 ft. 3 in., and with 1 on 1½ slopes. This chute empties into a stilling-pool, and the water is carried off in an unlined ditch. The wasteway and canal are furnished with hand-operated gates. At Station 14+00 on the wasteway, the Bruton (private) Ditch crosses under the wasteway channel in a 24-in. pre-cast pipe siphon (see Fig. 2(*b*)).

The Manastash Wasteway on the South Branch Canal is 120 ft. long. It has a relatively gradual fall and is constructed of 36-in. pre-cast concrete pipe. The inlet is in the head-works of the Manastash Siphon, and the flow is regulated by hand-operated gates. As this is the end of the South

Branch Canal, there is an 8-ft. Cipolletti metal-crest weir installed in a baffle wall in the siphon transition. From this point the flow of the South Branch Canal is carried in a main lateral (see Fig. 2).

In the case of Naneum Creek, Cook Creek, and Caribou Creek Wasteways, the base of the canal is approximately at the same level as the bed of the creek. The canal flow can be diverted, but it is not anticipated that it will be necessary to waste the entire capacity of the canals at either of these places.

The Johnson Creek Wasteway is near the inlet of the siphon at that point. The wasteway chute, a 3 by 6-ft. reinforced concrete flume, is 260 ft. long with a drop in elevation of 97.2 ft. Flow into the wasteway is controlled by a hand-operated radial gate.

TUNNELS

On the project there are 16 878 ft. of tunnel work in a total of eleven bores. These vary in size from 5 ft. 0 in. to 12 ft. 3 in. in diameter. They all have concrete-lined sections of the horseshoe type, except the Yakima Crossing Tunnel, which is round. Fig. 11 shows a typical tunnel plan. The two pressure tunnels under the Northern Pacific and the Chicago, Milwaukee, St. Paul and Pacific Railway tracks and parts of the tunnel under the Yakima River are reinforced both longitudinally and transversely. The other linings are not reinforced. Table 3 gives the dimensions and hydraulic properties of all the tunnels. Except for Item No. 6, which is a circular section, all the tunnel sections are of the horseshoe type. The value of Kutter's *n*, in every case, was assumed to be equal to 0.014. The lining of all tunnels is poured without expansion joints, key-way construction joints being provided between pours.

FIG. 11.—PLAN AND TYPICAL SECTIONS, TUNNEL NO. 3, NORTH BRANCH CANAL

Some parts of the tunnels require timbering. These are provided with five-segment, timber sets with 2-in. lagging (see Fig. 11). Where this timbering is permanent, it is used as a back form for the concrete lining. One line of open-joint drain-tile, 4 in., 6 in., or 8 in., is laid in a 12-in. gravel-filled trench in the base of the tunnel. The transition from the canal section to a square section with curved top is accomplished in about 40 ft., the transition from the square section to the horseshoe section is about 15 ft. long. In some tunnels on the North Branch, where they went directly into a siphon, with only a transition between (Fig. 11), the horseshoe base of the tunnel was carried through the closed transition of the tunnel and the open transition, to the closed or barrel transition in the siphon.

MINOR STRUCTURES

There are four types of bridges on the project classified as to use: The highway bridge, the farm bridge, the stock bridge, and the ditch rider bridge. Those used for highway purposes are truss, steel girder, or wood stringer bridges. They all have 4 by 12-in. floors, with $\frac{1}{4}$ in. by 24-in. checkered plate runners. The farm and stock bridges are steel girder or all wood construction. All these bridges are built very sturdily. Those that cross the major canals have reinforced concrete abutments and piers. All the ditch rider bridges over laterals are of timber.

Box culverts are either double or single. They are furnished with apron inlets, and, in most cases, with apron outlets. All box culverts have 6-in. side walls and from 6 to 9-in. bottom and top slabs. There are also a number of reinforced lock-joint concrete pipe culverts, 18 to 60 in. in diameter. These are also fitted with inlet and, ordinarily, with outlet aprons.

Turnouts are 2 by 2-ft., or 2.5 by 2.5-ft., reinforced concrete box structures, or reinforced concrete lock-joint pipe structures. The box turnouts have 6-in. side walls and 7-in. top and bottom slabs. Hand-operated steel gates are used to regulate the flow of water. Dry rock paving is used at the outlet of turnouts and culverts. Fig. 12 shows a typical box turnout.

THE LATERAL SYSTEM

The total length of laterals on the Main Canal is approximately 12 miles, the shortest being 170 ft. and the longest 12 200 ft. The average length is 2 400 ft. in twenty-seven laterals. The estimated quantities for the entire 12 miles, disregarding excavation for structures, is 41 200 cu. yd. The total length of laterals on the South Branch Canal is approximately 25 miles, the shortest being 350 ft. and the longest 17 600 ft., averaging 6 172 ft. in twenty-one laterals. The estimate for the excavation of the 25 miles, disregarding structure excavation, is 87 000 cu. yd. The average excavation for both systems of laterals is only approximately 60 cu. yd. per 100-ft. station. The total length of laterals under the North Branch Canal is 205 miles. The maximum length of a lateral is 19.1 miles, while the minimum length is 90 ft. There are 161 laterals under the North Branch Canal. The total excavation in these laterals, excluding structure excavation, is 931 600 cu. yd., or an approximate average excavation per 100-ft. station of 86 cu. yd.

FIG. 12.—TYPICAL BOX TURNOUT

All laterals are ordinary unlined ditches. In most cases the side slopes are 1 on 1½, with two side banks. An attempt is made to balance "cut" so as to use all the material excavated in the side banks. The bottom width of ditches varies from 3 to 12 ft. and the depth from base to ditch to top of bank, from 1.5 to 5.5 ft. The width of bank top is 3 or 4 ft., with 1 on 1½ side slopes on the outside. The water depth varies from 0.4 ft. to 3.0 ft. As a rule, the velocities are about 2.0 ft. per sec., but in a few instances the designed velocities are as great as 3.7 ft. per sec., the higher velocities being in material which will not easily scour. The capacities range from 6 to 75 cu. ft. per sec. In the design of all lateral ditches Kutter's *n* was assumed equal to 0.025.

On account of the very rough topography a large number of structures was necessary and in order to hold the velocities within allowable values, a large number of drops and chutes was constructed. There were fifty-three drops alone in one lateral 2½ miles long, under the South Branch Canal. All lateral structures, except bridges, are constructed of reinforced concrete. The bridges across the lateral ditches are all timber structures with wood mudsills; some of the longer spans have steel girders resting on concrete abutments. The same type of bridge is used in lateral work as in canal work. All weirs are of the Cipolletti type, with metal weir plates (see Fig. 13). In all weir structures, including weir drops and weir chutes, the wooden faceboard, as shown on the plan, was eliminated, the plate being bolted directly on the face of the concrete. The floor of the pool may be raised, if required, to place the maximum elevation of the water surface at the weir crest, or depressed to permit a maximum drop of 3.0 ft. in the water surface. In Fig. 13, $H = 3h + 12$ in.; $H' = D' + 6$ in.; $1 = 3h + 24$ in.; $m = 0.3l$; $n = F + d' + 0.5 - h'$; and $W = \sqrt{Q}$ to the nearest foot. The maximum value permissible for F_w, the total drop in the water surface, was 3 ft. Minimum values specified were: $l = 4$ ft.; $m = 18$ in.; $n = d' + 6$ in.; and $W = 3$ ft.

FIG. 13.—PLAN OF STANDARD WEIR, CAPACITY 70 CUBIC FEET PER SECOND

The checks are similar in construction to the weirs, except that the first wall is fitted with grooves for the insertion of the flash-boards. In the weirs this wall has the trapezoidal notch and weir plate. Three types of drops are used: The inclined, the inclined weir, and the inclined drop with flash-board control. The last two are fitted at the upper end as weirs and checks, thus eliminating these separate structures. There are only very minor differences in design of the three structures, except the addition of the wall that carries the weir plate or is notched for the flash-boards. Fig. 14 is a typical plan of the inclined drop. Note that $B' = B + 1\frac{1}{2}d$; $e = \frac{3}{4}(1\frac{1}{4}H' - 1\frac{1}{2}H)$; $H = 1.2d + 6$ in.; $H' = P + 1.2d' + 0.5F + 12$ in.; $l = 1.5(F + P)$; $l' = (F + 1.5d')$; and $P = \frac{1}{4}(\sqrt{d'F} + d')$. The following values are the maximum permissible; $B = b$; $B' = b$; and $F = 15$ ft. The minimum permissible values are $H = 18$ in. and $l' = 4$ ft.

Chutes are either paved with dry rock or are lined with reinforced concrete. The flow through sub-lateral turnouts is controlled by hand-operated gates and the barrels of these turnouts are reinforced "lock-joint" concrete pipe, 18 to 48 in. in diameter. The intakes and pipe collars are monolithic except on one South Branch lateral where, for experiment, they were pre-cast slabs, with mesh reinforcement at the joints arranged so that they joined together when placed, in the same manner as "lock-joint" pipe. The slabs are 3 in. thick and are reinforced with mesh and $\frac{3}{8}$-in. round bars. A number of low-head siphons are used in connection with the laterals as crossings under roads, canals, and railroads. These are all reinforced "lock-joint" concrete pipe with monolithic intakes and outlets.

FIG. 14.—TYPICAL PLAN OF INCLINED DROP; MAXIMUM CAPACITY, 70 CUBIC FEET PER SECOND

THE YAKIMA RIVER CROSSING

About 26 miles from the diversion dam, the Main Canal crosses the tracks of the Chicago, Milwaukee, St. Paul, and Pacific, and the Northern Pacific Railways, the proposed location of the Swauk Creek Logging Railway, the Yakima River, Swauk Creek, and the proposed location of the Inland Empire Highway (see Fig. 1). The difference in elevation of the water surface in the canal above the location and the normal water surface in the river is 390.8 ft. The railway tracks are near, and a few feet above, the water surface in the river. Between the 2 100-ft. contours (which is approximately the elevation of the canal) on either side of the river, the horizontal distance is about 3 125 ft. Fig. 15 shows the location of the tunnel. The vertical wasteway shaft in the photograph was also used as a construction shaft.

Thirteen test holes were drilled at the location, along the line of the proposed tunnel. These tests indicate that, in general, the bore will be through shattered basalt formation. The tunnel section is round, 9 ft. 3 in. in diameter, and lined with concrete throughout. Its horizontal length is 3 125 ft. The first 350 ft. has a slope of —1.428, the lower part has a slope of — 0.003 and + 0.003, and the outlet (334 ft.) has a slope of + 1.428. Of course, these are not the hydraulic slopes. The maximum head is 533.2 ft. measured from the water surface at the intake to the lowest point of the tunnel.

Three types of lining sections are to be used varying with the material encountered. The section lined with plain concrete, to be used in stable rock, has an average thickness of 15 in. with a minimum of 9 in. In the steel-lined section the pipe segments are pressure grouted on the outside, with an 18-in. reinforced concrete lining on the inside. The reinforced concrete section

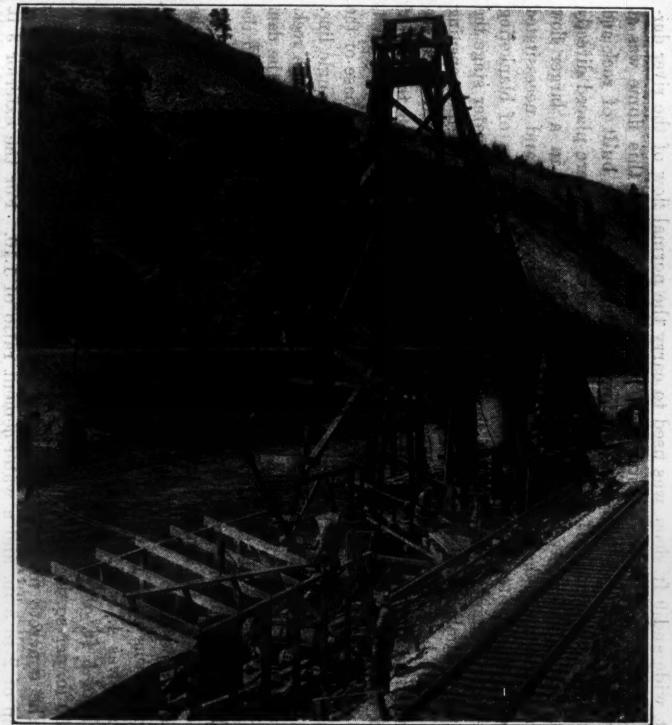

FIG. 15.—LOCATION OF THE YAKIMA RIVER PRESSURE TUNNEL

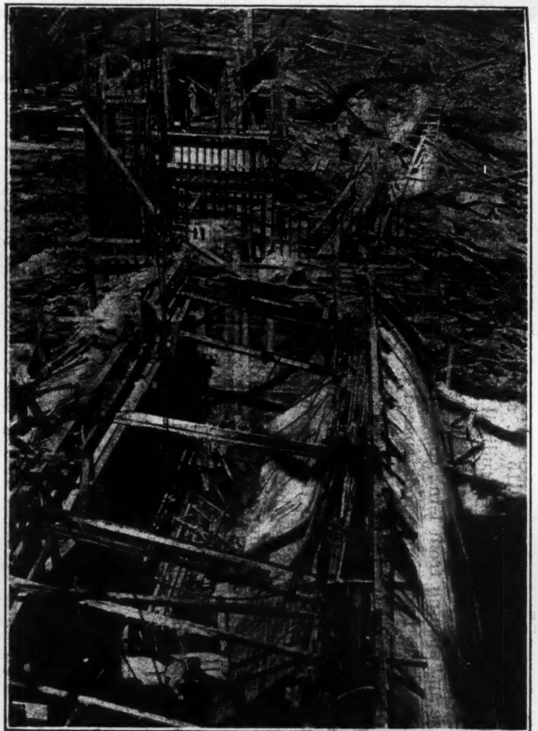

FIG. 16.—CONSTRUCTION VIEW OF DIVERSION DAM

has an average thickness of 15 in. and a minimum, of 9 in. (see Table 3, Item No. 6). For the longitudinal reinforcement, forty-eight ⅝-in. round bars were specified. The transverse reinforcements consist of hoops varying in size and spacing from 1-in., round rods, spaced 10 in. apart, for heads from 30 to 40 ft., to 1-in. square rods, spaced 4 in. apart, for heads from 90 to 100 ft. The steel-lined pipe is used for sections at which the head is greater than 100 ft. where permanent timbering is necessary. The tunnel is provided with a vertical wasteway shaft, 78 in. in diameter. This shaft is lined with ⅜-in. hammer-welded, steel pipe throughout and is grouted with a minimum of 9 in. of concrete outside the pipe. The wasteway outlet is furnished with two 42-in. internal, differential valves discharging into the Yakima River. The structure is also equipped with a motor-driven, direct-flow turbine pump, with a capacity of 600 gal. per min. against a head of 155 ft. The hydraulic properties of the tunnel are given in Table 3.

CONSTRUCTION METHODS

The Diversion Dam.—The diversion dam to the Main Canal was constructed during the spring, summer, and fall of 1928 and 1929. Due to very severe weather very little work was done during the winter months. No serious high water occurred during the construction period. A timber flume, 12 ft. wide and 9 ft. deep, was used to carry the normal flow of the river during the early period of construction. The inlet floor of this flume was at Elevation 2 142.5. The upper and lower coffer-dams were built of rock and gravel, to Elevations 2 155 and 2 143, respectively. They were placed directly on the sand and gravel bed of the river. This resulted in a larger flow through the coffer-dams than could be cared for by pumps, and necessitated the driving of interlocking sheet-steel piling and the addition of blanketing material. When the structure of the dam was above the high-water stage the temporary timber flume was removed, and the river passed through an opening left in the base of the dam near the north side. This was closed when the sluice-gates had been placed. The base of the dam was set in 3 to 4 ft. of solid rock, which was encountered under a stratum of 6 to 15 ft. of sand, gravel, and boulders. The cut-off wall was carried 5 ft. below the base of the dam. In the center of the key-way, grout holes were spaced in a single line, 5 ft. apart. Additional holes were drilled in soft or seamy spots in the rock. The depth of the grout holes ranged from 25 ft. in the main part of the dam to 10 ft. under the abutments. In addition, 20 grout holes were drilled in the south half of the spillway section below the key-way. There were 107 holes drilled with a total length of 2 233 ft. They were 2½ in. in diameter at the top and tapered to 1 in. in diameter at the bottom. As much as 38½ cu. ft. of grout was used in one hole, while some holes would take no grout. The average was 4.75 cu. ft. per hole. The grouting was done after a minimum depth of 5 ft. of concrete had been poured, and forced in under a pressure of 100 lb. per sq. in.

The concrete mix for the interior of the dam was 1 : 2.75 : 6.25, with a slump of 2 to 3 in. and a water-cement ratio of 1.10. For the exterior 3 ft.

of the dam, a mix of 1.5: 2.75: 6.25, with a slump of 3 to 5 in. and a water-cement ratio of 0.80, was used. Of diatomaceous earth, 3 lb. per sack of cement was used for both mixes. The maximum size of aggregate was 3 in. These mixes were quickly interchangeable at the mixer. By the addition of an extra sack of cement to each mixer batch, of the mixer used, the interior mix could be changed to the exterior mix. In the fish ladder, head-works, and other parts, where greater strength was required, the mix was 1: 2.4: 3.6, with a 1¼-in. maximum size of aggregate. An admixture of 3% was used with a slump of 4 to 6 in. and a water-cement ratio of 0.93. In binding successive horizontal lifts about ¾ in. of the old concrete was removed with picks, and the surface was thoroughly cleaned with air, steel brushes, and water. Then a 1-in. layer of 1.5: 2.75 grout was added and brushed with steel brushes. This was followed with a 6-in. layer of 1.5: 2.75: 6.25 concrete. The concreting was then continued with the 1: 2.75: 6.25 mix. An efficient arrangement for pouring concrete was made. Gravel, sand, and cement were chuted to the mixer, and the mixed concrete was chuted to the larger part of the work. The total concrete in the structure was 5 706 cu. yd.

Metal-lined forms, 5 by 6 ft., were used. These were anchored with ½-in. anchor rods. The pours varied in thickness from 4 to 10 ft. and horizontal key-ways were provided between them. These key-ways were formed with two 2 by 12-in. planks standing on edge and placed 18 in. apart at the top and 24 in. at the bottom. They were held in place by a steel rail bent in a U-shape. A richer mix with smaller aggregate than the 3 in. was used in pouring the key-ways.

Great care was exercised in placing the drum-gate in order that this gate would swing freely. Fig. 16 is a construction view of the dam.

Canals.—Earthwork was divided into three classes for payment, both in canal and structure excavation. The specifications are as follows:

"*Class No. 1.*—Material that can be plowed to a depth of six inches or more with a 6-horse or 6-mule team, each animal weighing not less than 1 400 pounds, attached to a suitable plow, all well handled by four men; also material that is loose and can be handled with team-drawn scrapers, and material that can be excavated efficiently, without blasting, by power shovels or dragline excavators of recognized standard manufacture, equipped with suitable dippers or buckets having minimum capacities of ¾ and 1 cubic yard, respectively, well handled by skilled operators; also all boulders or pieces of rock not exceeding 2 cubic feet in volume, that are detached or are embedded in Class 1 material.

"*Class No. 2.*—All material other than Class 1 and Class 3, including, but not restricted to, indurated material of all kinds, such as hard pan, cemented gravel and soft or disintegrated rock, which can not be excavated efficiently by power shovels or dragline excavators of the size and class above described, or by the use of plows and team-drawn scrapers, until loosened by blasting; also, all boulders or detached pieces of rock more than 2 cubic feet and not exceeding one-half cubic yard in volume, and all slide rock or similar loose rock occurring in masses which can not be handled efficiently with team-drawn scrapers, except pieces exceeding one-half cubic yard in volume.

"*Class No. 3.*—All solid rock in place which can not be removed until loosened by blasting, and all boulders or detached pieces of solid rock more than one-half cubic yard in volume. Solid rock under this class, as distinguished from soft or disintegrated rock under Class 2, is defined as sound rock of such hardness and texture that it can not be effectively loosened or broken down by hand drifting picks."

Canal sections were excavated with draglines, shovels being used only in rare instances. The bucket capacity varied from 1 cu. yd. to 2½ cu. yd. Some cuts as deep as 65 ft. were excavated with two draglines, one of them passing dirt to the other higher up.

Concrete for the lining of the Main Canal and the North Branch Canal was mixed in a 3-bag, paving mixer. The slopes were paved by the use of a machine made expressly for that purpose. It had a structural steel framework adjustable to the size and form of the canal section and was equipped with a movable steel form on each side the length of one panel and extending up the slope about 3 ft. The concrete was poured between the form and the trimmed canal slope, the form being held in place so that a lining of the proper thickness was secured. The steel form could be pulled up the slope by a winch mounted upon it, as the concrete was poured and tamped. The bottom was poured last, well tamped, and finished. When the machine had been moved in place for the next panel, the preceding one was finished by hand.

Smaller mixers were used on the South Branch Canal and on lateral chutes and for this work the proper thickness was obtained with screed boards. Fig. 17 shows alternate panels being poured on the South Branch lining. This method was not found to be successful because of the expansion of steel in the open panels. On this work concrete was mixed at a central plant and hauled in trucks. One contractor used this system with some success on lateral structures, but most of them were poured on location, with small ½-bag or 1-bag mixers. Fig. 18 shows a lateral chute being constructed.

The reinforcing steel was cut and bent on the job and was placed and wired ahead of the concreting. It was supported in place by small concrete blocks made to the proper thickness.

In the Combination Section a novel arrangement of panel forms was used (see Fig. 5). The timbers were bolted so that a very rigid structure was obtained, and, at the same time, they could be assembled and taken apart quickly. The lagging was made in large panels bolted together and lined with metal. Arrangements were made so that concrete was poured every third day and the forms were moved up and made ready for the next pour during the intervening days.

Ordinarily, in pouring canal lining on the Main Canal and on the North Branch Canal, the gravel, sand, cement, and admixture were proportioned at the bunkers and hauled dry to the job in batch trucks, three to six 3-bag batches per truck. The proportioning as well as the placing of the concrete in the canal lining was under the direction of an inspector. In most cases both sand and gravel were weighed, but in some instances the gravel was measured by volume.

A full description of the construction of the main canal lining has been presented by Messrs. Arthur Ruettgers and A. A. Whitmore.[4]

---

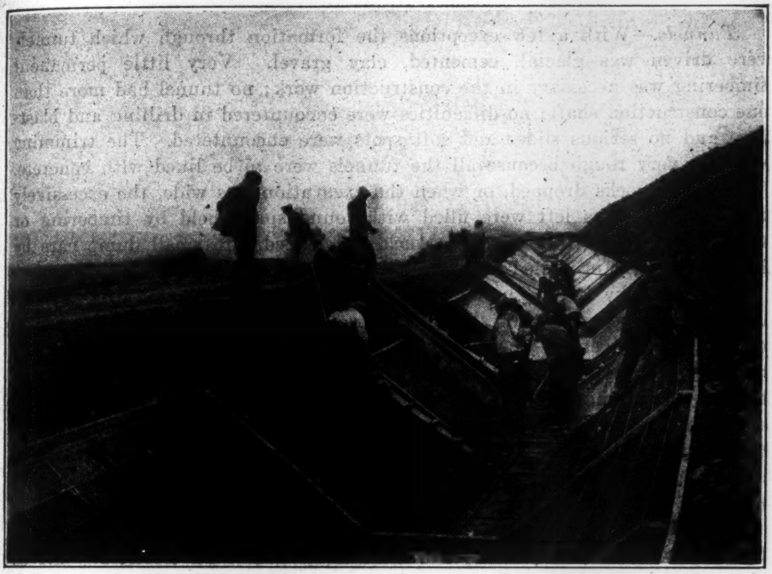

Fig. 17.—Pouring Concrete Lining on South Branch Canal. Alternate Panels Being Poured and Screeded to Proper Thickness

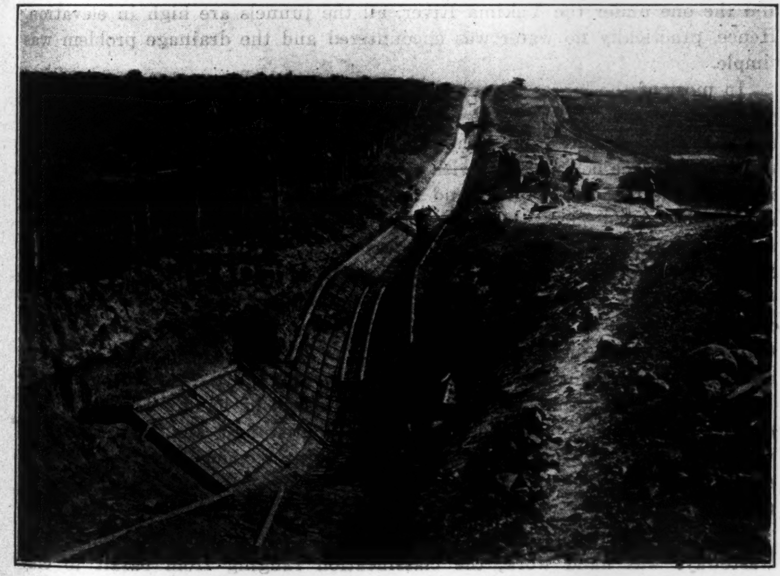

Fig. 18.—Pouring Concrete in a Lateral Chute

Tunnels.—With a few exceptions the formation through which tunnels were driven was glacial, cemented, clay gravel. Very little permanent timbering was necessary in the construction work; no tunnel had more than one construction shaft; no difficulties were encountered in drilling and blasting; and no serious slides and soft spots were encountered. The trimming was left very rough because all the tunnels were to be lined with concrete. When loose rocks dropped, or when the excavation was wide, the excessively large pockets thus left were filled with sound spalls held by timbering or tamped in place with concrete. Muck was loaded into small dump cars by hand and the cars hauled away by horse or mule.

In the Rocky Point Tunnel, an endless electrically operated dragline was used to load the muck train. The cable ran through one pulley connected to an eye-bolt driven in the heading; the other end was wound around a reversible electrically driven drum. The bucket was pulled up an incline to a tramway over the muck train, where it was automatically dumped. The action of the drum was then reversed, the empty bucket being pulled down the muck pile and loaded on the return. The incline and tramway could be moved up as the work progressed. The muck train was hauled by horses or mules on 36-in. gauge track. All permanent timbering was composed of 5-segment timber sets, the size in the smaller tunnels being 6 by 6 in., and in the larger tunnels, 8 by 8 in., with 2-in. lagging. Small electrically driven blowers were used for ventilating purposes and the air was good in all tunnels. Except for the two tunnels under the railway tracks near the diversion dam and the one under the Yakima River, all the tunnels are high in elevation. Hence, practically no water was encountered and the drainage problem was simple.

In most of the larger tunnels the floor was poured by hand and provided a support for the collapsible steel forms. A key-way joint was placed between the floor and the side walls. The forms had timber lagging and the concrete was shot in place behind them with air, the pipe for this purpose being placed inside at the top of the forms and then pushed to the back or to the beginning of the day's pour. Jack hammers were used on the inside face of the forms and no other kind of tamping was done. Open inspection holes were left in the lagging and closed as the concrete pouring progressed. The concrete was mixed outside the tunnel near the most accessible end for delivery of material and was transported to the "gun" by means of a gas locomotive. Only two crews of men were employed, one to set the forms during the night and the other to pour the concrete during the day shift.

The concrete in the smaller tunnels was placed by hand. The same type of forms was used. The side walls were poured first and then the floor, which provided additional head-room. No reinforcement steel was used in the concrete lining of the "no-pressure" tunnels, except in the portal transitions.

Siphons and Wasteways.—The excavation in the majority of siphons and wasteways was hand work, the classification ranging from basalt to clay gravel.

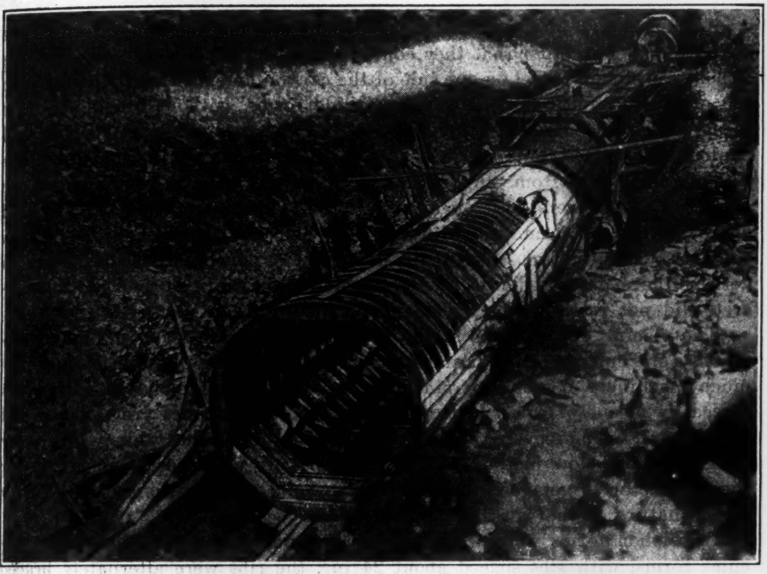

FIG. 19.—PART OF INSIDE FORMS FOR DRY CREEK SIPHON IN PLACE AND SUPPORTED ON INSIDE FORM SUPPORTS.

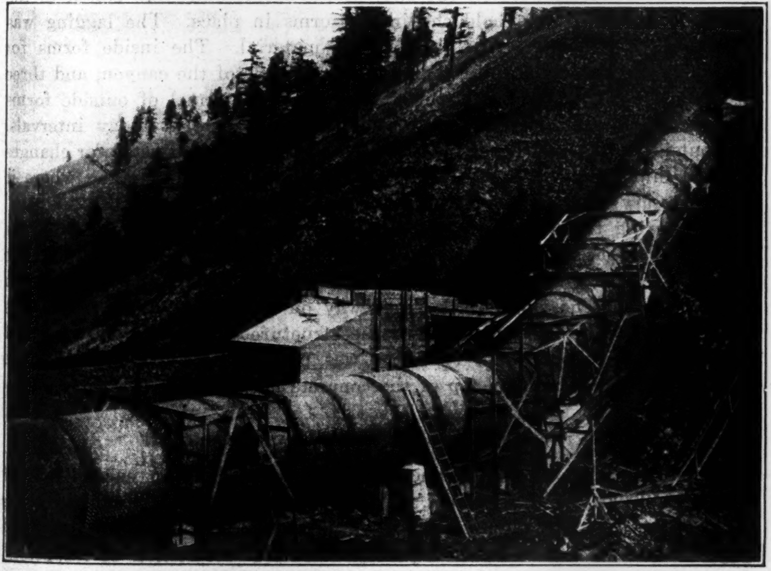

FIG. 20.—PLACING STEEL PIPE ON MORRISON CANYON SIPHON

All form work in these structures was timber, but the siphon forms were bolted together in order that they could be re-used. The usual procedure was to pour the siphon barrel on one side of the canyon and then move the forms to the other side and pour there. The inside forms, without bracing, can be seen in Fig. 19. On most siphons the concrete was mixed at the top and chuted in to place, but on some structures, material could be more easily assembled at the bottom. An aerial cable line was used at two siphons. No elevating towers were used on any structure. The larger siphons contained approximately 1 300 cu. yd., with the exception of Dry Creek Siphon which contained 2 640 cu. yd. The main difficulty in pouring the barrels was in getting the expansion joints properly installed as the men pouring the concrete did not realize the extreme importance of these joints.

The placing of steel pipe at the bottom of Morrison Canyon Siphon presented a difficult problem. Particularly, it involved the question of just how much machinery it was economical to assemble for a small job. Pipe was placed by means of gin-pole rigging, but the canyon sides are so steep and treacherous, being covered with loose, sliding rock, that this was a very dangerous and slow method. (See Fig. 20.) It was nearly impossible for the contractor to get good steel men who would stay on the job, due partly to the nature of the work and partly to the location.

All siphon forms were of timber. The inside forms were 8-segment, circular forms, with ribs spaced about 24 in.; the ribs were alternately braced with two 4 by 4-in. posts at right angles which, in turn, rested on 4 by 4-in. walers. Two walers were in the base of the forms and were bolted to the inside form supports to hold the inside forms in place. The lagging was 2 by 6-in., tongue-and-groove, bevel-edged material. The inside forms for the siphons were usually built complete for one side of the canyon, and three or more, panels of the outside forms were used. A panel of outside forms was moved ahead each third day, pouring being done at 3-day intervals. The outside forms were constructed so that they could be adjusted for changes in shell thickness. Inspection holes were cut in the inside lagging where it was necessary to see that the concrete was thoroughly tamped.

In pouring the lower part of the wasteway at Station 1146+30 and the culvert under the railroad, it was necessary to construct a track on top of the structure. The mixed concrete was carried in small cars controlled by an endless cable. The slope of the wasteway on the lower end is 0.65. The mixed concrete in the remainder of the structure was poured by means of chutes and wheel-barrows. The floor was poured first, and then the side walls, forms being built on top of the concrete floor after it had set.

METHOD OF CONTROLLING QUALITY OF CONCRETE

About 150 000 cu. yd. of concrete were produced at an expenditure of about $4 500 000 on this project. Consequently, the problem of producing concrete of a desired quality and at a minimum expense was considered important. The maintenance of quality was under the control of inspectors. Success in the production of concrete of a desired quality is dependent on the proper performance of all operations from the time the materials are selected and the mixture is designed until the concrete is placed and adequately cured. Failure to perform or control any individual operation properly is likely to result in a product that is non-uniform in character and either inferior in quality or wasteful in cement.

The desire of the engineers in charge to produce concrete of a uniform quality led to the incorporation of all the directions and tables to be used by inspectors in a small blue-print pamphlet entitled, "Instructions for

* Sprayed with "process" after removal of mould, no damp sand curing.

Concrete Inspection and Control." Information in this section of the paper was secured from that pamphlet. Its use is not an attempt to supplant the employment of experienced inspectors, but to standardize the method of control. The method of control is the same as that advocated by the Portland Cement Association, but adapted to local conditions. Table 4 gives the results of strength tests on cylinders taken from the various structures on the project during 1928.

Aggregate.—Very complete investigations were made of local sources for sand and gravel, but it was decided to secure the material from a company that had pits near Steilacoom, Wash., on Puget Sound. These aggregates are washed with salt water; the average fineness modulus of the 1¼-in. gravel was 7.15; and the average fineness modulus of the sand was 3.08. The grading of aggregates for the dam and the reinforced concrete pipe differs from these figures.

Concrete.—In the determination of the proper mixes, extensive laboratory tests were made of the aggregates. The assigned proportions were slightly revised to meet the field conditions as the work progressed. The properties required for the concrete were high strength, high impermeability, and good workability. All these qualities were considered equally important. In most of the structures, high strength was an absolute necessity. In siphon structures subjected to high heads, the concrete must be of a known high strength and furthermore must be highly impermeable. In order to be worked around the barrel and between crowded steel bars, the concrete must also be very workable. The mixes as designed had these characteristics, as demonstrated in the field and by laboratory tests with actual specimens under compression and under hydrostatic pressure.

Method of Supervision.—An assumed strength, impermeability, and workability having been decided, and the proper mix to gain these characteristics fixed by test, the problem was to obtain the same results in the field as in the laboratory. On canal lining, for which the assigned mix is 1: 2.4: 3.6 (dry rodded) the percentages of moisture in the sand and gravel, for example, are assumed to be 3.1 and 0.1, respectively.

By consulting the Reclamation Service Instruction Book, previously mentioned, the inspector would find Table (*a*), the proper field mix, proportioned by volume (moist loose, taking into account the bulking of sand); Table (*b*), surface moisture in gravel (per sack of cement); Table (*c*), surface moisture in sand (per sack of cement); Table (*d*), batch weight for sand and gravel per sack of cement (including moisture); and Table (*e*), water-cement ratios for varying quantities of water used per sack of cement. The amount of sand bulking for different percentages of moisture in the sand is also given; no allowance is made for bulking because of moisture content in gravel.

A complete set of these tables is given in the pamphlet for all the assigned mixes used on the project. By their use, it is a simple matter for the inspector to calculate the water to be added to secure the specified water-cement ratio, because the number of gallons of water per sack of cement contained in the sand and gravel can be taken from Tables (*b*) and (*c*), the weight of sand per sack of cement to be used is found in Table (*d*), and the volume of gravel is taken from Table (*a*), or if proportioning by weight, the weight of gravel may be taken from Table (*d*). The number of gallons of water to be added, the weight of sand and the volume or weight of gravel to be used being known, a trial batch is mixed. A slump test is made and more or less water is added to hold the slump below 2 in. which is the maximum allowable for canal lining. No change in the quantity of water or of the weight of aggregate need be made until a noticeable change occurs in the slump, due to more or less moisture in the sand.

Inspectors' Reports.—Form 1 is a sample of a daily concrete report. Each inspector was required to make a report for each structure poured or for the work of each shift. Form 2 is a sample of the report made for each cylinder or group of cylinders. One cylinder was made from the work of each shift. When a patented paint coating method of curing was used, two cylinders were made, one treated with the "process" and one cured in damp sand. All inspectors' reports were checked in the Division offices the day after they were made, and any mistakes corrected and brought to the attention of the inspector. The reports were then forwarded to the project testing laboratory. Cylinders were collected on the same day each week. In this way a very close check was kept of the quality of the concrete that was being poured under each inspector. Any cylinders that tested abnormally high or low were brought to the attention of the inspector, and he was required to make an explanation of the cause. The standard 6 by 12-in. cylinder was used.

The type of report used in the 1928 construction season was improved for the 1929 season. The cylinder report and the concrete report were combined on one 5 by 8-in. card as shown in Form 3. This type of report was found to be better in some respects than Forms 1 and 2, which were mimeographed blanks on separate sheets of 8½ by 11-in. letter paper. The information was more compact and the filing was easier.

Use of Admixture.—It is to be noted that no allowance is made for admixture when computing the water-cement ratio. The usual practice in this respect is to allow 200% absorption, that is, when 3% admixture is used, it is assumed that 6 lb. of water per sack of cement will be taken up by the admixture and is not available for mixing with the cement. In the design of mixes this allowance was not made; thus, there is no difference in the field conditions and the laboratory design. To disregard this feature simplifies the calculations and control of field mixing. The only objection is encountered in comparison of the concrete strength for a certain combined fineness modulus and water-cement ratio on this job with that secured with the same values on any other job. A ratio of $W = 0.90$, computed as described herein, would become approximately 0.80 if the admixture were assumed to absorb 200% of its weight of water. In canal lining and in small and low-head structures 3% of admixture is used. In the parts of siphon barrels under heads of less than 100 ft., 1½% is used; for heads greater than 100 ft., no admixture is used. In the rich mixtures in the lower part of the high-head siphons, it has been found that the addition of admixture is a detriment.

FORM 1.—SAMPLE INSPECTOR'S DAILY CONCRETE REPORT

United States
Department of the Interior
Bureau of Reclamation
Kittitas Division—Yakima Project
Inspector's Daily Report (Concrete)

Contractor: Blank Construction Co. : Day Shift: 10/14 1928

Main Canal, Div. No. 3 : Feature lining : Sta. 1359+20 to 1360+07

Weather Cloudy Warm — 65°

Instrument work performed None

Delays: 1 hour due to making water connections for mixer

Mixer: Type Ransome 13E ; Size 3 sk ; Ran 6 Hrs.; 86 Batches

Cement: Brand Spokane , sax per batch 3 , sax used 258

Admixture: Kind Diatomite ; % by Wgt. Cement 3 %; Lbs. used 774

Mix: Designed 1:2.4:3.6 {Dry / Rodded}; field 1:3.14:3.77 {Moist / Loose}; Slump 2 in.

Sand: Source Pioneer ; 3.1 % moisture; 25 % bulk; 816 lbs. per batch

Gravel: Source Pioneer ; 0.1 % moisture; 1-1/4 in. size; 11.31 C. F. per batch

Water: In sand 2.94 gals. per batch; in gravel 0.15 gals. per batch.

15.81 gals. added; 18.90 gals. total per batch; W/C ratio 84

FORM 3.—CONCRETE INSPECTOR'S REPORT USED DURING THE 1929 SEASON

The burning method was used on gravel in all cases. Each inspector was furnished with a pair of balances and an alcohol flask. Each sample was burned with alcohol two or three times, or until all the moisture had been expelled. The prescribed weight of damp material for each analysis was 500 grammes. A table was given showing the percentage of moisture opposite dry weights, assuming a damp weight of 500 grammes. The values in this table were derived by allowing 0.5% for absorbed moisture in the aggregate.

At the sand and gravel bunkers the displacement method of moisture determination was adopted for sand, and the burning method for gravel. Two types of apparatus were used in the displacement method. One consisted of a 3 by 27-in. cylindrical, brass tube container with a water-gauge glass attachment. This tube would accommodate a 2 000-gramme sample of sand or gravel. It was calibrated in cubic centimeters within the range of the gauge glass and a scale graduated to 5 cu. cm. was placed directly behind the glass. The other apparatus was a graduated glass container 18 in. high, designed to accommodate a 500-gramme sample of sand. The flask had a lower and upper chamber or bulb connected by a short tubular section called the lower neck. The upper bulb gradually tapered to a uniform tube about 6 to 8 in. long, called the upper neck. The 200-cu. cm. point was marked on the lower neck, and the upper neck was marked in cubic centimeters throughout that portion used in obtaining the necessary readings for testing sand samples. Tables were given for each type of apparatus showing the percentage of moisture opposite the flask or tube reading, assuming a 500-gramme, damp weight. These tables were compiled by determining the difference in the quantity of water displaced by dry and by damp samples. The volume of water displaced by the dry sand was assumed to be constant as long as the grading, unit weight, or specific gravity of the sand did not change materially.

Removal of Forms.—When the concrete had been poured under normal conditions the forms were required to remain for various periods (days), as follows:

	Days.
Diversion Dam:	
Mass concrete	2 to 3
Thin walls	5 to 7
Tunnels and other openings	14
Transitions, Flumes, and Combined Sections:	
Vertical walls and steel slopes	3 to 4
Flat slopes	2 to 3
Siphon Barrels:	
Outside supports and lagging	3 to 4
Inside diagonal braces	3
Inside horizontal braces	7
Inside vertical braces, arch rings, and lagging	14
Tunnel Lining:	
Tunnels	3 to 4
Beams and Slabs:	
Beams and slabs (subject to flexural stress)	21 to 28
Bridges:	
Piers	3 to 4
Abutments	5 to 7
Turnouts, Culverts, and Ditch Crossings:	
Intake or outlet	3 to 4
Outside of barrel, and cut-off collars	3 to 4
Inside of barrel	14
Lateral Drains:	
(*a*) If puddled immediately	2
(*b*) Otherwise	3 to 4

When concrete was poured at low temperatures the forms were moved at the discretion of the Division Engineer.

Curing.—It has been stated, and apparently with considerable justification, that improper curing is responsible for more defective or short-lived concrete than any other single element in its manufacture. Although curing has had a place in concrete specifications for years past, it is only in recent years that its high relative importance has become generally known, or sufficiently appreciated by construction supervisors to command whole-hearted observance of the specification provisions.

Water can make or ruin concrete. If used too freely in the mixing precess, it weakens the concrete by thinning the cementing fluid. A similar injury results if, after the cement has taken its final set, its affinity for water to effect hydration is not satisfied. Inasmuch as the plastic concrete contains sufficient water for complete hydration of the cement, the process of curing resolves itself into one of retaining the original mixing water, or of supplying additional moisture to counteract evaporation and other losses.

Compressive strength tests of cylinders that were cured under damp sand or were permitted to dry out, indicate increases in strength for sand-cured specimens of about 75% at 10 days, 100% at 14 days, 125% at 28 days, and 145% at 4 months.

The resistance of concrete to abrasive action is similarly increased by moisture curing, since the strength relation has been found to be a reliable index of the efficiency of concrete to withstand wear.

The effect of proper curing in building up the internal structure of the concrete and making it less pervious to water is very marked. Experiments in the laboratory at Ellensburg, have shown that properly cured concrete, made of 1 part cement and 9 parts aggregate, is far less pervious than a rich uncured concrete made of 1 part cement and 3½ parts aggregate, the rich concrete being allowed to dry out, with forms removed, in 24 hours. The importance of proper curing is manifest when it is realized that impermeability, which depends on effective curing, is now regarded as concrete's most effective defense against the forces leading to disintegration, such as frost action, leaching, alternate wetting and drying, and contact with acid or alkali-bearing soil or water.

For best results the curing process should not be interrupted. This is particularly true during the early stage of hardening, because when the interior is moist and swollen, rapid surface drying induces hair cracks (known as crazing) which may subsequently develop into structural cracks. Curing, therefore, should be started as soon as possible, and the concrete should not be permitted to dry out before it is adequately cured.

All concrete, except that cured by patented process, was kept continuously wet for at least 14 days after being poured. Except in cases where small structures could be readily covered with moist earth, the concrete was cured under wet burlap. In the case of canal lining, the first half (7 days) of the curing period was under burlap. The barrels of the concrete siphons were cured inside and outside for a period of 28 days, the outside under burlap. The cost of water-curing the canal lining was stated by one contractor to be approximately $0.15 per sq. yd. The cost of the "process" curing averaged about $0.135 per sq. yd.

CONSTRUCTION COSTS

There is considerable difference in the unit bids received from various contractors. This condition is not common to this project alone. It is difficult to understand why one contractor should receive 100% more payment per unit than another operating on the same work and under the same conditions. It indicates that the competitive system of bidding is at fault.

Table 5 gives a list of unit prices as paid contractors. No attempt has been made to select either the extreme high or the extreme low, but the selections were made at random from the thirty-six contractors operating on the project. Only the more important items are given. On this project the

Government furnished all material that became a part of the completed construction work. The contractor furnished all lumber, nails, wire, etc., used in form work.

The cost to the contractors of common labor ranged from $4.00 to $5.00 per 8-hour day, probably the more common price being $4.50. The approximate prices paid to the skilled labor are as follows: Shovel runners, $1.43 per hour; foremen, $1.00 per hour; carpenters, $0.75 per hour; and concrete finishers (in canal lining), $1.00 per hour. Other labor was paid a proportionate price.

GENERAL CONCLUSIONS

Probably the most noticeable difference in the construction work on this project and other projects that have been built by the U. S. Bureau of Reclamation was the use of more scientific methods in the control of concrete manufacture. There was a distinct improvement in the quality and uniformity of the concrete over that poured by the more common method which was used on some of the earlier concrete on these projects. This was shown principally by appearances and the strength of cylinders and samples taken from the cured concrete, and by leakage tests made on siphons. Many engineers have a deep-seated conviction that scientific concrete control is a laboratory procedure alone. In the application of the method of concrete control used on this project, the inspectors and others engaged in directing the operations, were instructed as to the many influences affecting concrete in the making and the necessity for co-ordinating and controlling the various detail processes if concrete of uniformly high quality was to be produced. There is an apparent increase in cost incident to closer control, but a more complete analysis will show a probable decrease in cost for the same quality concrete, due to a more careful check on the cement and aggregate quantities. It is sometimes difficult to convince a practical man on concrete work, who has had some experience, that scientific control has any advantage over the old method.

A study of Table 4 reveals some interesting facts. There were 145 cylinders made from small structures. As a general rule, these were 1 or 2 cylinders per structure. The probable number of structures from which they were taken was about 100. Their average strength was 3 848 lb. per sq. in. and 78% were within 20% of that value. They were made by thirty to forty different inspectors under temperature conditions ranging from nearly freezing to more than 100° Fahr.

The writer is indebted to the Engineers of the U. S. Bureau of Reclamation at the Main Office in Denver, Colo., the Project Office, at Ellensburg, Wash., and the Division Offices at South Cle Elum and Thorp, Wash., for kind assistance in the preparation of this paper. This included the contribution of much of the information and material and the reading and correction of the manuscript.

DISCUSSION

John Sanford Peck,[5] **Assoc. M. Am. Soc. C. E.** (by letter).—In reading this paper, the writer's interest was captured primarily by the sections devoted to the description of the methods used to insure high quality concrete. The success of the project, from a service standpoint, depended entirely upon the quality of the concrete produced on the job. The greatest possible skill in hydraulic design would have been nullified entirely if the concrete had failed under the extremely severe conditions of service to which it was exposed. The results obtained, as judged by the test cylinders taken from the job, are another vindication of scientific methods of concrete manufacture.

The successful results that were obtained depended entirely on the degree of knowledge and skill of the concrete inspectors, and the author's description of the "Instructions for Concrete Inspectors" that were prepared for use on this project, together with the tables that he mentions in detail, point to a handbook of more than passing interest. It must have been successful in teaching the essential features of the control of the water-cement ratio on the job to practical-minded men to whom anything resembling theory is anathema.

With reference to the use of an admixture of diatomaceous earth in the concrete, the writer would like to know what the reasons were for using an admixture at all, and just how much this admixture contributed to the workable properties of the concrete? A description of the laboratory technique used in determining the need for the admixture and in actually measuring the increase in the workability secured by using it, would be of great interest and value.

For some time the writer has been of the opinion that, while admixtures in the proper proportions do no harm to the concrete, they do not appreciably improve a mix, except perhaps to add an indefinite and unmeasurable quality of "fatness," which can only be detected by the eye. The results of several series of laboratory tests made by the writer have confirmed this opinion and have tended to show that the best and cheapest admixture is an increase in the cement of from 5 to 10 per cent.

This part of Mr. Mason's paper again shows the results that can be obtained by scientific methods of concrete control, and it is worth noting that a paper[6] by William M. Hall, M. Am. Soc. C. E., also discusses the practical use in the field of the results that have been obtained and thoroughly proved in the laboratory.

Edward W. Bush,[7] **M. Am. Soc. C. E.** (by letter).—Near the end of this interesting paper, under "Construction Costs," the author makes the statement that:

"It is difficult to understand why one contractor should receive 100% more payment per unit than another operating on the same work and under the same conditions. It indicates that the competitive system of bidding is at fault."

---

[7] Engr., Aetna Casualty & Surety Co., Hartford, Conn.

The writer offers the suggestion that probably the greater part of these discrepancies were caused by the contractors unbalancing their bid items either by increasing the prices on the items completed during the early part of the work—and thus obtaining money needed to finance the job—or by increasing the amounts bid on items which it was thought might be increased in quantity and, at the same time, decreasing the prices on other items which might be decreased in quantity. Competitive bidding is not to blame for the discrepancies mentioned by the author and, in most cases, these discrepancies can be prevented if the engineer, in the instructions to bidders, includes a condition stating that grossly unbalanced bids will not be given consideration when making the award.

It is thought that most engineers expect a certain amount of unbalancing unless they include in the set-up items like installation of equipment, organization expense, over-head, pumping, coffer-dams, etc., which often are real items appearing in the cost estimate of the bidder and which he naturally desires to load on to the early items if this is possible. It is not unusual to find items like foundation excavation running from $6 to $10 per cu. yd., provided a coffer-dam not elsewhere paid for must be built before the "pay" yardage work is started. In general, it is to be expected that, whenever the engineer has carefully analyzed the work to be done and has set up plenty of items so that each part can be bid separately, rather close bids will be received from the really experienced contenders for the job.

The defense against the gross unbalancing of items that might be increased or diminished in quantity is found in making such thorough preliminary investigations of the site or in working out the details of the design so that little doubt exists as to the quantities that will be required.

Some rather disturbing results may arise from grossly unbalanced bids on a unit price contract. The contractor may accumulate a considerable amount of early profits and expend them on some other jobs being performed at a loss; he may install equipment or an organization on other subsequent contracts; or, he may send his family to Europe, or otherwise expend the profits, and then lack sufficient funds with which to complete the contract on which the unbalancing occurred. Another interesting fact is that during the first part of the work the owner may be holding his own money as the retained percentage instead of any sum that has been earned by the contractor.

Even if the bid items are unbalanced a moderate sum, it is the total price that interests the owner and is considered when making the award; and if the case has been carefully prepared for bidding the totals coming from the experienced bidders will generally be found to compare favorably with one another and only vary because no two persons are apt to think alike on the probable cost or the amount of profit to be added. The average bid seldom has the importance frequently given to it, because there are generally a number of high bidders who only bid because they were asked, or they are bidders who lack an available plant or organization, or possibly a seasoned experience in doing similar work; hence they do not possess reliable cost data and, therefore, bid high. Some high bidders are supplied with enough current work to keep them fairly well occupied and only desire another contract if it can be secured at a favorable price.

Probably in most cases the real contenders for the contract are to be found in the lower third or half of the bids, provided those offering these bids are experienced contractors on the class of work bid upon. Complementary bids are generally high and many of these are offered merely because the engineer or architect sent the plans to the bidder. Others bid merely to see their names among those bidding, thinking that a certain prestige is obtained if the job happens to be a large one. Bankers at times will extend rather large credits for certified checks when it is known that the bidders will put in such high prices that the jobs will not be obtained except at very attractive figures. It is not worth while to give too much consideration to the high bidders if a fairly large number of bids are offered, but when judging the lowest bids before making an award it is desirable to give full consideration to the bidder's experience, financial strength, available plant, and organization; also, whether the new work taken in connection with the other work on hand will be inside the volume which the contractor is considered competent to handle and finance.

ORRIN H. PILKEY,[8] JUN. AM. SOC C. E. (by letter).—It is interesting to note that actual construction was begun on some high-line canals of this project before the U. S. Bureau of Reclamation took part, but that this early attempt resulted in failure because of lack of funds. This is an example of the value of the Federal Bureau. With its greater financial backing it is able to undertake and complete desirable projects which otherwise would not be attempted, or, if attempted, would result in failure.

One of the features of the Kittitas Project worth mentioning is the use of safeguards of several types in the main canal to prevent accidents, especially drowning. Just above each siphon or tunnel intake is a creosoted timber float fastened to a 1-in. guide rope. If a person is being swept down with the current he might be able to catch hold of this timber and hang on to it, thus saving himself from being carried through the siphon or tunnel. If he missed the timber he would scarcely be alive by the time he reached the outlet.

In addition to the timber there are metal ladders placed on both sides of the canal at the siphon entrances. Other ladders are spaced about 250 ft. apart on alternate sides of the lined canal. Their purpose is to provide egress from the canal itself. The side slope of 1 on $1\frac{1}{4}$ of the concrete lining is so steep that it is almost impossible for a person to climb out when the concrete is wet and slippery.

Timber fences of heavy construction border the edges of the canal at both the inlet and outlet ends of the siphons, and metal railings built of angle irons are placed around the operating platforms. The bridges crossing the canal also have angle-iron railings.

---

[8] New York, N. Y.

The author has given figures which he states indicate that the competitive system of bidding is at fault. It is certainly interesting to note the great variations in unit prices paid to different contractors operating on the same work and under the same conditions. Some of the bids must have been extremely unbalanced. It is admitted that competitive bidding leaves much to be desired, but other methods of bidding on public work are likely to be far more unsatisfactory. The writer would like to inquire what the author recommends to alleviate the faults of the competitive system.

CLIFFORD A. BETTS,[9] M. AM. SOC. C. E. (by letter).—The description of the scientific control of concrete production and of the up-to-date construction methods and costs on the Kittitas Division of the Yakima Project draws attention to the economies that can be effected by the use of laboratory control and modern machinery. There is a well defined trend in this direction.

The uniformity that can be assured in concrete by effective control permits closer design, lower safety factors, and correspondingly greater savings. On projects involving large yardages, the net savings from this source alone have amounted to as much as 2% of the total cost of the concrete, as evidenced by one case in which the cost of laboratory control and inspection was $0.035 and the saving in cement $0.18 per cu. yd. of concrete. Costly control becomes burdensome; but practical inspection administered with common sense can be made indispensable. Furthermore, on work that is being done on a three-shift program, it becomes highly advantageous to make the proportioning, mixing, and placing as "fool-proof" as possible by standardization of all operations.

In attaining the impermeability, strength, and workability required for long-lived hydraulic structures the following procedure has been found to have merit:

(*a*) Screen both sand and gravel into two or more sizes in order that the screened aggregates may be reblended accurately in such a manner as to produce concrete with a minimum percentage of voids. In this way a troublesome variation in consistency—which inevitably adds to the difficulties of water control and intermittently causes harshness, with water rising to the surface—can be avoided and a satisfactory gradation, which is a vital element, can be obtained.

(*b*) Locate washing and screening plant and arrange the stock-piles so that aggregates will not carry a wide variation of moisture into the mixer bins to interfere with moisture control.

(*c*) Proportion by weight, with graphic corrections for surface moisture and carry-over, the latter requiring attention only when screens are changed. The use of charts at the mixer eliminates interpolation and reduces computations to the subtraction of the surface moisture from the mixing water.

In Fig. 21, a typical illustration, the proportions of each size of aggregate are expressed in terms of parts by weight of cement per batch (diagonal lines marked "stock-pile proportions"). The percentages of surface moisture are ordinates and the weights of aggregates plus moisture, are abscissas. For example, when the surface moisture of a certain aggregate is 5% and the specified proportions are 2 parts to 1 part of cement, the total weight of this moist aggregate required for 1 cu. yd. batch is 1 050 lb. Similarly, the quantity of water to be deducted from the mixing water (in gallons or pounds) can be read from a diagram, such as Fig. 22, having "parts of aggregate by weight" as ordinate, "water to be deducted from total mixing water" as abscissa, and "percentage of surface moisture" as diagonals, with angles of inclination as determined in the laboratory. As an example, if sand contains 4% moisture, the chart shows that 4.8 gal. of mixing water should be deducted per batch.

---

[9] Engr., U. S. Bureau of Reclamation, Ontario, Ore.

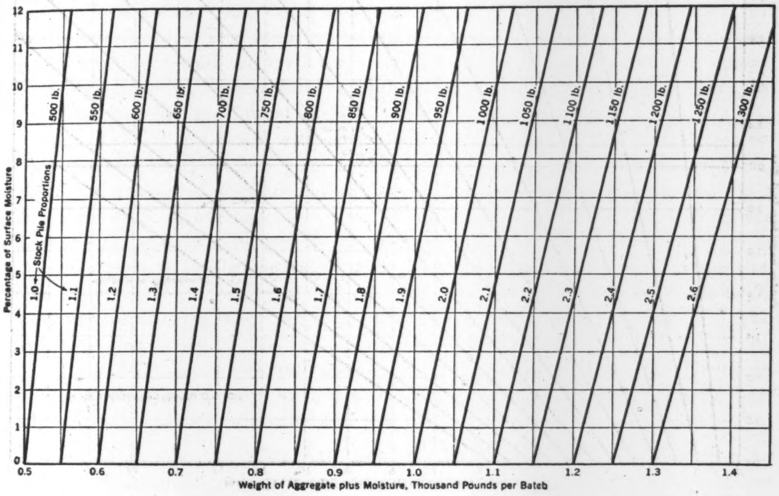

FIG. 21.—WEIGHTS OF AGGREGATES FOR 1 CUBIC YARD BATCH.

In addition to the methods of surface-moisture determinations described in the paper, reference might be made to patented scales reading the percentage of moisture directly on the dial.

Such control applied to a job of sufficient yardage to give a large number of representative samples will permit strength control tolerance so close that no specimens will vary more than 15% above or below the average of all the samples taken, and 90% will be within 10% of the average. As a rule, works involving considerable concrete yardage and extending over several years, show a gradual improvement in quality of concrete produced, as time goes on. The better the control the more nearly all the concrete will approach the perfected product.

The statement by Mr. Mason that "high strength, high impermeability, and good workability * * * were considered equally important," is a reminder that a standard test for impermeability is greatly needed. In fact, it frequently happens in hydraulic structures that water-tightness rather than strength is the criterion controlling the richness of the mix. Unfortunately, there is no well-defined quantitative relation between strength, which is readily tested, and impermeability, which is more difficult to measure, although, in general, both are improved by the same factors. For example, placing and curing, like gradation, have a greater effect on permeability than on strength, whereas wetting a mix may decrease the strength, but increase imperviousness. Pending the perfection of a generally acceptable permeability test apparatus a simple qualitative test can be made by inserting flanged pipes into mass concrete and determining by trial the permissible hydrostatic head.

FIG. 22.—SURFACE MOISTURE IN AGGREGATES, 1 CUBIC YARD BATCH.

GEORGE C. IMRIE,[10] ESQ. (by letter).—Taken as a whole this paper gives a true picture of the construction work as conducted on the Kittitas Division of the Yakima Project. Because of conditions encountered as the work progressed, some major changes were made in the construction program. In driving the horizontal leg of the tunnel several sections were excavated through tuffaceous shale, and it was decided to change the type of lining through this part of the tunnel from plain to reinforced concrete, and to increase the thickness of the shell from 15 to 30 in. Where the tunnel was excavated through a substantial covering of basalt, it was lined with 15 in. of plain concrete as covered in the specifications.

---

[10] Office Engr., U. S. Bureau of Reclamation, Ellensburg, Wash.

In the 30-in. reinforced sections of the horizontal leg of the tunnel, the transverse reinforcement consists of two layers of 1½-in., square, hard, steel hoops on 8, 9, or 10-in. centers, depending on the classification of the backing. For the longitudinal reinforcement, twenty-two ¾-in., round bars, two 1-in. square bars, and two 1¼-in. square bars were used. The 1-in. square and the 1¼-in. square bars were substituted for the ¾-in. round bars, and were placed to assist in supporting the cages in position. In the upper parts of the inclined raises, the 15-in. concrete lining was reinforced against full hydrostatic head. The longitudinal reinforcement consisted of forty-eight ⅝-in. round bars, and the transverse reinforcement varied from 1½-in. square hoop bars, on 6-in. centers for the highest head, to 1-in. round hoop bars, on 10-in. centers for the lowest head.

The tunnel is provided with a vertical wasteway shaft 78 in. in diameter. This shaft is lined with a ¾-in. copper-bearing, steel plate to a point 17 ft. above the invert of the horizontal leg of the tunnel, and is encased in a minimum of 9 in. of concrete. Two 42-in. internal differential needle-valves discharging into the Yakima River are provided.

The structure is also provided with an electrically driven direct-flow turbine pump with a capacity of 600 gal. per min. against a 155-ft. head, to be used for unwatering the tunnel at the end of the irrigation season. The hydraulic properties of the tunnel are given in Table 3.

Of the 6 750 acres of land shown in the paper as held by the Northern Pacific Railway Company, all but 639 acres have now (February, 1932) been sold at the appraised value to *bona fide* settlers.

ARTHUR RUETTGERS,[11] M. AM. SOC. C. E. (by letter).—This interesting paper is a commendable presentation of the salient construction features of the Kittitas Division of the Yakima Project—a work which included one of the most difficult and extraordinary pieces of canal construction ever undertaken by the U. S. Bureau of Reclamation.

Inasmuch as approximately one-half of the $9 000 000 investment was expended for concrete, the author fittingly emphasizes the importance of the procedure for controlling the quality of this material. The use of diatomaceous earth as a concrete admixture is briefly mentioned in the paper and the writer is taking this opportunity to submit some data on the subject.

The various concrete mixes established by laboratory tests and subsequently modified to some extent by early field experience on the Kittitas work have been presented previously in a paper by the writer and Mr. A. A. Whitmore.[12] No admixture was used in rich mixes having 4½ or less parts of aggregate; 1½% admixture was used in the 1 : 2 : 3.25 mix; and 3% admixture was used in mixes containing 6 parts or more of aggregate.

At first, diatomaceous silica was considered as a means of overcoming a noticeable harshness or lack of plasticity in the leaner laboratory mixes, including those that were over-sanded. This condition was attributed to a natural deficiency of fines in the sand and was alleviated by the admixture treatment, in so far as could be judged by the appearance, "feel," and finishing of the concrete. Before permitting the use of admixture in the field, however, the laboratory tests on plain concrete were extended to determine the effect of admixture on compressive strength for some of the more practicable mixes. Comparisons were made on the basis of equivalent slumps, which resulted in generally higher water-cement ratios for the concrete with admixture. The average results of the 28-day strength tests are given in

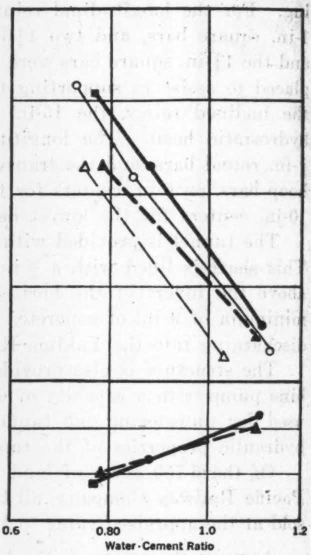

FIG. 24.

TABLE 6.—STRENGTH TESTS

Sum of aggregates	Gravel to sand ratio	Slump, in inches	No Admixture		With Admixture			
			Water-cement ratio	28-day strength in compression	Percentage, admixture	Water-cement ratio	28-day strength in compression	Percentage, increase in strength
FOR CONCRETE OF 1½-INCH MAXIMUM SIZE OF AGGREGATE								
5.25.....	1.84	2	0.70	5 410	1.5	0.74	5 230	−3.8
5.25.....	1.84	6	0.76	4 910	1.5	0.80	4 955	0.9
6.0......	1.62	2	0.83	4 425	3	0.85	4 550	2.8
6.0......	1.62	6	0.87	3 935	3	0.91	4 045	2.8
7.5......	1.35	2	1.09	2 395	3	1.09	2 750	14.8
7.5......	1.35	6	1.17	2 330	3	1.16	2 570	10.3
FOR CONCRETE OF 3-INCH MAXIMUM SIZE OF AGGREGATE								
6.0......	2.28	2	0.75	4 290	3	0.78	4 305	0.4
9.0......	2.28	2	1.03	2 265	3	1.10	2 495	10.2

Table 6 and Figs. 23 and 24 and show that, with one exception, the strengths were increased from 1% to 15% by the use of admixture. It is interesting to note, in this connection, that the greater proportionate increases in strength accompanied the leaner mixes. In other words, the mixes most in need of admixture to counteract harshness and tendency to segregation were, fortunately, also the ones most greatly benefited from the standpoint of strength. In these figures the sum of aggregates is by volume, dry rodded, and the water-cement ratios are by volume.

Permeability tests, conducted principally for the determination of appropriate mixes for high-head concrete siphons, also furnished information on the comparative advantages of concrete with and without admixture. A brief description of these tests may be of interest, due to the fact that the procedure was materially different from that generally used in testing for permeability.

The test procedure consisted in forcing water through concrete disks 12 in. in diameter and 4 in. thick by applying air pressure to a column of water connected to the top surface of the disk. The volume of water entering each specimen was measured by noting water-surface readings on a gauge glass attached to the pipe water column. An ordinary water gauge was used for determining applied pressures. Except at night, on Sundays, and holidays, the flow into the specimens was maintained as nearly as practicable at a fixed rate, sufficient to exceed, slightly, the evaporation losses from the exposed surfaces of the disk, by increasing the pressure slightly whenever the periodically observed gauge-glass readings indicated a rate of inflow less than the established rate. The resulting pressure curve, except for porous specimens, and excluding the effect of periods outside working hours, was a gradually ascending one from zero pressure to (in some instances) 500 lb. per sq. in., the safe limiting capacity of the apparatus. Water outflow was collected and the accretions were measured at frequent intervals. Concrete disks were moist-cured for 14 days and then heat-dried to constant weight before being subjected to test.

A typical graphic test record, with gauge pressures, cumulative flows, and rates of flow plotted against time, is shown in Fig. 25. A photograph of the test apparatus is included in the paper previously cited.[13] The following test data apply to the typical case illustrated in Fig. 25: Real mix, 1:3.84; sum of aggregates (by volume), 4.50; nominal mix, 1:2.25:2.25; ratio of gravel to sand, 1.0; admixture in percentage (by weight) of cement, 0; slump, 6 in.; water-cement ratio (by volume), 0.70; average compressive strength (28 days), 4 645 lb. per sq. in.; maximum size of gravel, 1¼ in.; weight of disk at 14 days (moist), 39.56 lb.; weight of disk at test (heat-dried), 38.58 lb.; loss of water (by weight), 0.98 lb.; and loss of water, 444 cu. cm. The points plotted at breaks in the rate curves (Fig. 25(*a*)) represent average rates for the intervals preceding. Intervening points on the sloping connecting lines do not indicate actual rates. The line indicating the water-absorbing capacity of the disk is approximate, and is based on the loss in weight of the disk after it has been removed from the curing vat and heated. At Point 3, the total absorption was 1.22 lb., or 553 cu. cm., based on the increase in the weight of the disk at the end of the test.

---

[13] "Construction of Main Canal Lining on Kittitas Division, Yakima Reclamation Project, Washington," *Proceedings*, Am. Concrete Inst., Vol. 27, 1931, Fig. 20, p. 144.

Approximately fifty concrete disks, ranging from very rich to very lean mixes, were tested for permeability and in only two specimens was the available pressure of 500 lb. per sq. in. insufficient to produce outflow eventually. The average results of the tests, using "pressure to produce outflow" as a permeability index, are summarized in Table 7. As will be noted from the tabular values the resistance to permeation was markedly increased by the use of admixture in concrete having 1¼-in. maximum size of aggregate, especially in the mixes containing a total of 6 parts of aggregate to 1 part of cement. The improvement was inappreciable, however, in concrete made with 3-in.

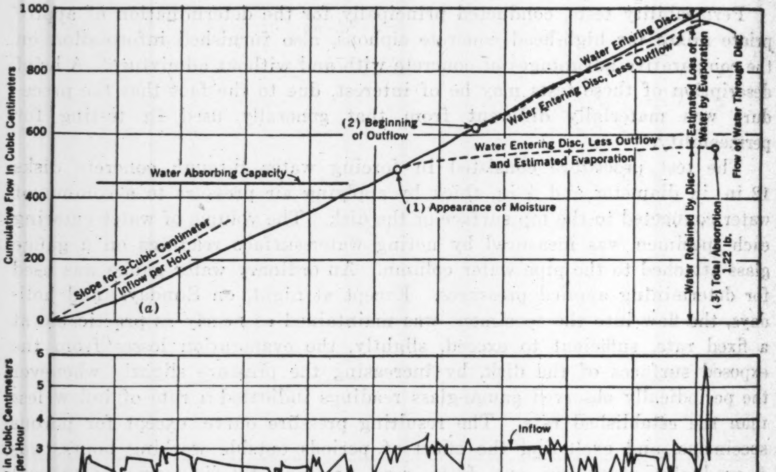

FIG. 25.—TYPICAL GRAPHICAL RECORD OF A PERMEABILITY TEST.

maximum size of aggregate. These results would indicate that admixture is most effective in promoting water-tightness where the voids in the concrete are relatively small in size and where large pieces of aggregate are not present to form direct water channels along their under surfaces.

TABLE 7.—PERMEABILITY TESTS

Sum of aggregates	Gravel to sand ratio	No Admixture: Average water-cement ratio	No Admixture: Pressure required to produce outflow	With Admixture: Percentage, admixtur	With Admixture: Average water-cement ratio	With Admixture: Pressure required to produce outflow
For Concrete of 1½-Inch Maximum Size of Aggregate						
3.5......	2.83	0.575	410	....	....	....
4.5......	1.0 to 2.12	0.69	254	....	....	....
5.25.....	1.84	0.73	78	1.5	0.78	110
6.0......	1.0 to 2.0	0.87	75	3	0.92	310
7.5......	1.0 to 2.5	1.06	13	3	1.13	44
9.0......	1.18	1.39	1	....	....	....
For Concrete of 3-Inch Maximum Size of Aggregate						
6.0......	2.28	0.75	40	3	0.78	45
9.0......	2.28	1.03	2	3	1.06	6

A third series of laboratory tests was conducted on the Kittitas Project in an effort to obtain comparative data on the durability or weather-resisting properties of concrete of various mixes, with and without admixture. The test specimens were made of concrete having 1¼-in. maximum size of aggregate and were basin-shaped to hold water. One set was moist-cured for 14 days before testing and a second duplicate set was simply air-cured. The two sets of specimens were subjected simultaneously to frequent alternations of wetting and heat-drying and, during cold weather, to freezing and thawing for a total period of ten months. In general, the results were as follows:

(1) There was no perceptible difference, for concrete of the same mix, between specimens containing admixture and those made without admixture.

(2) Specimens of richer mix showed more crazing and a larger number of structural cracks.

(3) Specimens of leaner mix were more affected by leaching action.

(4) Air-cured specimens were much more absorptive and affected to a much greater degree by crazing, leaching action, and spalling than companion moist-cured specimens.

It is the writer's opinion that the substitution of cement for diatomaceous earth, or other siliceous admixture, on an equivalent cost basis, may sometimes be (although not always) the best procedure. A large part of the diatomaceous silica used on the Kittitas Division was mined locally and purchased at a price that made the delivered cost approximately 1 cent per lb. The delivered cost of cement was approximately 0.67 cent per lb., which means that 1½ lb. of cement might have been used in lieu of each pound of diatomaceous earth admixture.

Considering the increased strengths obtained from the use of the diatomaceous silica, it seems reasonable to expect that the substitution of cement would have yielded similar strength increases. On the other hand, the permeability test data available indicate that the improvement in water-tightness to be expected from the increased use of cement would have fallen far short of that accomplished by the introduction of diatomaceous silica. This is especially true, as previously pointed out, for the 1:6 mix which was used on most of the concrete work on the Kittitas Division. The substitution of cement would not have imparted those qualities of smoothness and uniform jelly-like consistency so characteristic of admixture-treated concrete and so helpful to a harsh mix in obtaining proper field placement and finishing. In this connection the writer is reminded of a preference expressed by one of the siphon contractors for the 1:2.0:3.25 mix with $1\frac{1}{2}\%$ admixture over the 1:1.7:2.8 mix without admixture, notwithstanding the fact that the latter mix is richer in cement by 14% and that both mixes have essentially the same gravel-to-sand ratio.

In conclusion, the writer does not wish to go one record as advocating the promiscuous use of diatomaceous earth or any other of the innumerable preparations of concrete admixture being promoted. However, some brands or types of admixture have a rightful place in concrete work and the problem is primarily one of determining experimentally their field of application and then applying such knowledge to the advantageous use of the materials in meeting individual requirements.

Morris Mason,[14] Jun. Am. Soc. C. E. (by letter).—It is gratifying to note that there is much unanimity of opinion concerning the advisability of using more scientific methods of concrete control as exemplified by practice on the Kittitas Division of the Yakima Project.

Mr. Peck approves the use of the pamphlet, "Instructions for Concrete Inspectors" and states that it must have been successful in teaching the essential features of the control of the water-cement ratio on the job to practical-minded men "to whom anything resembling theory is anathema." The use of the pamphlet was indeed a success. The education and experience of the inspectors on this work ranged from men of little education and many years of experience, to college professors, out for the summer, with very little experience, but well founded in theory, and to young college men who, in the beginning, were deficient in either or both respects. There were also a number of able engineers among the force of inspectors. The uniformity and good quality of the concrete produced under the supervision of these men speaks well for the method of inspection. The writer is of the opinion that the employment of inspectors of the grade of Assistant Engineers (Civil Service rating) or higher is amply repaid. The effect of employing better inspectors is generally noted in the loss of friction between owner and contractor. For the best work the contractor should respect the ability of the inspector. A chief inspector who is likely to appear on the job at any time, either day or night, proved useful in keeping the inspectors always on the alert.

Mr. Peck questions the use of admixtures and just how much the admixture used contributed to the workable properties of the concrete. It is hoped that the discussion by Mr. Ruettgers has answered this question. The writer agrees with Mr. Peck that, generally speaking, the qualities attributed to the use of admixtures, with the exception of workability, may be attained by the additional use of 5 to 10% of cement. For the most part, it was a question of the relative cost of cement and admixture in place in the concrete. Little unbiased information is to be had on this subject.

---

[14] Engr., Standard Oil Co. (Indiana), Wood River Refinery, Wood River, Ill.

The analysis of "unbalanced bidding" which was given by Mr. Bush is concise and to the point. Almost any one with construction experience can cite examples in which the contractor has collected on the "cream" of the work and then has left further worries to the surety or the owner. A. P. Greensfelder, M. Am. Soc. C. E., has emphasized[15] the fact that unbalanced bidding should be guarded against. He states that one is likely to feel that practical experience warrants certain maneuvering of unit bid prices. According to Mr. Greensfelder there is usually enough gambling in construction without this, and it is only warranted through the viewpoint of equity of the owner when the engineers' quantities are themselves unbalanced. On many jobs the retained percentage is retained in name only. As Mr. Bush states during the first part of the work the owner may be holding his own money as the retained percentage instead of any sum that has been earned by the contractor. Where the contractor is responsible and will complete the work, the total amount bid is the important factor. There are exceptional cases in which the work will be in progress a number of years and most of the large items will be completed within the first few years, leaving the miscellaneous low-profit items to be carried for some time. The contract for a large dam is of this type. The contractor may honestly be using the owner's money rather than other money on which interest must be paid, for the larger part of his operating expenses. Mr. Bush believes that most engineers expect a certain amount of unbalancing unless they include in the set-up, items such as installation of equipment, organization expense, over-head, pumping, and coffer-dams. It is becoming general practice to include many of these in the list of contract items.

In most instances the experienced contractor will bid high on the small items that will possibly be increased in amount, and low on the large items that will be reduced in the final estimate. A contractor who has been operating in one particular line for some years may prove a better estimator than the engineer whose work may extend to many lines and locations. The writer agrees with Mr. Bush that the upper 50% of the bidders are of no importance in connection with a true cost analysis. As a general rule, the lower three or four bidders will be found to agree closely on the total bid.

Mr. Pilkey requests the writer's palliative for the faults of the competitive system of bidding. There is no easy solution of the problem; but more intelligent estimating, by only experienced engineers, will induce the submission of more balanced bids by responsible contractors. The safety features used in connection with the canals on the Kittitas Project were discussed by Mr. Pilkey. If a man were sucked into one of the siphons it is scarcely possible that he would reach the outlet alive. It is impossible even for a deer to climb the sides of these canals, in which the slopes are 1 on 1¼. When the canals are empty the deer that accidently happen in the canal must be stunned and removed by hand. As was pointed out by Mr. Pilkey, some of the early canals that were not completed, would not have been abandoned if they had been under Government supervision. The U. S. Bureau of Reclamation has been able to complete work that would otherwise never have been attempted. Construction work on the storage dam at Lake Cle Elum (see Fig. 1) was begun August 18, 1931, and will be completed about October, 1933. This reservoir, with Lake Kachess and Lake Keechelus Reservoirs, stores water for the entire Yakima River Irrigation District. Little of this work could have been done under private supervision. The early canals were constructed when water was plentiful and when any measurements made were in terms of the miner's inch. As more land was put under irrigation it was necessary to prorate the water, and as more water was needed it was necessary to construct storage reservoirs.

---

[15] See p. 215.

The exact items used in Mr. Betts' analysis of savings due to effective concrete control are not given, but the writer feels that any concrete job of importance will show a comparable saving. The writer agrees with Mr. Betts that costly control is burdensome and that practical inspection, administered with common sense, can be made indispensable. With the batching equipment now on the market the control of batching quantities, including the allowance for surface moisture in the aggregate, is semi-automatic. The charts mentioned should be useful in a large plant where they might be made to a large scale and tacked to the wall. Mr. Betts quotes some strength tolerances in which no test specimens varied more than 15% and in which 90% of the specimens varied within 10% of the average. That is an additional point in favor of effective control. It is better control than could be expected in scattered small structures on the same job. The writer reported 78% on the specimens within 20% of the average of probably one hundred structures, which were poured under possibly forty different inspectors. Mr. Ruettgers' discussion presents a usable method of testing impermeability of concrete. The writer agrees with Mr. Betts that there is need of a standardized test for impermeability. Thus far, no one has proved a direct relation between strength and impermeability, although, in general, they are both improved by the same factors. The writer does not agree that, as a general rule, wetting the mix will increase the imperviousness, other factors remaining the same.

The writer is indebted to Mr. Imrie for the enumeration of changes made in the design of the Yakima River Pressure Tunnel during construction. This structure is a novel design of the type. It is interesting to note that of the 6 750 acres of land shown as held by the Northern Pacific Railroad Company, all but 639 acres had, up to February, 1932, been sold to *bona fide* settlers at the appraised value. A large part of this acreage was very rough terrain.

Unbiased testimony on the use of admixtures in concrete is scarce. The tests reported by Mr. Ruettgers are an important addition to the subject.

The water-cement ratios given in the paper did not allow for the absorption of mixing water by the admixture. The water-cement ratios reported by Mr. Ruettgers as 0.90 would become approximately 0.80 if allowance were made for 200% absorption by the 3% of admixture; this would possibly account for part of the 1% to 15% increase in strength due to the use of admixture. The method of testing for permeability, and the effect of admixtures on the imperviousness of concrete, as reported by Mr. Ruettgers, is also of interest. Engineers concerned with the design of concrete mixes for hydraulic structures should be much interested in his statement concerning this method and the tests upon which the statement is based. The tests to determine the weathering properties are also interesting and instructive. The evidence of men in charge of actual concrete placing generally substantiates the fact that the concrete containing admixture is much more easily placed; that is, it is much more workable, because it contains the necessary "oiliness" or "fatness" for ease in placing. This characteristic can not be obtained by the addition of extra cement.

WATER PRESSURES ON DAMS DURING EARTHQUAKES

By H. M. Westergaard,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Theodor von Kármán, Paul Bauman, R. Robinson Rowe, L. Prandtl, Cecil E. Pearce, John H. A. Brahtz and C. H. Heilbron, Jr., Boris A. Bakhmeteff, N. Mononobe, and H. M. Westergaard

Synopsis

Formulas are derived for the changes of water pressures during an earthquake for the case of a straight dam with a vertical up-stream face. The vibrations in the earthquake are assumed horizontal in a direction perpendicular to the dam. A formula is obtained involving a series of sines (Equation (31)). This series, however, may be replaced with satisfactory approximation by a simpler formula (Equation (49)). The results are also expressed in the following manner: The pressures are the same as if a certain body of water were forced to move back and forth with the dam while the remainder of the reservoir is left inactive; Fig. 3 shows approximately the shape of this body of water. The influence of the dynamic action of the water is found to be neither excessively large nor negligible.

Introductory Remarks Concerning Stresses in Dams During Earthquakes

Two causes account for added stresses in a concrete dam during an earthquake: First, the accelerations of the mass of the dam; and, second, the changes of water pressures. If no fault crosses the site of the dam, one may assume for the purpose of determining the accelerations that all points of the foundation have the same displacement, velocity, and acceleration at the same time, because the wave lengths of the main vibrations in the crust of the earth are so great that the differences of accelerations and the tiltings may be considered negligible.

Note.—Published in November, 1931, *Proceedings*.

[1] Prof. of Theoretical and Applied Mechanics, Univ. of Illinois, Urbana, Ill.; Cons. Engr., U. S. Bureau of Reclamation.

For a straight concrete gravity dam with triangular cross-section, with height, H, and base, B, and with a modulus of elasticity of the concrete of 2 000 000 lb. per sq. in., the period of free vibrations (with the reservoir empty) would be approximately $T_0 = \frac{H^2}{2000\,B}\,\frac{\text{sec.}}{\text{ft.}}$ if the base were rigid.[2] With $B = 0.8H$, the formula gives $T_0 = \frac{H}{1600\text{ ft.}}$ sec.; for example, $T_0 = \frac{1}{8}$ sec. when $H = 200$ ft. On account of the elasticity of the base the actual period is longer, but remains a quantity of the same order. In an arch dam the stiffness of the arches reduces the period, as compared with that given by the formula.

Hence, since the period of free vibrations of the dam, T_0, is usually a fraction of a second, while the period of vibration, T, of the earthquake may be assumed to be not less than a second[3] (1.35 sec. measured during the great earthquake in Japan in 1923[4]), resonance—with vibrations of the structure becoming large compared with those of the foundation—need not be expected ordinarily, although the possibility of part resonance may well be investigated in some cases of high dams. When the ratio, $\frac{T_0}{T}$, is small, all points of the dam may be assumed at each time to have the same acceleration as the base. If the maximum horizontal acceleration is $a = \alpha\, g$, in which g is the acceleration due to gravity, the ratio, α, is used as a measure of the intensity of the earthquake. The value, $\alpha = 0.1$, appears to be a reasonable one to use in investigating dams founded on rock in earthquake regions in the United States.

The problem of the dynamic action of the mass of the dam is transformed into an equivalent problem of statics by introducing the inertia forces, expressed as mass times the acceleration reversed (d'Alembert's principle); that is, on each part of the dam weighing 1 lb. there is introduced a horizontal inertia force, opposite the direction of the acceleration and equal to $\frac{1\text{ lb}}{g} \times \alpha\, g = \alpha$ lb. The vertical accelerations, which by the nature of the phenomenon are smaller, either may be treated similarly or may possibly be ignored. If they are ignored, the combined effect of the dead weight and the inertia forces may be described as follows: Each gravity force of 1 lb. is changed into an inclined force, which has a vertical component equal to 1 lb., and a slope relative to the vertical equal to α. If α is not larger than, say, 0.1, the effect is nearly the same as though the dam were tilted so that a line that was horizontal will have a slope, α. The determination of the corresponding stresses involves no new difficulties that have not already been encountered in dealing with static loads.

---

[2] See, for example, S. Timoshenko and J. M. Lessells, "Applied Elasticity," 1925, p. 323.

[3] Handbuch der Physik, Vol. 6, 1928, p. 596. The short periods occur only when the center of the earthquake is close.

[4] "Effect of Earth Shocks on Structures," M. de Bussy, *Proceedings*, Am. Soc. C. E., May, 1928, Papers and Discussions, p. 1449.

When the water pressures are known, their influence on the stresses may be computed by the methods applying to static loads. The problem that needs particular attention, therefore, is that of the changes of the water pressures during the earthquake.

NOTATION

The following notation is adopted:

x, y, z = rectangular co-ordinates x and y as shown in Fig. 1; the axis of x is along the undisturbed surface of the water, is directed up stream, and is perpendicular to the plane up-stream face of the dam; the axis of y is vertical downward.

t = time.

h = depth of reservoir.

g = acceleration due to gravity. (See Equations (10).)

w = weight of water per unit of volume. (See Equations (10).)

k = modulus of elasticity of volume of the water (pressure divided by reduction of volume per unit of volume). (See Equations (10).)

ξ and η = displacements of a particle of water in the directions of x and y, respectively.

ξ_0 = value of ξ at up-stream face of the dam.

σ = stress in the water due to the dynamic action, positive as tension (to be combined with the hydrostatic pressure existing beforehand).

α = ratio measuring the intensity of the earthquake = maximum horizontal component of the acceleration of the foundation divided by g.

T = period of horizontal vibrations of the foundation.

r, v = amplitude and maximum velocity of horizontal vibrations of the foundation.

v_s = velocity of sound in water.

l = length of waves of expansion in the water when the period is T.

c_n = value defined by Equations (17), (23), and (32) ($n = 1, 3, 5 \ldots$).

p = maximum pressure of the water on the dam at the depth, y, due to the dynamic action.

p_0 = value of p at the bottom ($y = h$).

Q = horizontal shear produced in a straight gravity dam at the depth, y, by the pressures, p.

Q_0 = value of Q at the bottom ($y = h$).

M = bending moment produced in a straight gravity dam at the depth, y, by the pressures, p.

M_0 = value of M at the bottom ($y = h$).

C, K = coefficients in approximate formulas (Equations (40) to (48).

b, b' = dimensions shown in Fig. 3.

EQUATIONS OF MOTION OF THE WATER

Since the motions involved are small, the relatively simple equations may be used, that apply to sound in liquids.[5] These equations may be interpreted in terms of the theory of elasticity of solids as equations of elasticity without shearing stresses.

The forces acting on an element of volume, $dx\ dy\ dz$, are expressed in terms of the tensile stress, σ, which must be superimposed on the hydrostatic pressure existing before the disturbance. The force on the face with the abscissa, $x + dx$, exceeds that on the face with the abscissa, x, by the amount, $\frac{\partial \sigma}{\partial x} dx$ per unit of area, or, by a total amount of $\frac{\partial \sigma}{\partial x} dx\, dy\, dz$. The mass of the element is $\frac{w}{g} dx\, dy\, dz$, and its acceleration is $\frac{\partial^2 \xi}{\partial t^2}$ (ξ being the displacement in the direction of x). Equating the force to the mass times the acceleration one finds the first of the following two equations:

---

[5] "Hydrodynamics," by Horace Lamb, Fifth Edition, 1924, Chapter X.

$$\frac{\partial \sigma}{\partial x} = \frac{w}{g} \frac{\partial^2 \xi}{\partial t^2} \quad \text{.........................} (1)$$

$$\frac{\partial \sigma}{\partial y} = \frac{w}{g} \frac{\partial^2 \eta}{\partial t^2} \quad \text{.........................} (2)$$

Equation (2) refers to the motion in the direction of y, and applies by analogy; a third analogous equation, for the direction of z, need not be written, since only plane motions, parallel to the xy-plane, will be considered.

The stress, σ, in Equations (1) and (2), has the relation,

$$\sigma = k\, \epsilon \quad \text{.........................} (3)$$

to the increase of volume per unit of volume, ϵ, that it produces. The constant, k, is the modulus of elasticity of volume. One may write,

$$\epsilon = \frac{\partial \xi}{\partial x} + \frac{\partial \eta}{\partial y} \quad \text{.........................} (4)$$

Consequently,

$$\sigma = k \left(\frac{\partial \xi}{\partial x} + \frac{\partial \eta}{\partial y} \right) \quad \text{.........................} (5)$$

The motion is governed by Equations (1), (2), and (5). A comparison with the general equations of hydrodynamics for compressible fluids[6] shows that Equations (1), (2), and (5) may be assumed to apply when ξ and η are small, and when, in addition, the ratios of the products, $\frac{\partial \xi}{\partial t} \times \frac{\partial \sigma}{\partial x}$ and $\frac{\partial \eta}{\partial t} \times \frac{\partial \sigma}{\partial y}$ to $\frac{\partial \sigma}{\partial t}$, are negligible. In the solutions given in Equations (15), (16), and (20), these ratios are found to be of the order of the amplitude of the motions divided by the depth of the reservoir.

PRELIMINARY STUDY, ASSUMING HORIZONTAL MOTION ONLY

The fact that the water, when pressed by the dam, may escape vertically, is important. A preliminary study in which this vertical motion is assumed to be barred, will nevertheless throw some light on the problem.

With $\eta = 0$, Equations (1) and (5) give:

$$k \frac{\partial^2 \xi}{\partial x^2} = \frac{w}{g} \frac{\partial^2 \xi}{\partial t^2} \quad \text{.........................} (6)$$

---

[6] See, for example, Handbuch der Physik, Vol. VII, 1927, p. 291.

Assume that the dam moves during the earthquake in a simple harmonic motion with period, T, and a maximum acceleration, αg, occurring when $t = 0$, T, $2T$, etc. This motion is expressed by the equation,

$$\xi_0 = -\frac{\alpha g T^2}{4\pi^2}\cos\frac{2\pi t}{T} \qquad \text{(7)}$$

The requirement, $\xi_{x=0} = \xi_0$, and Equation (6) are satisfied by the solution,[7]

$$\xi = -\frac{\alpha g T^2}{4\pi^2}\left[\beta\cos\frac{2\pi}{T}\left(t-\frac{x}{v_s}\right)+(1-\beta)\cos\frac{2\pi}{T}\left(t+\frac{x}{v_s}\right)\right] \qquad \text{(8)}$$

in which, β is a constant, and,

$$v_s = \sqrt{\frac{gk}{w}} \qquad \text{(9)}$$

The quantity, v_s, is the velocity of the waves of expansion in the water; that is, the velocity of sound (on account of the low frequency, these waves, of course, would not be audible as sound). The values,

$$\left.\begin{aligned} k &= 300\,000\,\frac{\text{lb.}}{\text{in.}^2} = 21\,600\,\frac{\text{ton}}{\text{ft.}^2} \\ g &= 32.2\,\frac{\text{ft.}}{\text{sec.}^2} \\ w &= 0.03125\,\frac{\text{ton}}{\text{ft.}^3} \end{aligned}\right\} \qquad \text{(10)}$$

give $v_s = 4\,718$ ft. per sec. The value, $v_s = 4\,714$ ft. per sec., was measured by Wertheim in the Seine River at the temperature of 15° cent.[8]

The term in Equation (8) containing the factor, β, in front of the cosine represents waves moving away from the dam, while that containing the factor, $1-\beta$, represents waves moving toward the dam.

Equations (8) and (5) give for $x = 0$ (that is, at the up-stream face of the dam):

$$\sigma = (1-2\beta)\frac{\alpha T}{2\pi}\sqrt{gkw}\,\sin\frac{2\pi t}{T} \qquad \text{(11)}$$

When $\beta > \frac{1}{2}$, that is, when the waves moving away from the dam predominate over those moving toward it, Equation (11) shows that the maximum pressure on the dam, that is, $(-\sigma)_{\max.}$, occurs at the times $t = \frac{T}{4}, \frac{5T}{4}, \frac{9T}{4}, \ldots$, and is equal to,

$$p = (2\beta-1)\frac{\alpha T}{2\pi}\sqrt{gkw} \qquad \text{(12)}$$

It is noted that the greatest acceleration of the dam, and, consequently, the greatest inertia forces due to the moving mass of the dam, occur when $t = 0, T, 2T, \ldots$ The stresses in the dam due to the pressures, p, and the inertia forces, therefore, would have to be combined in the manner of two alternating currents with a difference of phase of one-quarter of the period.

---

[7] "Hydrodynamics", by Horace Lamb, Fifth Edition, 1924, p. 452.

[8] Smithsonian Physical Tables, Seventh Edition, 1921, p. 147.

Since, according to Equation (7), the maximum velocity of the dam is,

$$v = \frac{\alpha g T}{2\pi} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

Equation (12) may be rewritten, by the use of Equation (9), in the form,

$$p = (2\beta - 1)\frac{v}{v_s}k \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

With $\beta = 1$, that is, when the waves move away from the dam only, Equation (12) (or, if one prefers, Equation (14)), with the numerical constants stated in Equations (10), and with $\alpha = 0.1$ and $T = \frac{4}{3}$ sec., gives $p = 3.13$ tons per sq. ft. On account of the freedom of the water to escape vertically the pressures are actually much less, and are not distributed uniformly through the depth of the reservoir. A solution which is to be used must show the pressures in the water to be zero at the top.

Solution Considering Horizontal and Vertical Motions of the Water

A solution is desired which satisfies Equations (1), (2), and (5), and, in addition, the following conditions at the boundary:

(1) $\sigma = 0$, when $y = 0$;

(2) $\eta = 0$, when $y = h$;

(3) $\xi = -\frac{\alpha g T^2}{4\pi^2}\cos\frac{2\pi t}{T}$, when $x = 0$; and,

(4) σ converges toward 0 when x becomes large.

In connection with Condition (1), it is noted that when the values of η are small, it makes no appreciable difference whether one specifies $\sigma = 0$ at the undisturbed or the disturbed surface.

The following solution will be shown to satisfy all these conditions:

$$\xi = -\frac{\alpha g T^2}{\pi^3}\cos\frac{2\pi t}{T}\sum_{1,3,5,..}^{n}\frac{1}{n}e^{-q_n}\sin\frac{n\pi y}{2h} \quad \ldots\ldots\ldots\ldots\ldots (15)$$

and,

$$\eta = \frac{\alpha g T^2}{\pi^3}\cos\frac{2\pi t}{T}\sum_{1,3,5,..}^{n}\frac{1}{n c_n}e^{-q_n}\cos\frac{n\pi y}{2h} \quad \ldots\ldots\ldots\ldots\ldots (16)$$

in which,

$$c_n = \sqrt{1 - \frac{16 w h^2}{n^2 g k T^2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (17)$$

and,

$$q_n = \frac{n \pi c_n x}{2h} \quad \text{.........................} (18)$$

Equation (17) gives,

$$\frac{1}{c_n} - c_n = \frac{16 w h^2}{n^2 c_n g k T^2} \quad \text{.........................} (19)$$

Then Equations (5), (15), (16), and (19) lead to the value of the stress,

$$\sigma = -\frac{8 \alpha w h}{\pi^2} \cos \frac{2 \pi t}{T} \sum_{1, 3, 5, \ldots}^{n} \frac{1}{n^2 c_n} e^{-q_n} \sin \frac{n \pi y}{2h} \quad \text{..............} (20)$$

That the solution represented by Equations (15), (16), and (20) satisfies Equations (1) and (2) at all points is verified easily by performing the required differentiations with respect to t, x, and y. Equation (5) is satisfied because it was used in deriving Equation (20) from Equations (15) and (16). Furthermore, inspection of the expressions for η and σ shows immediately that Conditions (1), (2), and (4) are satisfied. That Condition (3), for $x = 0$, is satisfied, is seen by comparing Equation (15) for $x = 0$ with the expression for $\frac{\pi}{4}$, in terms of a Fourier series,[9] applicable when $0 < u < \pi$,

$$\frac{\pi}{4} = \sin u + \frac{1}{3} \sin 3u + \frac{1}{5} \sin 5u + \quad \text{............} (21)$$

In the present application, $u = \frac{\pi y}{2h}$.

Thus, all the specified conditions are satisfied. The applicability of the equations depends, however, on an additional condition: The displacements defined by the solution, as well as their derivatives with respect to x and y,[10] must be small. It is necessary then to examine the possibilities of large displacements. One possibility is identified with resonance in the water; another will be investigated by determining the shape of the wave formed by the surface of the water and the vertical motions along the up-stream face of the dam.

POSSIBILITY OF RESONANCE IN THE WATER

The waves of expansion (or waves of sound) represented by Equations (8) and (9) have the wave length,

$$l = v_s T = T \sqrt{\frac{gk}{w}} \quad \text{.........................} (22)$$

By use of this value Equation (17) may be rewritten in the form,

$$c_n = \sqrt{1 - \frac{16 h^2}{n^2 l^2}} \quad \text{.........................} (23)$$

---

[9] See, for example, "Short Table of Integrals", by B. O. Pierce, Second Edition, 1910, p. 95, Formula 808.

[10] Compare the remark following Equation (5).

With $n = 1$, one finds $c_1 = 0$ if $h = \frac{l}{4}$, that is, if the depth of the reservoir is one-fourth of a wave length. This case is analogous to that of an organ pipe open at the top; one may expect the water to vibrate like the air in the pipe. That resonance occurs, is shown by Equations (16) and (20); they give infinite values of η and σ in this case. If h approaches the value, $\frac{l}{4}$, the equations lead to large values of η and σ.

With the period, $T = 1$ sec., $\frac{l}{4}$ becomes $\frac{1}{4} \times 4\,718 \frac{\text{ft.}}{\text{sec.}} \times 1 \text{ sec.} = 1\,180$ ft. Since the main vibrations in the earthquake are not likely to have a period less than 1 sec., this form of resonance need not be expected in any project now contemplated.

SHAPE OF THE WAVE AND VERTICAL MOTIONS AT UP-STREAM FACE OF DAM

In actual cases the values of c_n do not differ greatly from 1. In examining the vertical displacements it will be permissible, therefore, to write $c_n = 1$. In terms of the maximum displacement of the dam according to Condition (3) (stated shortly before Equation (15)),

$$r = \frac{\alpha g T^2}{4 \pi^2} \quad \text{.......................} (24)$$

Equation (16) gives then the following expressions for η at the top ($y = 0$) and at the up-stream face ($x = 0$) when $t = 0, T, 2T, \ldots$:

$$\eta_{y=0} = \frac{4\,r}{\pi} \sum_{1,3,5,..}^{n} \frac{1}{n}\, e^{-\frac{n \pi x}{2h}} \quad \text{.......................} (25)$$

and,

$$\eta_{x=0} = \frac{4\,r}{\pi} \sum_{1,3,5,..}^{n} \frac{1}{n} \cos \frac{n \pi y}{2h} \quad \text{.......................} (26)$$

By use of the formulas,[11]

$$\left.\begin{aligned} &\tfrac{1}{2} \log_e \frac{1+u}{1-u} = u + \frac{u^3}{3} + \frac{u^5}{5} + \frac{u^7}{7} + \ldots\ldots\ldots \\ &\text{and,} \\ &-\tfrac{1}{2} \log_e \tan \frac{U}{2} = \cos U + \frac{1}{3} \cos 3\,U + \frac{1}{5} \cos 5\,U + \ldots \end{aligned}\right\} \ldots\ldots (27)$$

---

[11] "Short Table of Integrals", by B. O. Pierce, Second Edition, 1910, pp. 82, 94, and 96, Formulas 681, 797, 813, and 814.

with the substitutions, $u = e^{-\frac{\pi x}{2h}}$, $U = \frac{\pi y}{2h}$, one finds,

$$\eta_{y=0} = \frac{2r}{\pi} \log_e \frac{1 + e^{-\frac{\pi x}{2h}}}{1 - e^{-\frac{\pi x}{2h}}} = -\frac{2r}{\pi} \log_e \tanh \frac{\pi x}{4h} \ldots\ldots\ldots (28)$$

and,

$$\eta_{x=0} = -\frac{2r}{\pi} \log_e \tan \frac{\pi y}{4h} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

These formulas give $\eta = \infty$ at the point, $x = 0$, $y = 0$; that is, the solution in Equations (15), (16), and (20) has a singularity (infinite values) at this point, and the condition that the displacements and their first derivatives must remain small, is not satisfied at this point and in the neighborhood of this point. The solution, nevertheless, may very well be adequate (except at and near the singularity), if only the region of large values of η can be shown to be small.

When $x = 0.1h$, one finds $\tanh \frac{\pi x}{4h} = \tanh 0.07854 = 0.07838$. Likewise, when $y = 0.1h$, one finds $\tan \frac{\pi y}{4h} = \tan 0.07854 = 0.07870$. For these and smaller values of x and y, one may accordingly replace Equations (28) and (29) by the simpler approximate formula,

$$\eta_{y=0} \text{ or } \eta_{x=0} = -\frac{2r}{\pi} \log_e \frac{\pi (x \text{ or } y)}{4h} = \left(1.466 \log_{10} \frac{h}{x \text{ or } y} + 0.1538\right) r \ldots (30)$$

Assume, for example, that $\alpha = 0.1$, $T = \frac{4}{3}$ sec.; then Equation (24) gives the amplitude of the motion of the dam, $r = 0.1450$ ft. With $h = 200$ ft., Equation (30) gives the values shown in Table 1.

TABLE 1.—VALUES OF η BY EQUATION (30) FOR $h = 200$ FEET

At distance, x or y (in feet)	0.1	1	5	10	20
Movement, $\eta_{y=0}$, or $\eta_{x=0}$ (in feet)	0.724	0.511	0.363	0.299	0.235

These computations show that the region about the point, $x = 0$, $y = 0$, within which the displacements become large, is so small that the discrepancies introduced by the singularity at this point can have only a negligible influence on the solution as a whole. The solution in Equations (15), (16) and (20) has no other singularities (points at which infinite values are found), and therefore may be accepted as applying to the case.

PRESSURES ON THE DAM

According to Equation (20), the maximum pressures, p $(= -\sigma \text{ for } x = 0)$, of the water on the dam occur when $t = 0, T, 2T$, etc. One finds,

$$p = \frac{8\,\alpha\,w\,h}{\pi^2} \sum_{1,3,5,\ldots}^{n} \frac{1}{n^2 c_n} \sin\frac{n\,\pi\,y}{2\,h} \ldots\ldots\ldots\ldots\ldots\ldots (31)$$

in which, as before, according to Equation (17), and with the numerical constants stated in Equations (10):

$$c_n = \sqrt{1 - \frac{16\,w\,h^2}{n^2\,g\,k\,T^2}} = \sqrt{1 - \frac{0.71889}{n^2}\left(\frac{h \text{ sec.}}{1\,000\,T \text{ ft.}}\right)^2} \ldots\ldots\ldots (32)$$

The greatest value of the pressure, p, occurs at the bottom of the reservoir $(y = h)$, and is,

$$p_0 = \frac{8\,\alpha\,w\,h}{\pi^2} \sum_{1,3,5,\ldots}^{n} \frac{(-1)^{\frac{n-1}{2}}}{n^2\,c_n} \ldots\ldots\ldots\ldots\ldots\ldots (33)$$

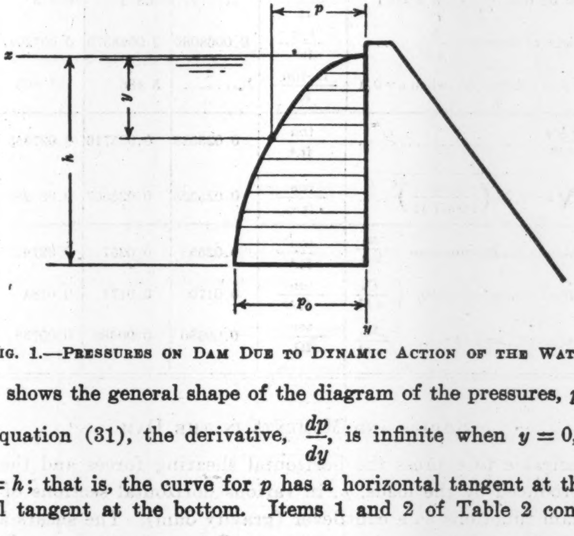

FIG. 1.—PRESSURES ON DAM DUE TO DYNAMIC ACTION OF THE WATER

Fig. 1 shows the general shape of the diagram of the pressures, p. According to Equation (31), the derivative, $\frac{dp}{dy}$, is infinite when $y = 0$, and zero when $y = h$; that is, the curve for p has a horizontal tangent at the top and a vertical tangent at the bottom. Items 1 and 2 of Table 2 contain some numerical values of the ratio, $\frac{p_0}{\alpha h}$, and of p_0, computed from Equations (32) and (33). The ratio, $\frac{p_0}{\alpha h}$, is seen to vary only slowly with h. In the case of $h = 600$ ft., $T = \frac{4}{3}$ sec. (or $h = 200$ ft., $T = \frac{4}{9}$ sec.), the pressure at the depth, $y = \frac{h}{2}$, was found to be $p = 0.814 p_0$.

TABLE 2.—NUMERICAL RESULTS CORRESPONDING TO THE PERIOD, $T = \frac{4}{3}$ SECOND

(The maximum horizontal acceleration equals $\alpha\, g$. When T is varied, the coefficients stated remain constant if h is changed by the same ratio; for example, the coefficients stated for $h = 800$ ft., $T = \frac{4}{3}$ sec., apply to the cases, $h = 600$ ft., $T = 1$ sec., and $h = 200$ ft., $T = \frac{1}{3}$ sec.; the coefficients stated for $h = 200$ ft., $T = \frac{4}{3}$ sec., apply to the case, $h = 600$ ft., $T = 4$ sec.)

SHEARS AND MOMENTS IN THE DAM

It is desirable to express the horizontal shearing forces and the bending moments produced by the loads, p, in various horizontal sections of the dam when the dam functions as a cantilever (gravity dam). The shears are stated as force per unit of width of the cantilever, for example, in tons per foot, and the moments are stated as moment per unit of width, for example, in foot-tons per foot (or simply in tons). The shears, Q, at the depth, y, and Q_0, at the depth, h, and the moments, M, at the depth, y, and M_0, at the depth, h, are obtained from p in Equation (31) by the integrations,

$$Q = \int_0^y p\, dy;\ Q_0 = \int_0^h p\, dy;\ M = \int_0^y Q\, dy;\ M_0 = \int_0^h Q\, dy \quad \text{.....(34)}$$

With the notation,

$$q = \sum_{1,3,5,\ldots}^{n} \frac{1}{n^3 c_n} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (35)$$

one finds by this process:

$$Q = \frac{16\,\alpha\,w\,h^2}{\pi^3}\left(q - \sum_{1,3,5,\ldots}^{n} \frac{1}{n^3 c_n} \cos\frac{n\,\pi\,y}{2\,h}\right) \ldots\ldots\ldots\ldots (36)$$

$$Q_0 = \frac{16}{\pi^3}\,\alpha\,w\,h^2\,q \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (37)$$

$$M = \alpha\,w\,h^3\left(\frac{16q}{\pi^3}\,\frac{y}{h} - \frac{32}{\pi^4}\sum_{1,3,5,\ldots}^{n}\frac{1}{n^4 c_n}\sin\frac{n\,\pi\,y}{2\,h}\right) \ldots\ldots\ldots (38)$$

and,

$$M_0 = \alpha\,w\,h^3\left(\frac{16q}{\pi^3} - \frac{32}{\pi^4}\sum_{1,3,5,\ldots}^{n}\frac{(-1)^{\frac{n-1}{2}}}{n^4 c_n}\right) \ldots\ldots\ldots\ldots (39)$$

Numerical values of the ratios, $\frac{Q_0}{\alpha\,h^2}$ and $\frac{M_0}{\alpha\,h^3}$, and of Q_0 and M_0, computed from Equations (35), (37), and (39), are stated in Table 2 (see, Items, 3, 4, 5, and 6).

Derivation of Approximate Formulas

For the purpose of approximate computations one might replace the diagram of pressures in Fig. 1 by a quadrant of an ellipse (see Equation (50) derived subsequently); the ellipse becomes a circle when drawn to some particular scale for p. A more satisfactory approximate representation is obtained, however, by replacing the curve in Fig. 1 by a parabola with vertical axis, as shown in Fig. 2, even if this parabola has a sloping tangent at the bottom.

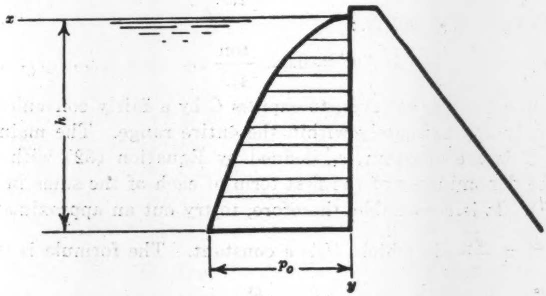

Fig. 2.—Approximate Distribution of Pressures.

The parabola leads to the following simple formulas, in which, C is a coefficient depending on the ratio of h to T:

$$p = C\,\alpha\,\sqrt{hy}\;;\; p_0 = C\,\alpha\,h \tag{40}$$

$$Q = \frac{2}{3}\,C\,\alpha\,y\,\sqrt{hy}\;;\; Q_0 = \frac{2}{3}\,C\,\alpha\,h^2 \tag{41}$$

and,

$$M = \frac{4}{15}\,C\,\alpha\,y^2\,\sqrt{hy}\;;\; M_0 = \frac{4}{15}\,C\,\alpha\,h^3 \tag{42}$$

The coefficient, C, might be determined so that p_0 will have the value computed from Equation (33), but one obtains a better representation of the diagram of pressures as a whole, by determining C so that the moment, M_0, will have the value computed from Equation (39). In terms of a known M_0, one finds then,

$$C = \frac{15\,M_0}{4\,\alpha\,h^3} \tag{43}$$

Table 2 (Item 7) shows some numerical values of C. It is noted that the dimension of C is force per unit of volume; C multiplied by αh gives the pressure as force per unit of area.

The coefficient, C, varies slowly within the range considered. For quick estimates one may very well assume some constant value of C; for example, with $T \geqq \frac{4}{3}$ sec.:

When $h < 310$ ft.:

$$C = 0.026\,\frac{\text{ton}}{\text{ft.}^3} \tag{44}$$

when 310 ft. $< h <$ 540 ft.:

$$C = 0.027\,\frac{\text{ton}}{\text{ft.}^3} \tag{45}$$

and when 540 ft. $< h <$ 680 ft.:

$$C = 0.028\,\frac{\text{ton}}{\text{ft.}^3} \tag{46}$$

It is a simple matter, however, to express C by a fairly convenient formula which will apply approximately within the entire range. The main source of variation of C is the constant, c_1, defined by Equation (32) with $n = 1$; c_1 appears in the denominator of the first term of each of the sums in Equations (35) and (39). It is reasonable, therefore, to try out an approximate formula of the type, $C = \dfrac{K}{c_1}$, in which, K is a constant. The formula is written,

$$C = \frac{K}{\sqrt{1 - 0.72\left(\dfrac{h\ \text{sec.}}{1\,000\ T\ \text{ft.}}\right)^2}} \tag{47}$$

The values of K shown in Table 2 (Item 8) were computed from this formula by using the values of C in Item 7. Inspection of these results shows that one may adopt the value, $K = 0.0255 \text{ ton-ft.}^{-3}$. It is concluded that the coefficient, C, in Equations (40), (41), and (42), is expressed with satisfactory approximation by the formula,

$$C = \frac{0.0255 \text{ ton-ft.}^{-3}}{\sqrt{1 - 0.72\left(\frac{h \text{ sec.}}{1\,000\, T \text{ ft.}}\right)^2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (48)$$

RESULTING APPROXIMATE FORMULA FOR THE WATER PRESSURES

The following approximate formula for the maximum water pressures, to be added to the hydrostatic pressures existing before the earthquake, represents the main conclusion from this study; it is obtained directly from Equations (40) and (48):

$$p = \frac{0.0255 \text{ ton-ft.}^{-3}\ \alpha \sqrt{hy}}{\sqrt{1 - 0.72\left(\frac{h \text{ sec.}}{1\,000\, T \text{ ft.}}\right)^2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (49)$$

For quick computations, however, Equations (40), (44), (45), and (46) may be used. Values of the coefficients, $\frac{p_0}{\alpha h}$, $\frac{Q_0}{\alpha h^2}$, and $\frac{M_0}{\alpha h^3}$, obtained by use of Equation (49), are stated as Items 9, 10, and 11 in Table 2. A comparison with Items 1, 3, and 5, respectively, shows that the approximation is satisfactory.

By using a quadrant of an ellipse (as suggested under "Derivation of Approximate Formulas") instead of the parabola to represent the pressures, one obtains the following approximate formula by a process similar to that leading to Equation (49):

$$p = \frac{0.0204 \text{ ton-ft.}^{-3}\ \alpha \sqrt{y\,(2h - y)}}{\sqrt{1 - 0.72\left(\frac{h \text{ sec.}}{1\,000\, T \text{ ft.}}\right)^2}} \quad \ldots\ldots\ldots\ldots\ldots (50)$$

This formula gives exactly the same values of M_0 as Equation (49), but gives too small values of p_0 and of the total force, Q_0. Equation (49) gives slightly too large values of p_0 and Q_0, and is preferable.

It is noted that the pressures, p, occur when $t = 0$, T, $2T$, etc., that is, (see Condition (3)), when the dam (during the vibration) is in the extreme position down stream. The stresses due to these water pressures, therefore, must be added to the maximum stresses due to the accelerations of the mass of the dam iself.

When, during the vibration, the dam is in the extreme position up stream, the pressures, p, are reversed and become tensions. These tensions, like the pressures in the extreme position down stream, are to be combined with the hydrostatic pressures existing beforehand. Inspection of the numerical values in Table 2 shows that when the pressure of the atmosphere is included, there is no prospect of the resultant stress in the water becoming either a tension or a very small compression.

Applicability of Formulas to Cases Other than Those Assumed

The formulas were derived under the assumption that there is no overflow. In case of overflow over a spillway it is suggested that Equation (49) be used with the depths, h and y, measured from the plane surface of the reservoir at some distance behind the dam. The parabolic diagram of pressures is then used as before, only the top is cut off.

While the formulas were derived under the assumption that the up-stream face is a vertical plane, they will furnish an indication of the pressures which may be expected in other cases, for example, in the case of arch dams.

The Body of Water Which May Be Considered to Move with the Dam

To visualize the dynamic action of the water on the dam, one may think of a certain body of water as moving with the dam while the remainder of the reservoir remains inactive. For this purpose the body of water moving with the dam may be imagined as frozen into horizontal layers of ice (the expansion by freezing being ignored), while the remainder of the reservoir is emptied. The layers of ice are imagined to support one another by vertical forces only, without friction between the layers; the layers are attached firmly to the dam, so that the dam will exert the horizontal forces necessary to move them back and forth with it. The advantage of picturing the action in this manner is that the forces exerted on the up-stream face of the dam will then be represented as inertia forces like those due to the moving mass of the dam itself.

The shape of the body of water or ice thus considered to move with the dam must be determined so that the inertia forces become equal to the pressures actually exerted by the water due to the dynamic action. With b denoting the dimension of this body in the direction of x at the depth, y, the corresponding mass per unit of area of the up-stream face of the dam becomes $\frac{b\,w}{g}$, and the corresponding inertia force when the acceleration is $\alpha\,g$ becomes $\frac{b\,w}{g} \times \alpha\,g = \alpha\,wb$, which must be equal to p. One finds then:

$$b = \frac{p}{\alpha\,w} \qquad \text{(51)}$$

That is, the shape of this body of water or ice is the same as that of the diagram for p when the pressures are laid off to a proper scale.

It will be sufficient for the present purpose to determine b by one of the approximate expressions for p; for example (compare Equations (40), (44), (45), and (46)),

$$p = 0.02734 \text{ ton-ft.}^{-3}\,\alpha\sqrt{hy} \qquad \text{(52)}$$

which gives, with $w = 0.03125$ ton-ft.$^{-3}$,

$$b = \frac{7}{8}\sqrt{hy} \qquad \text{(53)}$$

Fig. 3 shows the body of water or ice defined by Equation (53).

Instead of the body of water, one may prefer to consider an equivalent body of concrete, having the same mass. If the concrete weighs 144 lb. per cu. ft., the dimension corresponding to b becomes,

$$b' = 0.38\sqrt{hy} \quad \text{(54)}$$

The dotted curve in Fig. 3 indicates this body of concrete. Like the body of ice that was described, it should be imagined as divided into layers resting on one another without friction. The picture then represents no addition to the strength of the dam, but a proper addition to the mass.

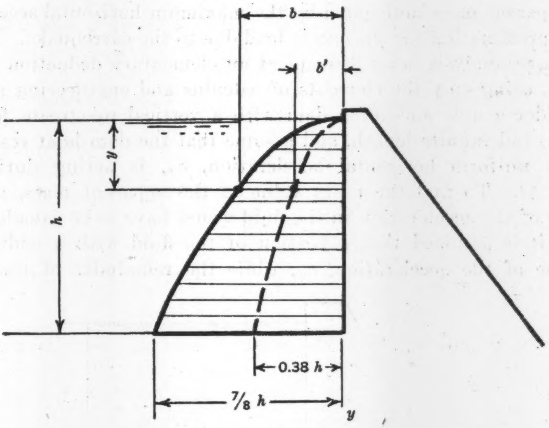

FIG. 3.—BODY OF WATER WHICH MAY BE CONSIDERED TO MOVE WITH DAM. DOTTED CURVE SHOWS EQUIVALENT BODY OF CONCRETE.

ACKNOWLEDGMENTS

This study was made in Denver, Colo., at the United States Bureau of Reclamation, in connection with the design of the Hoover Dam, during a leave of absence of the writer from the University of Illinois. All the important designing work of the Bureau of Reclamation is done in Denver, under the general supervision of J. L. Savage, M. Am. Soc. C. E., Chief Designing Engineer; all engineering and construction are under the general charge of R. F. Walter, M. Am. Soc. C. E., Chief Engineer, with headquarters in Denver; and all the activities of the Bureau are under the general charge of Elwood Mead, M. Am. Soc. C. E., Commissioner, with headquarters in Washington, D. C.

DISCUSSION

Theodor von Kármán,[12] **M. Am. Soc. C. E.** (by letter).—In his paper Professor Westergaard has presented a beautiful and complete analysis of the pressure distribution on a dam undergoing horizontal oscillations of sinusoidal law. He has investigated both the influence of compression waves in the fluid and the effect of the so-called "apparent mass." It is found that, in the range of the frequencies supposed to occur in oscillations due to earthquake, the effect of compressibility is comparatively small, so that the value of the apparent mass multiplied by the maximum horizontal acceleration gives a first approximation for the excess load due to the earthquake. The following approximate analysis is an attempt at an elementary deduction of the apparent mass, using only the elements of calculus and engineering mechanics.

Consider a unit slice of a dam with a vertical up-stream face, with the height, h, and infinite length, and assume that the dam is at rest when $t = 0$, and that uniform horizontal acceleration, a_x, is acting during the time interval, Δt. To find the exact value of the apparent mass, the exact distribution of the acceleration in the fluid would have to be calculated. Instead of that, it is assumed that a portion of the fluid with a width, b, has the full value of the acceleration, a_x, while the remainder of the fluid is not affected in the process. The width, b, varies with the height (see Fig. 4). With this assumption, Conditions (a), (b), and (c) are readily obtained as follows:

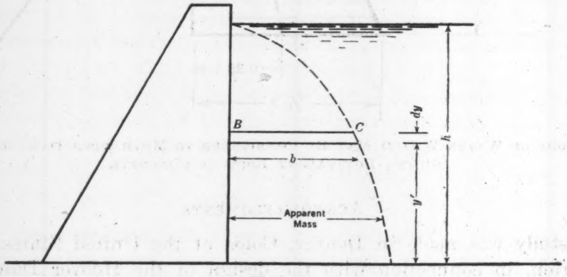

FIG. 4.

(a) *Condition for "Continuity" of Flow.*—Consider the part of the dam between the bottom at $y' = 0$, and an arbitrary height, y'. Then, the fluid mass displaced by this part of the dam must pass through the section, BC. Assume that the vertical acceleration is variable with the height, and has the mean value, a_y', between $x = 0$ and $x = b$, while for $x > b$, the fluid is supposed to be at rest. The displacement of the dam during the time, Δt, is, obviously, $a_x \dfrac{\Delta t^2}{2}$, and the displacement of the fluid through the section,

---

[12] Prof., and Director, Aeronautical Laboratory, California Inst. of Technology, Pasadena, Calif.

$BC = b$, is $a_y' \dfrac{\Delta t^2}{2}$, so that the condition of continuity requires that $y' a_x \dfrac{\Delta t^2}{2} = b\, a_y' \dfrac{\Delta t^2}{2}$, or,

$$y'\, a_x = b\, a_y' \ldots\ldots\ldots\ldots\ldots\ldots (55)$$

(*b*) *Equilibrium Between Pressure and Horizontal Mass Forces.*—Let the pressure at an arbitrary height, y', be $p_{y'}$, and let the density of the fluid be ρ. Then, the pressure is obviously equal to $p\, dy' = \rho\, b\, dy'\, a_x$, or,

$$p = \rho\, b\, a_x \ldots\ldots\ldots\ldots\ldots\ldots (56)$$

(*c*) *Equilibrium Between Pressure and Vertical Mass Forces.*—Consider a portion of the fluid body with the variable width, b, between two sections in the height, y', and $y' + dy'$. The resultant of the pressure on the bottom surface of the element is equal to $p\, b$, and that of the pressure acting on the top surface equals $p\, b + \dfrac{d}{dy'}(p\, b)\, dy'$. Now, the difference, $-\dfrac{d}{dy'}(p\, b)\, dy'$, must be equal to the product of the mass of the element, $\rho\, b\, dy'$, and the vertical acceleration, a_y'. Hence, $-\dfrac{d}{dy'}(p\, b)\, dy' = \rho\, a_y'\, b\, dy'$, or,

$$\frac{d}{dy'}(p\, b) = -\rho\, b\, a_y' \ldots\ldots\ldots\ldots\ldots\ldots (57)$$

Substituting $a_y' = \dfrac{y'}{b} a_x$ from Equation (55) and $p = \rho\, b\, a_x$ from Equation (56), Equation (57) becomes,

$$\frac{d}{dy'}\left[\rho\, b^2\, a_x\right] = -\rho\, y'\, a_x \ldots\ldots\ldots\ldots\ldots\ldots (58)$$

or, since p and a_x have been assumed constant, $\dfrac{d}{dy'}(b^2) = -y'$, and,

$$b^2 = b^2_o \ldots\ldots\ldots\ldots\ldots\ldots (59)$$

For $y' = h$, the pressure vanishes, so that $b\ (h) = b^2_o - \dfrac{h^2}{2} = 0$, or $b^2_o = \dfrac{h^2}{2}$.

Substituting in Equation (59), $b^2 = \frac{1}{2}\left[h^2 - (y')^2\right]$, or,

$$b = 0.707\sqrt{h^2 - (y')^2} = 0.707\sqrt{y'(2h - y')} \ldots\ldots\ldots (60)$$

Hence, with this approximation the shape of the fluid body moving with the dam is shown to be a quadrant of an ellipse. One-half the axis equals $b_o = 0.707\, h$, the corresponding pressure equals $p_o = 0.707\, \rho\, h\, a_x$, or, substituting $a_x = \alpha\, g\, l$ and $\rho\, g = w$,

$$p_o = 0.707\, \alpha\, w\, h \ldots\ldots\ldots\ldots\ldots\ldots (61)$$

Professor Westergaard's calculation gives,

$$p_0 = \frac{8}{\pi^2}\left(1 - \frac{1}{3^2} + \frac{1}{5^2} - \ldots.\right) \alpha\, w\, h \ldots\ldots\ldots\ldots\ldots (62)$$

or,

$$p_0 = 0.743\ \alpha\, w\, h \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (63)$$

The difference is about 4 or 5 per cent. By the approximate formula (Equation (60)), the total load on the dam is,

$$Q = 0.707\ \frac{\pi}{4}\ \alpha\, w\, h^2 = 0.555\ \alpha\, w\, h^2 \ldots\ldots\ldots\ldots\ldots (64)$$

While the exact solution gives,

$$Q = \frac{16}{\pi^3}\left(1 + \frac{1}{3^3} + \frac{1}{5^3} + \ldots.\right) \alpha\, w\, h^2 = 0.543\ \alpha\, w\, h^2 \ldots\ldots (65)$$

It is apparent that the approximation is close.

PAUL BAUMAN,[13] M. AM. SOC. C. E. (by letter).—The author's excellent treatise enables the designer to analyze accurately the increase of water pressure on the face of dams due to earthquakes. Until quite recently this phase of the subject has been a matter of considerable speculation.

In 1928 the writer was making studies on the effect of earthquakes in connection with the statical analysis of a dam in Southern California. While discussing this analysis with Dr. Fritz Zwicky, of the California Institute of Technology, the writer's attention was called to the fact that the inertia of the water might be more important than its flow, which, according to the analysis, was the only cause of an increase in pressure due to simple harmonic vibrations of the dam. The reasoning was that due to a motion of the dam in an up-stream direction, the water is partly displaced (vertically) and partly compressed. Neglecting for the moment the latter effect and considering the displacement only, the dam acts as a pump, or, better, as a reversed hydraulic ram, forcing the water immediately up stream from it to the surface, as shown in Fig. 5. This displaced water will flow over the top of the dam if the reservoir is full at the beginning of motion, or, if conditions are as shown in Fig. 5, it will flow back into the reservoir.

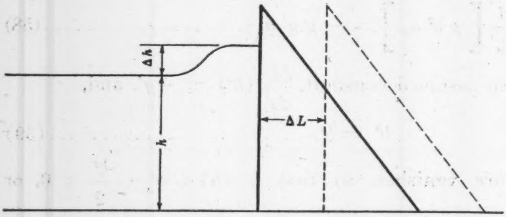

FIG. 5.

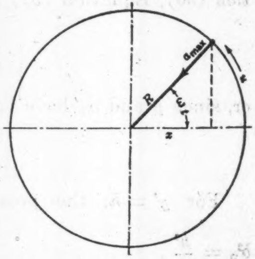

FIG. 6.

---

[13] Chf. Designer, Quinton, Code & Hill-Leeds & Barnard, Engrs., Consolidated, Los Angeles, Calif.

Principally, the two cases are identical; that is, Δh is the head required for a discharge equal to the maximum volume displaced per unit of time. Thus, if the dam moves at a velocity, v:

$$vh = \tfrac{2}{3}\,\mu\sqrt{2g}\,\Delta\, h^{\frac{3}{2}} \quad \text{.....................(66)}$$

in which (in addition to Professor Westergaard's notation), v = maximum velocity and μ = discharge coefficient. From the law of simple harmonic motion (see Fig. 6):

$$u = \omega\, R = \frac{2\pi R}{T} \quad \text{.....................(67)}$$

$$v_{\max.} = u \quad \text{.....................(68)}$$

$$a_{\max.} = \frac{u^2}{R} = \frac{4\pi^2 R}{T^2} \quad \text{.....................(69)}$$

and,

$$\Delta L = 2\, R \quad \text{.....................(70)}$$

For a period, $T = 1$ sec. and $a_{\max.} = \frac{g}{10}$:

$$v_{\max.} = 2\,\pi\, R \quad \text{.....................(71)}$$

and R follows from $\frac{g}{10} = 4\pi^2 R$, or $R = \frac{g}{40\pi^2}$, which checks Equation (7). The total motion then becomes $2\,R = \Delta\, L = \frac{g}{20\,\pi^2} = 0.159' = 1.9''$.

Introducing $v_{\max.}$ in Equation (66):

$$h\,\pi\,\frac{g}{20\,\pi^2} = \tfrac{2}{3}\,\mu\,\sqrt{2g}\,\Delta\, h^{\frac{3}{2}} \quad \text{.....................(72)}$$

and,

$$\Delta\, h = \sqrt[3]{\left(\frac{3\,hg}{40\,\pi\,\mu\,\sqrt{2g}}\right)^2} \quad \text{.....................(73)}$$

for $\mu = 0.80$, and $h = 200$ ft., $\Delta\, h = 8.30$ ft.

Due to this head the pressure increase on a 200-ft. dam would be $\frac{8.30 \times 62.50 \times 200}{2\,000} = 52\ \frac{\text{ton}}{\text{ft.}}$, as against $Q_o = 68.4\ \frac{\text{ton}}{\text{ft.}}$, according to the author's Equation (36); and the moment about the base would be $52 \times 100 = 5\,200\ \frac{\text{ft-ton}}{\text{ft.}}$, as against $M_o = 5\,486\ \frac{\text{ft-ton}}{\text{ft.}}$, according to Equation (39).

Although the moments about the base check within a few per cent. for this height of dam, it is obvious that the higher the dam the more the physical difficulties grow, involving the movement of water particles all the way from the bottom to the surface within the time of the up-stream motion of the dam. Therefore, it may be stated that although a displacement of all particles immediately in front of the dam necessarily takes place, this displacement is retarded as the depth increases, thereby increasing the volume of inertia, or, in other words, the mass force.

Based on this cognition, Dr. Theodor von Kármán, of the California Institute of Technology, has derived a simple solution of this problem by neglecting the elastic compression of the water and by considering a body of inertia of water, which must be accelerated with the dam and, therefore, offers a resistance equal to its mass times the maximum acceleration of the dam, as also outlined by the author.

Based on Euler's fundamental equation,

$$dp = \frac{w}{g}\,(X dx + Y dy + Z dz) \quad \ldots\ldots\ldots\ldots\ldots\ldots (74)$$

a result has been derived by the writer which leads to an elliptic distribution of pressure and which checks the one due to Dr. von Kármán.

Applied to the problem of pressures on dams during earthquakes Equation (74) reduces to:

$$dp = -\frac{w}{g}\,Y dy \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (75)$$

As the acceleration, X, in a horizontal direction is constant, $dx = 0$, and the acceleration, Z, parallel to the dam, is zero.

The vertical acceleration, Y, as previously outlined, follows from the condition that the water which is displaced due to a horizontal, up-stream motion of the dam is forced upward. According to Fig. 6 this may be expressed as follows:

$$y\,X = 2\,b\,Y \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (76)$$

which is a modification of the condition of continuity as suggested by Dr. von Kármán due to the change of pressure from p at the face of the dam to zero at a distance of 2 b from it. In other words, the body of inertia is actually twice as large as shown in Fig. 6.

The pressure, p, per unit area of dam face follows from the basic law of dynamics, namely:

$$p = m\,X\,b \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (77)$$

in which, $m = \frac{w}{g}$ = mass of unit volume of water. Thus, $b = \frac{g p}{w X}$.

Introducing Equation (77) and Equation (75) into Equation (74):

$$2\,p\,dp = \left(\frac{w}{g}\right)^2 X^2\,(-y)\,dy \quad \ldots\ldots\ldots\ldots\ldots\ldots (78)$$

and integrating:

$$p^2 = \left(\frac{w}{g}\right)^2 X^2 \left(\frac{-y^2}{2}\right) + C \quad \ldots\ldots\ldots\ldots\ldots\ldots (79)$$

For $y = h$, therefore, $p = 0$ and $C = \frac{h^2}{2}$.

There follows,

$$p = \frac{w}{g} X \sqrt{\frac{h^2 - y^2}{2}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (80)$$

which is the equation of an ellipse. Numerical evaluations of Equation (80) check those due to the author's Equation (52) within a few per cent.

Finally, due to Equation (77):

$$b = \sqrt{\frac{h^2 - y^2}{2}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (81)$$

The author's efforts throughout the paper to make the same theory comprehensive to engineers who cannot be expected to be "high-powered" mathematicians is quite apparent. It is very thought-provoking indeed, and deserves both commendation and imitation.

R. ROBINSON ROWE,[14] M AM. SOC. C. E. (by letter).—The most useful and interesting theory for the design of structures to resist earthquakes, that has appeared in recent years, is given in this paper. It establishes a criterion applicable to existing as well as to proposed dams.

Although the author does not state positively that his solution is unique, the three differential equations (Equations (1), (2), and (5)) contain only three unknowns other than the dimensional variables, and should lead to a single primitive, made definite by the rigid boundary conditions. The latter should include the condition that ξ and η approach zero as x becomes large. Furthermore, Condition (3) should be modified to exclude the point of singularity; the condition is not met at that point, since Equation (21) is not true for $u = 0$.

That the solution is reasonable can well be judged by a study of the continuity of the dynamic action in the water, as shown graphically herewith. In each of the diagrams assumed the action is shown in the field, $0 < x$ (or y) $< h$, with $c_n = 1$, $T = \frac{4}{3}$, and $\alpha = 0.1$. No corrections have been made for phase difference.

In addition to the author's notation, the following are introduced: $u = \frac{\pi y}{2 h}$; $z = e^{\frac{\pi x}{2h}}$, $\delta = \sqrt{\xi^2 + \eta^2}$ equals the displacement of a particle in the direction of the action; $\theta = \tan^{-1} - \frac{n}{\xi}$ equals the angle between the line of action and the horizontal; and max. is a subscript indicating the maximum value of the variable.

---

[14] Civ. Engr. (Allen & Rowe), San Diego, Calif.

Fig. 7 shows lines of equal horizontal displacement for the field, the values shown being maxima for $\alpha = 0.1$ and $T = \frac{4}{3}$ sec., corresponding to $t = \frac{T}{2}, \frac{3T}{2}$, etc. From Equation (15), $\xi_{\text{max.}} = 0.1846 \sum_{1,3,5,\ldots}^{n} \frac{\sin nu}{n z^n}$; and $\xi = 0$ when $x = \infty$ or $y = 0$. When $x = 0$ and $y > 0$, $\xi_{\text{max.}} = 0.1460$; and when $y = h$, $\xi_{\text{max.}} = 0.1846 \cot^{-1} z$.

The curves indicate a gradual change in horizontal displacements, which is more rapid in the vicinity of the top of the dam, where the lines converge at the singular point. For $y = 0$ and $x < r$, the direct interference of the dam would make $\xi_{\text{max.}} > (r - x)$.

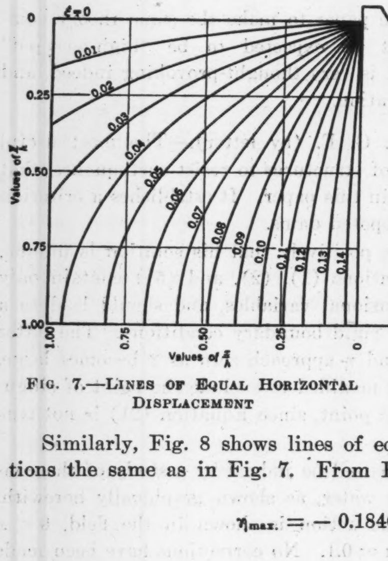

FIG. 7.—LINES OF EQUAL HORIZONTAL DISPLACEMENT

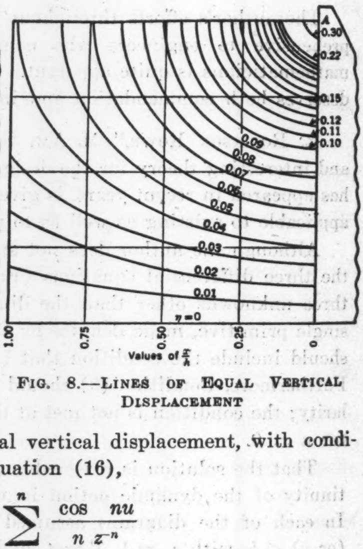

FIG. 8.—LINES OF EQUAL VERTICAL DISPLACEMENT

Similarly, Fig. 8 shows lines of equal vertical displacement, with conditions the same as in Fig. 7. From Equation (16),

$$\eta_{\text{max.}} = -0.1846 \sum_{1,3,5,\ldots}^{n} \frac{\cos nu}{n z^{-n}}$$

and $\eta = 0$ when $x = \infty$, or $y = h$. When $x = 0$,

$$\eta_{\text{max.}} = 0.09295 \log_e \tan \frac{u}{2}$$

and when $y = 0$,

$$\eta_{\text{max.}} = 0.09295 \log_e \left[\left(\frac{z-1}{z+1}\right)\right]$$

At Point A in Fig. 8, $\eta = \infty$.

As in Fig. 7, a gradual change in vertical displacements is evident, the change being more rapid in the vicinity of the top of the dam and infinite at the singular point. The lines are approximately normal to those of Fig. 7

throughout the field. Direct interference of the dam upsets the formula for $y = 0$ and $x < r$.

Fig. 9 shows lines of equal displacements in the direction of the action, being the resultant of values shown in Figs. 7 and 8, since the horizontal and vertical displacements are in the same phase. The conditions are the same as for Fig. 7; and $\delta = \infty$ at Point A. Furthermore, $\delta = 0$ when $x = \infty$; when $x = 0$,

$$\delta_{\text{max.}} = 0.1460 \sqrt{1 + 0.4053 \left(\log_e \tan \frac{u}{2}\right)^2}$$

when $y = 0$,

$$\delta_{max.} = 0.09295 \log_e \frac{z - 1}{z + 1}$$

and when $y = h$,

$$\delta_{\text{max.}} = 0.1846 \cot^{-1} z$$

When x is large, all terms of the summations except the first are negligible, and $\xi_{\text{max.}} = 0.1846 \dfrac{\sin u}{z}$; $\eta_{\text{max.}} = -0.1846 \dfrac{\cos u}{z}$; and $\delta_{\text{max.}} = \dfrac{0.1846}{z}$. Since z is independent of y, the lines of equal displacement approach vertical straight lines. For the singular point, $\delta_{\text{max.}} = \infty$, of course.

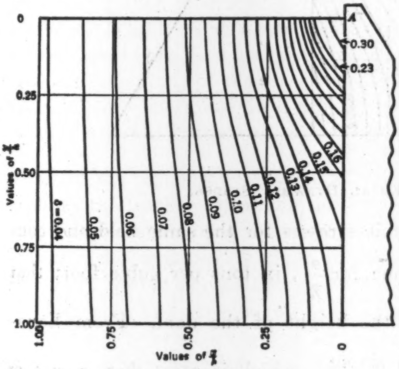

FIG 9.—LINES OF EQUAL DISPLACEMENT.

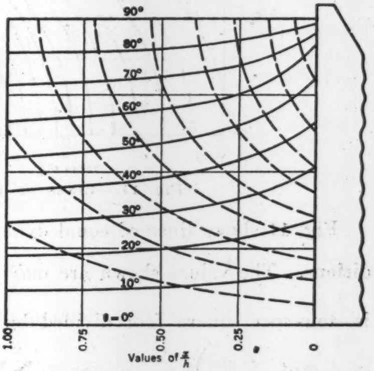

FIG. 10.—LINES OF ESCAPE AND OF EQUAL SLOPE

Dividing Equation (16) by Equation (15), $\tan \theta = F\ (x, y)$, and is independent of t. For any point, therefore, the slope angle of the displacement is constant throughout the cycle, and each particle moves in simple harmonic motion along an essentially straight line of length, $2\ \delta$, and inclined up and away from the dam, making an angle of θ with the horizontal. The solid curves in Fig. 10 are loci of equal inclinations; the action is vertical at the water surface and horizontal at the bottom. As in Fig. 7, c_n (assumed) $= 1$, and $T = \frac{4}{3}$ sec. When $x = 0$, $\tan \theta = 0.6366 \log_e \tan \dfrac{u}{2}$. When $x = \infty$, $\theta = u$.

The broken curves indicate lines of escape; that is, they are drawn tangent to the inclinations, and indicate the direction of the action. Since there is no motion across these lines, the volume of water between two such curves can be considered as acting independently. It is evident, therefore, that about 80% of the impulse finds surface escape within the limits of the field.

In this connection, the writer suggested in 1928 that the thrust due to earthquakes should not exceed that which would be caused by an assumed translation along circular quadrants centering at *A* (Fig. 9). With such an assumption, the surface escape within the field is 100%, and the following are easily computed: $p = 0.00491\,y$; $p_0 = 0.00491\,h$; $Q_0 = 0.00245\,h^2$; and $M_0 = 0.000818\,h^3$. The author's results for the last three, for an 800-ft. dam, are less by 44.6%, 20.1%, and 5.0%, respectively.

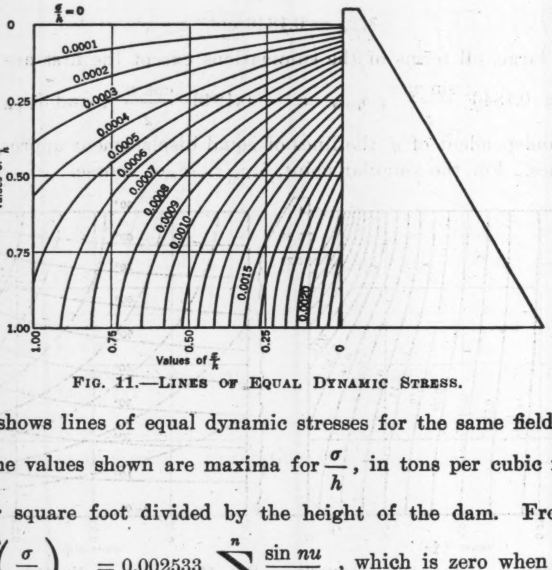

FIG. 11.—LINES OF EQUAL DYNAMIC STRESS.

Fig. 11 shows lines of equal dynamic stresses for the same field and conditions. The values shown are maxima for $\frac{\sigma}{h}$, in tons per cubic foot; that is, tons per square foot divided by the height of the dam. From Equation (19), $\left(\frac{\sigma}{h}\right)_{\max.} = 0.002533 \sum_{1,3,5,..}^{n} \frac{\sin nu}{n^2 z^n}$, which is zero when $x = \infty$ or $y = 0$. When $y = h$, $\left(\frac{\sigma}{h}\right)_{\max.} = 0.002533 \sum_{1,3,5,..}^{n} \frac{(-1)^{\frac{n-1}{2}}}{n^2 z^n}$; when $x = 0$, $\left(\frac{\sigma}{h}\right)_{\max.} = 0.002533 \sum_{1,3,5,..}^{n} \frac{\sin nu}{n^2}$, which reduces to the series,

$$0.001267\,u\,\left(1 - \log_e \frac{u}{2} - \frac{u^2}{36} - \frac{7\,u^4}{7\,200} - \frac{31\,u^6}{181\,440} \;....\right)$$

The change in stress is gradual and continuous, without singularity.

The curves do not represent true pictures of instantaneous conditions, because phase differences have been disregarded. When maxima occur at $x = \frac{h}{2}$, the angular phase difference for $x = 0$, or $x = h$, is $\frac{2 \pi t}{T}$, in which, $t = \frac{h}{2 v_s}$, so that the difference amounts to only $0.0004994\,h$. The distortion of the field at that time amounts to 0.5% for $h = 200$ and 7.9% for $h = 800$. Such distortion does not materially affect the representation intended.

It should be noted that the elastic deformation of the dam and the motion of the bed of the reservoir tend to diminish the stresses, and add to the security of the formulas. The possibility that the dam might be at the focus for compression waves set up in the water by the bed of the reservoir, seems to be exploded, in view of the large percentage of the impulse which escapes to the surface in a relatively short distance.

PROFESSOR DR. L. PRANDTL[15] (by letter).—In connection with this paper by Professor Westergaard, it might be of interest to note that this same mathematical problem is found in the theory of the distribution of lift on an aerofoil that is extended through an air stream of limited width and unlimited height. The water level in the problem by Professor Westergaard corresponds to the free boundary of the jet, and the bottom of the water tank to the middle plane of the jet. The calculations, that lead to exactly the same formulas, are contained in a paper[16] by Joseph Stüper, entitled "Der durch einen Freistrahl hindurchgesteckte Tragflügel."

CECIL E. PEARCE,[17] **ASSOC. M. SOC. C. E.** (by letter).—This paper explains the mathematical solution of a very difficult hydrodynamic problem. Particularly interesting is the fact that the result, although obtained by advanced mathematics, is given in such a convenient and simple form as to be readily usable by the average designer.

The paper and its results are of primary importance to engineers designing dams for localities where earthquakes may be expected, but it is also of use in other structural problems, as, for instance, in determining the horizontal load exerted on a building by the water in a swimming tank on an upper floor of the building.

A brief review of progress and developments in connection with the design of dams to resist earthquake oscillations, and particularly some of the specific findings in connection with the design of one dam to resist earthquakes, will be of general interest, because the next and logical question is: "What effect does it have upon the design of a dam?"

Design of Pine Canyon Dam to Resist Earthquakes.—In the summer of 1928 the writer was instructed to design the Pine Canyon Dam, a concrete gravity type structure on the San Gabriel River, California, to resist the earthquakes which might reasonably be expected to occur in this locality. At that time, as far as the writer knew, no dam had ever been designed to resist earthquakes. Formulas were developed for a theoretical triangular dam designed to resist the inertia effect of the mass of the dam, and, as a result, the writer and S. B. Morris, M. Am. Soc., C. E., presented a paper before the Seismological Society of America in June, 1929, entitled "Design of Gravity Dam in San Gabriel Canyon to Resist Earthquakes."[18] Then, after the World Engineering Congress in Tokyo, Japan, in October, 1929, a copy of Professor Nagabo Mononobe's paper on "Earthquake-Proof Construction of Masonry Dams," was made available to the writer, in which it was discovered that Professor Mononobe had designed and built, or had under construction, seven gravity dams designed to resist the inertia effects of the mass of the dam during earthquakes. The earliest of these dams was completed in 1927. When the proper changes in notation were made, it was found that Professor Mononobe's paper and the paper previously referred to, by the writer and Mr. Morris, contained practically the same equations although derived independently. It is seen, therefore, that Professor Mononobe's work preceded the work done by the writer and Mr. Morris by several years.

Hydrodynamic Pressure.—While investigating the forces brought upon dams during earthquake motions, attention was given to the possibility of an increased water pressure against the up-stream face of the dam as it moved toward the water. Mr. Harry O. Wood, in a discussion[19] of the report of the Committee on Arch Dam Investigation, being conducted by Engineering Foundation, stated: "There is a possible action of earthquakes on dams, dikes, etc., which appears to have been generally, if not universally, overlooked." And, still further, he summarized and stated that, if a dam moves back and forth and the water tends to remain still, being frictionless on the bottom, the water might

> "Act as a great sluggish pendulum bob, or a kind of soft-nosed battering ram of relatively great mass, which tends to remain still as the earth and the dam shift rapidly to and fro. Relatively, then, a soft-nosed, but very heavy battering ram may be caused to deliver, in rapid succession, blows or thrusts against the up-stream face of the dam."

It was suggested by the writer that if the dam moves toward the water, it would be just the same as if the water moved or flowed toward the dam, and hence the water would rise in the dam an amount equal to a velocity head, and cause an increase in pressure equal to twice the velocity head, which it was thought was somewhat analogous to the well-known problem of a jet of water impinging upon a flat surface. This was presented to two authorities on hydraulics. One answered that the foregoing viewpoint was correct, and the other thought not, and thought that the problem was a difficult hydrodynamic problem.

---

[18] *Bulletin*, Seismological Soc., Vol. 9, No. 3, September, 1929, p. 143.

[19] *Proceedings*, Am. Soc. C. E., November, 1928, Papers and Discussions, p. 2609.

Pursuing the problem further, it was then noted that if a rigid surface or lid could be fixed on the water surface, the problem would be akin to water-hammer in a pipe line. However, if the lid were not there, the bottom of the reservoir would tend to act somewhat like the water-hammer in the pipe line, being restrained, whereas at the water surface there would be instant upward release of the elastic compression in the water. This suggested that the portion of water which moved with the acceleration of the dam, and which offered resistance to that movement, was bounded by some straight or curved surface, such as, for example, a 45° plane, or the parabola given by Professor Westergaard, although no definite shape or value was determined.

The aforementioned velocity-head treatment (which, incidentally, gives a negligible force in any real case), was presented in the paper by Mr. Morris and the writer.[18] However, realizing that perhaps this solution might be bettered, the following statement was made:

"The difficult hydrodynamic problem of the determination of the forces applied to the dam, owing to oscillation of the dam against the body of the water in the reservoir, deserves further investigation both in mathematical analysis and in experimentation with models on a shaking table. There are a number of high masonry dams already constructed in close proximity to active fault lines. Recording devices installed on the up-stream face of such dams placed at intervals from top to bottom of the reservoir should definitely reveal the magnitude and distribution of such stresses. This would undoubtedly afford most certain and accurate answers to the question raised by Harry O. Wood."

In the spring of 1930, a copy of the "Report of Bureau of Reclamation on Boulder Canyon Dam," which contained Professor Westergaard's original treatment of the hydrodynamic force, became available. In all essential respects this treatment was identical to that contained in his present paper.

The writer has thought for some time that the fundamental part of the hydrodynamic force ought to be susceptible of reasonably simple explanation and fairly easy derivation without the somewhat complicated mathematics used by Professor Westergaard. Numerous attempts have been made to do this, and the writer has attempted to trace the elastic actions, following the elastic waves of compression and reflected waves of both compression and dilatation, somewhat in the manner commonly used in water-hammer problems. A graphic method soon became too complicated. The writer's ideas were presented to Dr. Theodor von Kármán, and he suggested the method of images, which is only a convenient way of treating the reflections which the writer was considering. Dr. von Kármán, however, suggested that since the waves of compression radiate from a point, the intensity of the compression, between parallel planes, would vary inversely as the distance from the source, somewhat as the intensity of light varies inversely as the square of the distance from the source, and this, therefore, suggested a method of attack. Following this, Mr. C. H. Heilbron, Jr., worked out the problem along these lines.

Mathematical Check.—In a report to the Pasadena, Calif., Water Department, Eugene Kalman, M. Am. Soc. C. E., derived the same equations as the author and stated that the original Westergaard treatment agrees fully with the general principle underlying hydraulics and that, therefore, an experimental check would not be necessary. Furthermore, he pointed out that it would be difficult because small models are influenced to a considerable extent by the point of singularity at the top of the dam. However, an experimental check has been made by Professor Lydik S. Jacobsen, on the shaking table at Stanford University, a preliminary account[29] of which shows that the experiments check the mathematics of Professor Westergaard. Professor Westergaard assumes that the dam moves in one piece as an integral part of the earth's crust. This is somewhat different from actual conditions since the natural, independent vibrations of the dam have some influence on the motion of the water. Professor Kalman pointed out the great difficulty of considering this effect and concluded that the results as presented must be accepted as a good approximation of the actual conditions.

Following Professor Kalman's report the Pasadena Water Department re-designed its Pine Canyon Dam to resist the hydrodynamic force, using Professor Westergaard's parabolic equivalent body of inertia, as well as the inertia effects upon the mass of the dam.

Effects of Earthquake Loads on the Size of a Dam.—For ease of comparison and calculation a typical triangular gravity dam section with a vertical up-stream face will be used as shown in Fig. 12.

An actual gravity dam design, straight in plan, does not differ materially from a triangular section and, hence, the general effects of any of the factors can be shown by using the simple triangular section. The principles involved in the actual design of a practical dam section with considerable top width are entirely similar to those of the ideal triangular section, except that the inter-relations cannot be expressed so simply. In addition to the symbols used by Professor Westergaard, the following nomenclature is introduced:

$W =$ total weight of the mass of the dam.
$G =$ specific gravity of concrete in mass of dam.
$H =$ total static water load on face of dam.
$U =$ total uplift pressure under dam.
$V =$ total re-active force of foundation upon dam.
$F =$ total force applied to dam by earthquake acceleration upon mass of dam.
$D =$ total force applied to dam by hydrodynamic load.
$h =$ height of dam.
$B =$ base width.
$\alpha =$ ratio of horizontal earthquake acceleration to that of gravity.
$r =$ coefficient of hydrostatic pressure to be used at heel of dam for uplift, which in this study is assumed to diminish uniformly in a straight line to zero at the down-stream toe.
$j_h =$ horizontal acceleration of earth movement during earthquake, in feet per second per second. ($j_h = \alpha g$.)
$j_v =$ vertical acceleration of earth movement during earthquake, in feet per second per second.
$g =$ acceleration of gravity.

All the forces in Fig. 12 are shown to a true scale of masonry units, and, hence, the areas of each loading diagram represent the relative value of each

load. It can easily be seen that the inertia load, F, should be a triangle because it is equal to the mass of the dam times the acceleration, and the mass of the dam has a triangular section. Similarly, the hydrodynamic loading diagram will be parabolic.

For the condition of static equilibrium, the summation of moments about any point, and the summation of the vertical components of all forces, must be equal to zero.

These simple algebraic equations may be solved to derive a formula for the base width, B, in terms of the height and physical properties, for the case of the earthquake acting upon the mass of the dam only (neglecting the hydrodynamic load at first), and for the case of no earthquake.

The formula reduced, including the inertia effect only, is:

$$B = h \left[\frac{G\alpha \pm \sqrt{G^2 \alpha^2 + 4\,(G - r)}}{2\,(G - r)} \right] \ldots\ldots\ldots\ldots\ldots (82)$$

When there is no earthquake, or when the inertia effect is not considered, $\alpha = 0$, and Equation (82) reduces to:

$$B = h \frac{1}{\sqrt{G - r}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (83)$$

Equation (83) has previously been derived by the writer independently without considering the inertia load.[31]

Using $G = 2.4$ (or assuming the weight of concrete as 150 lb. per cu. ft.), and $r = 0.5$ (or assuming an uplift of 50% at the heel), values for Equation (82) were calculated and plotted as Curve No. 1, on Fig. 13.

For these conditions there is only one value of $\frac{B}{h}$ for Equation (83), which is 0.725, and which checks as the point where Curve No. 1 crosses the ordinate, $\alpha = 0$. On these curves, a value of $\alpha = 0.1$ indicates an earthquake acceleration of $0.1g$.

When the parabolic hydrodynamic load is included, the relations are not so easily expressed algebraically, therefore, a number of separate arithmetical calculations were made for this case and plotted as Curve No. 2, Fig. 13. Suppose that a straight concrete gravity dam is to be designed using the foregoing unit weight of concrete, with uplift assumptions as before; and suppose that it is to be designed against a horizontal earthquake acceleration of $0.1g$. Using the curves in Fig. 13: If there is no earthquake, the down-stream batter is 0.725; if the inertia effect upon the mass of the dam only, is considered, the down-stream batter is 0.793; and, if both the inertia effect and the hydrodynamic effect are considered, the down-stream batter is 0.84.

From these values it is seen that to include the inertia effect increases the material in the dam by 9.38%, and that to include both the inertia and hydrodynamic effect increases the material in the dam by 15.85% over that required for the dam designed without earthquake.

---

[31] "Uplift Under Dams," by C. E. Pearce, *Western Construction News*, October 25, 1928.

Actually, although Pine Canyon Dam was first designed according to the foregoing uplift assumption (50% at the heel to 0% at the toe) and by assuming an earthquake acceleration of $0.1g$ for both inertia and hydrodynamic effects, it was later designed with the same earthquake assumptions and 100% uplift at the up-stream face, diminishing uniformly to 50% at the galleries near the up-stream face, and then to 0% at the down-stream face, all considered as acting upon 100% of the area. This uplift assumption, together with the parabolic hydrodynamic load, and the proper consideration of all forces for the actual dam (not a theoretical triangle), gave the cross-section shown in Fig. 14, in which, the maximum water level used in the design was 5 ft. below the roadway level. In this dam, vertical drains are 10 ft. apart in a line parallel and near the up-stream face as indicated in Fig. 14, but no allowance for such drainage was made in the design.

FIG. 14.—ADOPTED SECTION, PINE CANYON DAM.

Vertical Earthquake Acceleration.—In any actual case of dam design, one must investigate all the possible earthquake effects, including vertical acceleration and resonance. It can be shown easily that the vertical acceleration of the earthquake has no overturning effect upon a gravity dam, because the weight of the water, and, therefore, the water pressure on the dam, is increased in the same proportion and at the same time as the mass of the dam during the upward acceleration. In other words, an acceleration of g is acting upon both dam and water for ordinary static conditions, while an acceleration of $(g + j_v)$ is acting upon both dam and water during upward acceleration, and, hence, their moment relations are not changed. In a similar manner, a downward acceleration of the earth does not change the moment relations. The unit stresses in the dam and its foundation are increased or decreased accordingly, but there is no added tendency to overturn the structure. The vertical acceleration, however, does affect the sliding factors, and this must be investigated in each case.

Resonance.—If the natural period of vibration of the dam is the same as that of the earthquake, the elastic rebound of the stressed dam produces a force due to its kinetic energy of motion, which may come at exactly the same time as the application of the next impulse imparted by the earthquake, thereby making the two forces additive. In this manner, each additional earthquake impulse may add to the previous force, and, hence, the total force may build up. The engineer in each case must treat this matter as the situation warrants. There is ample evidence that earthquake motions do not continue as simple harmonic motions of a given period over any appreciable length of time, and, therefore, the dam would soon be out of tune again.

Timoshenko[23] gives for the natural period of vibration of a wedge the following formula:

$$T_d = 4.0952 \frac{h}{k} \sqrt{\frac{\rho}{E g}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (84)$$

Working independently, Mr. Frank Abbot derived an equation similar to that of Timoshenko for a wedge by equating the potential energy of maximum deflection to the maximum kinetic energy of a vibration, assuming harmonic motion of the free vibration; and, as a result, he obtained a coefficient of 3.9738 for Equation (84), which is about 3% smaller than the coefficient obtained by Timoshenko.

In Equation (84):

$T_d =$ natural period of vibration for dam, in seconds.
$h =$ height of wedge, in feet.
$k =$ total batter of wedge = ratio of breadth to height.
$\rho =$ weight of concrete, in pounds per cubic foot.
$E =$ modulus of elasticity of concrete.
$g =$ acceleration of gravity = 32.2 ft. per sec. per sec.

From Equation (84), it is seen that for a dam having a constant batter, k, the natural period varies as the first power of h.

For Pine Canyon Dam, using $h = 300$ ft.; $k = 0.86$; $\rho = 150$ lb. per cu. ft.; and $E = 360\,000\,000$ lb. per sq. ft.; Equation (84) gives $T_d = 0.16$ sec.

Since the dam is 300 ft. high only at the center and is fixed and less high along the abutments, it is seen that the higher cantilevers are not only fixed at the bottom, but are also restrained, to some degree, on the sides, and that, therefore, the natural period of the dam as a whole will be even less. Consequently, it will probably not be of much importance for the larger earthquakes having destructive value, during which the period of vibration is generally found to be much longer than 0.16 sec.

---

[23] "Applied Elasticity," Timoshenko and Lessells, First Edition, p. 323, Equations (e) and (i).

This seems to indicate that for a gravity dam of this height or less there is little cause for worry regarding resonance. For high slender arch dams, the natural period of vibration may be found to be longer, and to approach dangerously near the periods observed for destructive earthquakes. In such a case, the designer might be justified in assuming two, three, or more vibrations of the earthquake having the same period as the natural period of vibration of the dam. While a high slender arch dam tends to have longer periods, it, in turn, can take an over-stress without failure. The writer does not specifically recommend exactly the foregoing procedure for arch dams, but merely mentions it to show what might be done. As new cases arise, they must be treated as good judgment dictates, and, at the present time, any rational treatment is a forward step.

Earthquake Acceleration for Use in Design.—Since the subject of the hydrodynamic load has brought up the question of its effect on the size of a dam, it is proper, at this point, to discuss earthquake accelerations, because proper results depend upon proper premises.

In any specific case, the engineer designing a dam should investigate the records of past and probable future earthquake accelerations at the locality involved for the kind of material upon which the dam is to rest. Unfortunately, there are comparatively few data at hand that will set a definite value to acceleration for the United States, or for any particular location. However, computations have been made for such values for such major earthquakes as the California earthquake of April 18, 1906, and the Japan earthquake of September 1, 1923.[23] Study of such data is of much value in the selection of a maximum value of acceleration to be used.

Comments.—

(1) By referring to Fig. 12 on which all load areas are drawn to scale, it can be easily seen why numerous dams not designed to resist earthquakes have not failed. The sum of the inertia load plus the hydrodynamic load is small in comparison to the other loads.

(2) By increasing the cost of the dam by only about 15%, the structure may be made safe against earthquakes, and this may be a wise safeguard for a dam in a populous country where earthquakes are likely to occur.

(3) Those who have not given consideration to designing structures to withstand earthquake accelerations may be inclined at first to think that designs purporting to resist those accelerations are flighty mathematical theories. A little investigation, however, will show that the basic part of the problem is really very simple and quite easy of determination. The probable earthquake accelerations which may be expected have been measured by seismologists, and are fairly well known.

---

[23] Accelerations which have occurred, or which are recommended for use or have been used by others, are discussed in the *Bulletins* of the Seismological Society, September, 1929, p. 143, and September, 1931, p. 204; in Mononobe's work referred to herein; and in two articles by Henry D. Dewell, M. Am. Soc. C. E., in *Engineering News-Record*, Vol. 100, pp. 650 and 699, entitled "Earthquake-Resistant Construction."

(4) As far as is known by the writer at this time (1932), the following dams in the North American Continent have been designed against earthquakes: The Pine Canyon Dam, on the San Gabriel River; the Hoover Dam, on the Colorado River; and the Madden Dam, in the Panama Canal Zone.

(5) It is suggested that in his closure the author give a simple physical explanation of the difference between his first case, or case of ideal water-hammer, and the true case which he has solved, showing the elastic actions that actually take place in the water.

JOHN H. A. BRAHTZ,[24] ESQ., AND CARL H. HEILBRON, JR.,[25] ESQ. (by letter).—In connection with the design of the proposed Pine Canyon Dam, the writers have been able to follow up lines of thought suggested by Professor Westergaard. The studies made by them are as follows: (1) The author's assumption of an infinitely long reservoir is dropped, and formulas are developed for reservoirs of finite length; (2) the effect of assuming that the water is incompressible is shown; (3) the flexibility of the dam is taken into account and methods of allowing for it in finding earthquake stresses are presented; and (4), an independent method of arriving at the author's principal results is developed.

Effect of Finite Length of Reservoir.—If the reservoir is to be considered as other than infinitely long, several other assumptions may be substituted. Perhaps the simplest is that at a distance, L, from the dam there is an immovable vertical wall. Expressed mathematically, this means that the author's Boundary Condition (4) — σ converges toward 0 when x becomes large — is replaced by a new condition, (5) $\xi = 0$, when $x = L$.

A solution of the author's Equations (1), (2), and (5), which satisfies Conditions (1), (2), (3), and (5), is similar in form to the author's solution as expressed in his Equations (15), (16), and (20), differing only in that the factor, e^{-q_n}, occurring in these equations, is replaced by expressions involving hyperbolic functions. Further, the author's Equations (31), (35), (36), (38), and (39) are modified only in that in each equation the factor, $\coth \dfrac{n\,\pi\,c_n L}{2\,h}$, is inserted under the summation sign.

The effect of the use of Boundary Condition (5) is shown in the following tabulation giving the values of the correction factor for Q_0, for various values of the ratio, $\dfrac{L}{h}$:

Ratio, $\frac{L}{h}$	Correction factor	Ratio, $\frac{L}{h}$	Correction factor
0	∞	1.0	1.095
0.4	1.80	1.5	1.020
0.6	1.37	2.0	1.005
0.8	1.18	∞	1.000

---

[24] Teaching Fellow, California Inst. of Technology, Pasadena, Calif.

[25] Asst. Engr., Pasadena Water Dept., Pasadena, Calif.

This correction factor is defined as the ratio of the value of Q_0 computed by using the formula based on Condition (5) to the value computed by Equation (31). It will be seen that Q_0 increases not more than 0.5 of 1% if the length of the reservoir is more than twice its depth.

Inasmuch as in any actual earthquake any surface at the far end of a reservoir would probably vibrate with the earthquake, a better assumption than Condition (5) would be that both ends of the reservoir move with the same amplitude and period. To express this mathematically, the author's Boundary Condition (4) is replaced not by Condition (5), but by another condition, (6), $\xi = -\frac{\alpha g T^2}{4\pi^2} \cos \frac{2\pi t}{T}$, when $x = L$.

A solution of the author's differential equations which satisfies Boundary Conditions (1), (2), (3), and (6), differs from the author's solution as before only in the substitution of hyperbolic functions for the factor, e^{-qx}, in Equations (15), (16), and (20). In this case, Equations (31), (35), (36), (38), and (39) are modified by the insertion under the summation sign of the factor, $\coth \frac{n\pi c_n L}{2h} - \operatorname{csch} \frac{n\pi c_n L}{2h}$.

The effect of using Boundary Condition (6) instead of Condition (4) is shown in Table 3.

TABLE 3.—VALUES OF THE CORRECTION FACTOR FOR Q_0.

Ratio, $\frac{L}{h}$	Correction factor	Ratio, $\frac{L}{h}$	Correction factor
0.5	0.397	2.0	0.921
1.0	0.670	3.0	0.983
1.5	0.835	4.0	0.996
		∞	1.000

It will be seen that if Boundary Condition (6) is considered as correct, the error in assuming the reservoir infinitely long is negligible if the length of the reservoir is more than about three times its depth. Incidentally, if the value of L is small compared with the value of h, Boundary Conditions (1), (2), (3), and (6) represent conditions in an open well in the earth or in a structure during an earthquake, and the expression for the pressure, p, corresponding to Equation (31), reduces to approximately:

$$p = \frac{1}{2} \alpha w L \quad \ldots\ldots\ldots\ldots\ldots\ldots (85)$$

which means that the water pressure due to earthquake on one side of a well is equal to the "inertia force" of one-half the weight of water in the well.

Since the earthquake waves which cause the motion of the dam and of the up-stream end of the reservoir travel with a more or less definite velocity, the motions at the two ends of the reservoir in an actual case would be out of phase. However, it is shown in Table 3 that if the length of the reservoir is not small, one end has no appreciable effect on the other and, therefore, the phase difference is unimportant. On the other hand, if the length is small enough to affect the pressures, the phase difference must be so slight as to be negligible. Therefore, Table 3 gives a sufficiently close approximation to the effect of finite length of reservoir for all practical purposes.

Effect of Compressibility of Water.—If the author had considered the water to be incompressible, he would have written, instead of his Equation (5),

$$\frac{\partial \xi}{\partial x} + \frac{\partial \eta}{\partial y} = 0 \qquad (86)$$

Using Equation (86), he would have obtained exactly the same Equations (15), (16), and (20), except that the coefficients, c_n, the value of which is given in his Equation (21), would have the value, unity. Continuing, in his Table 2, he would have only one set of values applying to all heights of dam, and these would be the same as he has listed for "small" heights of dam. In other words, therefore, the compressibility of the water is of no importance except when the dam is high.

Effect of Flexibility of Dam.—The author states:

> " * * * since the period of free vibrations of the dam, T_0, is usually a fraction of a second, while the period of vibration, T, of the earthquake may be assumed to be not less than a second, * * * resonance * * * need not be expected ordinarily, although the possibility of part resonance may well be investigated in some cases of high dams."

Approximate formulas for calculating the effects of this part resonance have been developed by the writers. As part resonance is caused both by the hydrodynamic pressures and by the inertia effect of the weight of the dam, and as it adds to both the hydrodynamic pressures and the inertia forces, it is impossible to separate the two effects and both must be considered.

The procedure, in general, is as follows: The hydrodynamic pressures are first taken as those given by the author's formulas and the inertia forces are taken as if the dam were rigid; the deflections of the dam due to these forces are found; the displacement of the dam is now taken as the displacement of its base plus the deflection; the hydrodynamic pressures and the inertia forces are recalculated on the basis of the new displacements; and the process is repeated if a closer approximation is desired.

The most difficult part of the procedure is the solution of the author's differential Equations (1), (2), and (5) for a new set of boundary conditions. Conditions (1), (2), and (4) are unchanged. Condition (3) expresses that the face of the dam moves in a simple harmonic motion with the amplitude of the motion of the earth's crust. If the dam is flexible, only the base moves with the prescribed motion, and Condition (3) is replaced by some relation of the general form of Condition (7), $\xi_0 = f(y, t)$, in which, ξ_0 is the value of ξ for $x = 0$.

If the function, $f(y, t)$, of Condition (7) is considered as known, then a set of expressions for ξ, η, and σ, can be found which satisfy the differential equations and Boundary Conditions (1), (2), (4), and (7). These expressions need not be written here; it can be shown that they lead to equations for p and ξ_0 of the forms:

$$p = \frac{4\,\pi^2}{T^2}\;\frac{w}{g}\sum_{1,3,5..}^{n} E_n \sin\frac{n\,\pi\,y}{2h} \;\ldots\ldots\ldots\ldots\ldots\ldots(87)$$

and,

$$\xi_o = -\,\frac{\pi}{2\,h}\cos\frac{2\,\pi\,t}{T}\sum_{1,3,5..}^{n} n\,c_n\;E_n \sin\frac{n\,\pi\,y}{2\,h}\;\ldots\ldots\ldots(88)$$

in which, the factors, E_n, are constants to be determined so as to satisfy Equation (88). If the values of E_n are found, then p can be computed.

In order to find these values in Equation (88) it is desirable to have the function, $\xi_o = f(y, t)$, in as simple a form as possible; it is impracticable to use an expression for ξ_o involving several different powers of y. In choosing the form of the function, $f(y, t)$, it is convenient first to consider the very special case of a rectangular dam of height, H, the base of which moves according to the author's Equation (7), and which is flexible in shear but not in moment. It can be shown that the motion of such a dam is expressed by:

$$\xi_o = -\,r\,\frac{\cos\nu\gamma y}{\cos\nu\gamma H}\cos\nu t\;\ldots\ldots\ldots\ldots\ldots\ldots\ldots(89)$$

in which, $\nu = \dfrac{2\,\pi}{T}, \gamma = \sqrt{\dfrac{\rho}{Gg}}$, ρ is the density of concrete, and G is its elastic modulus in shear. It is seen that in this case the motion of every part of the dam is in phase with that of its base; and it can be shown that in the more general case this must also be true, so that the function, $f(y, t)$, is $\cos \nu t$ multiplied by a function of y.

If ξ_o of Equation (89) is plotted as a function of y for a given time, a curve, as shown in Fig. 15(*a*), is obtained. For a triangular dam, the shear deflections due to either inertia or hydrodynamic forces form curves of similar shape, while the moment deflections due to both effects form curves of the general shape of Fig. 15(*b*). The total deflections form curves of the shape shown in Fig. 15(*c*). This curve is nearly a straight line, and in most cases, little error will be introduced by assuming that it is straight.

Making this assumption, and with δ_o equal to the maximum deflection at the top due to dynamic forces, the expression for $f(y, t)$ must give $r \cos \nu\, t$ for $y = H$, and $(r + \delta_o) \cos \nu\, t$ for $y = 0$; therefore,

$$f(y, t) = \xi_o = \left[r + \delta_o\left(\frac{H-y}{H}\right)\right]\cos\nu\,t\ldots\ldots\ldots\ldots\ldots(90)$$

Substituting this value in Equation (88),

$$r + \delta_o\left(\frac{H-y}{H}\right) = \sum_{1,3,5,..}^{n} E_n\,\frac{n\,\pi\,c_n}{2\,h}\sin\frac{n\,\pi\,y}{2\,h}\;\ldots\ldots\ldots\ldots(91)$$

It can be shown that Equation (91) is satisfied, within the limits, $0 < y < h$, where it is applicable, by,

$$E_n = \frac{8\,h}{n^2\,\pi^2\,c_n}\left[r + \delta_o + (-1)^{\frac{n+1}{2}}\,\frac{2\,h}{n\,\pi}\,\frac{\delta_o}{H}\right] \ldots\ldots\ldots\ldots (92)$$

If $\delta_o = 0$, the substitution of E_n from Equation (92) in Equation (87) gives exactly the author's Equation (31).

(c) TOTAL DEFLECTION CURVE

FIG. 15.

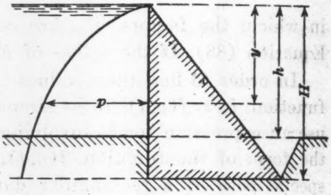

FIG. 16.

The inertia coefficient, a_1, defined as the maximum acceleration of any part of the dam divided by g, is $\frac{1}{g}\left(\frac{\partial^2 \xi_o}{\partial t^2}\right)$ for $t = 0$. Under the straight-line assumption this becomes,

$$a_1 = a\left(1 + \frac{\delta_o}{r}\,\frac{H - y}{H}\right) \ldots\ldots\ldots\ldots\ldots\ldots (93)$$

It will be noticed that a distinction is made between the depth of the reservoir, h, and the height of the dam, H. If the up-stream face of the dam is back-filled to the original stream bed, the depth, h, is probably best measured down to this point. The height, H, is measured down to the foundation of the dam, or lower, if it is desired to allow for foundation deflection (see Fig. 16).

The method and formulas here given have been applied to a straight masonry dam of triangular section, in which, H = 375 ft., h = 295 ft., the base is 0.85 of the height, the concrete weighs 150 lb. per cu. ft., the elastic moduli in bending and shear are 2 000 000 lb. per sq. in., and 900 000 lb. per sq. in., respectively. The reservoir is assumed to be full to the apex of the triangle, and an earthquake is assumed, for which a = 0.1 and T = 1.0 sec.

The deflection, δ_o, at the top of the dam is determined in the first approximation by applying the hydrodynamic forces for an assumed rigid dam in accordance with the author's parabolic distribution and the inertia forces for a rigid dam. The hydrodynamic forces are computed for $h = 295$, and the parabolic distribution is assumed to extend also over the lower part of the dam, where $h < y_1 < H$.

The top deflection due to moment is found to be 0.220 in. and that due to shear, 0.105 in.; whence δ_o = 0.325 in. This compares with r = 0.98 in.

The values of E_n are found by Equation (92) and then p is found by Equation (87) for several values of y. The values of p are plotted in Fig. 17, Curve (2), where they may be compared with the values found by Equation (31) and shown in Curve (1). The inertia coefficients as given by Equation (93) are plotted in Fig. 18.

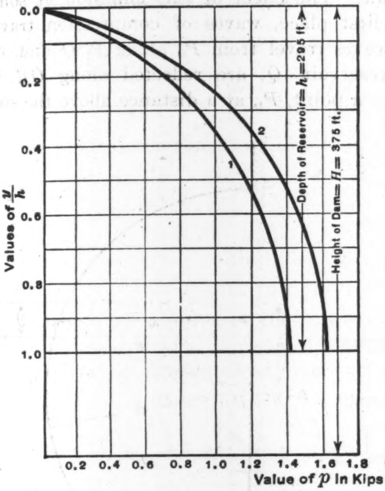

FIG. 17.—HYDRODYNAMIC PRESSURES.

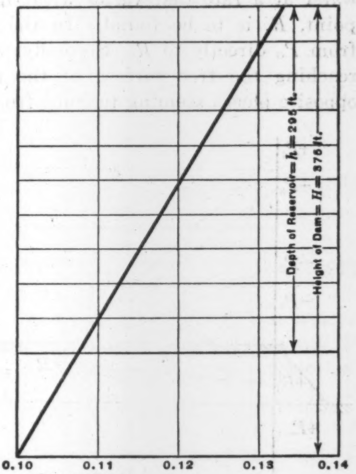

FIG. 18.—INERTIA COEFFICIENTS.

In the case of a dam of this height the increase in pressure due to flexibility is small and it appears unnecessary to carry the computations through another cycle. The shears, moments, and stresses in the dam due to earthquake are to be computed by applying the hydrodynamic pressures represented by Curve (2), Fig. 17, and the inertia forces corresponding to the inertia coefficients in Fig. 18.

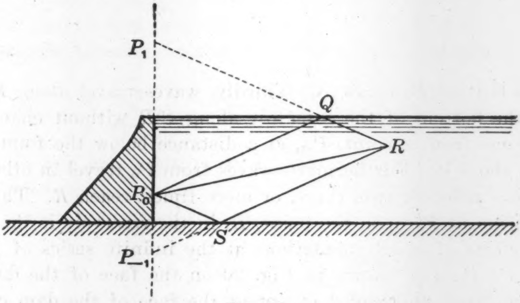

FIG. 19.

In order to place confidence in the author's result, it seems in keeping to explain the true physical picture, and to show that the use of a simple application of it produces the same result and, therefore, strengthens and proves the original result correct.

A point, P_0 (Fig. 19), in the face of the dam is considered to be emitting water at a rate that varies with time. The effect of this emission at some point, R, is to be found. In the first place, waves of compression travel from P_0 directly to R. Secondly, waves travel from P_0 along $P_0\,Q$ and, on reaching the free surface of the reservoir, Q, are reflected along QR in opposite phase, seeming to come from a point, P_1, at a distance above the surface equal to that of P_0 below it. Thirdly, waves travel along $P_0\,S$ and are reflected at the bottom of the reservoir along $S\,R$ without change of phase, seeming to come from a point, P_{-1}, at a distance below the foundation equal to that of P_0 above it. Furthermore, waves from P_0 travel in other directions and after being reflected two, three, or more times, reach R. The total effect of the emanation at P_0 upon the point, R, in the reservoir is the same as the sum of the effects of equal emanations at the infinite series of points $-P_{-3}$, P_{-2}, P_{-1}, P_0, P_1, P_2, P_3— shown in Fig. 20 on the face of the dam extended, acting in a medium unbounded except at the face of the dam extended and in phase or out of phase with P_0, according as they are marked plus or minus in the diagram.

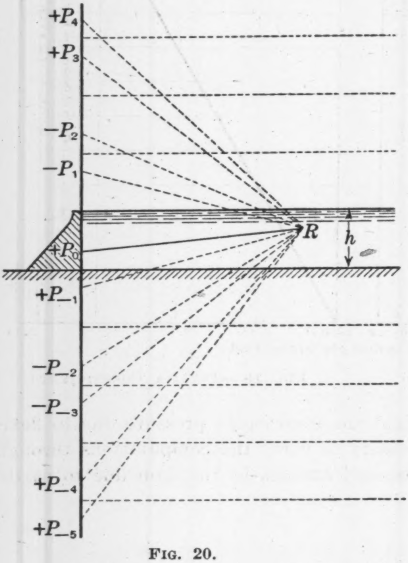

FIG. 20.

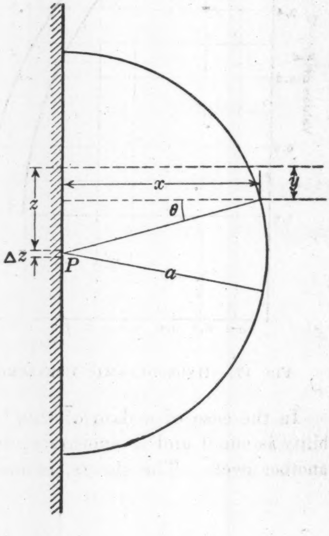

FIG. 21.

The emanation at any point, P (Fig. 21), is now to be considered as due to the motion of a part of the face of the dam of height, Δz, moving with an acceleration, $\alpha\, g$. Then, the rate of change of emission of water is,

$$\frac{dQ}{dt} = \alpha\, g\, \Delta z \ldots\ldots\ldots\ldots (94)$$

If the water is unbounded except along the one line the effect of this emanation will be the same at all points on a semi-circle of radius, a, and center at P, and if the water is considered incompressible, the radial acceleration, $\frac{dv_r}{dt}$, at a point, R, on the semi-circle is,

$$\frac{dv_r}{dt} = \frac{1}{\pi\, a}\,\frac{dQ}{dt} = \frac{\alpha\, g\, \Delta z}{\pi\, a} \ldots\ldots\ldots\ldots (95)$$

The vertical component of this acceleration is,

$$\frac{\partial^2 \eta}{\partial t^2} = \frac{dv_r}{dt} \sin\theta = \frac{\alpha\, g\, \Delta z}{\pi\, a} \sin\theta = \frac{\alpha\, g\, \Delta z}{\pi\, a}\,\frac{z - y}{a} \ldots\ldots\ldots\ldots (96)$$

and,

$$\frac{\partial^2 \eta}{\partial t^2} = \frac{\alpha\, g\, \Delta z}{\pi}\,\frac{z - y}{x^2 + (z - y)^2} \ldots\ldots\ldots\ldots (97)$$

If, now, R is a point in the reservoir, the total effect of emanation at a point, P_0, is as shown, the sum of the combined effects of all the points, P (Fig. 20), being considered as acting in an infinite medium; and the vertical acceleration at R is,

$$\frac{\partial^2 \eta}{\partial t^2} = \frac{\alpha\, g\, \Delta z}{\pi} \sum_{-\infty}^{+\infty} n\,(-1)^n \left[\frac{(2\,n\,h + z) - y}{x^2 + \left\{(2\,n\,h + z) - y\right\}^2} - \frac{(2\,n\,h - z) - y}{x^2 + \left\{(2\,n\,h - z) - y\right\}^2} \right] \ldots\ldots\ldots\ldots (98)$$

If the whole face of the dam is assumed to move with the acceleration, $\alpha\, g$, the value of $\frac{\partial^2 \eta}{\partial t^2}$ at R is given by Equation (98), with Δz replaced by dz and integrated from $z = 0$ to $z = h$.

Performing the integration and reducing,

$$\frac{\partial^2 \eta}{\partial t^2} = \frac{\alpha g}{\pi} \sum_{-\infty}^{+\infty} n\,(-1)^{n-1} \log_e \left[x^2 + (2\,n\,h - y)^2\right] \ldots\ldots\ldots\ldots (99)$$

In order to find the pressure at a point the author's Equation (2) and Condition (1) are necessary; if the former is integrated with the latter as a constant of integration, there results,

$$\sigma = \frac{w}{g} \int_0^y \frac{\partial^2 \eta}{\partial t^2}\, dy \ldots\ldots\ldots\ldots (100)$$

Substituting Equation (100) in Equation (99),

$$\sigma = \frac{w\,\alpha}{\pi} \sum_{-\infty}^{+\infty} n\,(-1)^{n-1} \int_0^y \log_e \left[x^2 + (2\,nh - y)^2\right] dy \ldots\ldots (101)$$

Integrating,

$$\sigma = \frac{w\,\alpha}{\pi} \sum_{-\infty}^{+\infty} n\,(-1)^n \left[2\,nh \log_e \frac{x^2 + (2\,nh - y)^2}{x^2 + (2\,nh)^2} - y \log_e \left\{ x^2 + (nh - y)^2 \right\} \right.$$
$$\left. + 2\,y + 2\,x \left\{ \tan^{-1} \frac{2\,nh - y}{x} - \tan^{-1} \frac{2\,nh}{x} \right\} \right] \ldots\ldots\ldots (102)$$

This is a general expression for σ. In particular, at the face of the dam, $x = 0$, and,

$$-p = \sigma = \frac{w\,\alpha}{\pi} \sum_{-\infty}^{+\infty} n\,(-1)^n \left[2\,nh \log_e \frac{(2\,nh - y)^2}{(2\,nh)^2} - y \log_e (2\,nh - y)^2 + 2\,y \right] . (103)$$

Equations (102) and (103) yield exactly the same numerical results as the author's Equations (20) and (31), respectively, when the C_n values are taken equal to unity.

The foregoing derivation assumes the water incompressible. To follow the same method with compressible water it would be necessary to use Bessel's functions, which are unfamiliar to most engineers.

BORIS A. BAKHMETEFF,[26] M. AM. SOC. C. E. (by letter).—The analysis of water pressure on dams during earthquakes presented in this paper should be considered a pioneer achievement in a realm heretofore unexplored. The engineer is often aided in gaining a grasp of new concepts by comparisons in terms of more familiar objects in other fields. For example, in studying the additional water pressure on dams caused by earthquake shocks, comparisons may be made with the well-known phenomenon of water-hammer in conduits caused when the velocity of flow changes rapidly.

In both cases, the problem deals with acoustical waves. For example, Equations (1), (2), and (5), in the paper, which the author integrates for given boundary conditions, are the general acoustical equations that Joukowsky[27] and Allievi[28] used for a general mathematical study of water-hammer. On the other hand, water-hammer lends itself to elementary treatment along the general lines suggested by St. Venant for the study of elastic impulses in bars[29] and of surface waves in open channels.[30]

Professor Westergaard's "preliminary" case, in which only the horizontal motion of the water layers is considered, is mechanically identical with the model used by Flamant[31] for the study of compression waves in connection with water-hammer. In analyzing the additional pressure, P, created in a conduit by a sudden reduction of the velocity of flow, v, Flamant reverses the movement and determines the pressure, caused by setting in motion a piston sliding in a cylinder that is filled with fluid originally at rest. (See Fig. 22.) By applying the momentum equation in connection with the continuity principle, it is found that the motion of the piston creates a compression wave that is propagated with a speed, c. The pressure exerted on the piston may be stated in terms of the velocity, v, of the piston by the simple equation:

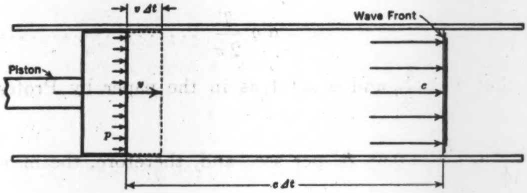

FIG. 22

$$\frac{p}{w} = z = \frac{c}{g}\, v \quad \ldots\ldots\ldots\ldots\ldots\ldots (104)$$

in which, w is the weight of a cubic foot of the liquid; g is the acceleration due to gravity; and z is the pressure head measured by the height of a column of fluid which corresponds to the water-hammer pressure, p. If the walls of the cylinder are assumed to be absolutely rigid, the movement will then be identical with that in the author's preliminary case. The dam will act as the piston, while the speed, c, will be the acoustical velocity, 4 715 ft. per sec. The numerical value of the ratio, $\frac{c}{g}$, will be $\frac{4\,715}{32.2} = 147$ sec. The significance of this value of the ratio, $\frac{c}{g}$, is that for every foot of velocity lost in a penstock or created by the motion of the dam (Fig. 22), a pressure will be exerted, equivalent to a head of $z = 147$ ft. of water, or if $w = 0.03125$ tons per cu. ft., to an equivalent pressure of $147 \times 0.03125 = 4.6$ tons per sq. ft.

The Direct Pressure Impulse.—Assume that in Fig. 23, $v = f\,(t)$ represents the increase in velocity of the piston (or of the dam) during the acceleration period from $v = 0$ to a maximum value of $\sqrt{v_0}$. The pressure equation will be:

$$\frac{p}{w} = \frac{c}{g}\, v = \frac{c}{g}\, f\,(t) \ldots\ldots\ldots\ldots\ldots\ldots (105)$$

In other words, the pressure curve will be identical in shape with the velocity curve, and the scale ratio will be $\frac{p}{v} = 4.6\, \frac{\text{ton}}{\text{ft.}^2} \times \frac{\text{sec.}}{\text{ft.}}$.

The instant of maximum pressure coincides with that of maximum velocity, and is equal to $4.6 \times v_0$. Assuming sinusoidal motion with a maximum acceleration, $\alpha\, g$, at $t = 0$, the maximum velocity will occur at $t = \frac{T}{4}$, and its value will be expressed by the equation:

$$v_0 = \alpha\, g\, \frac{T}{2\pi} \quad \text{.......................} (106)$$

Assuming that $T = \frac{4}{3}$, and $\alpha = 0.1$, as in the paper by Professor Westergaard, $v_0 = \frac{32.2}{10} \times \frac{\frac{4}{3}}{2\,\pi} = 0.68$ ft. per sec., and, therefore, the maximum pressure equals $p_0 = 4.6 \times 0.68 = 3.13$ tons per sq. ft., which is identical with values determined by the use of Equation (14).

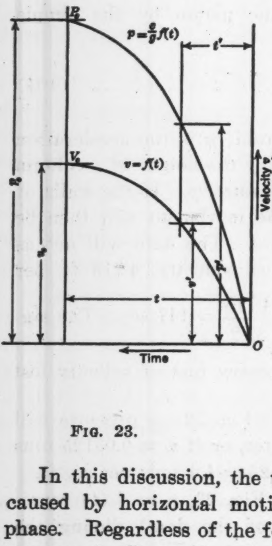

FIG. 23.

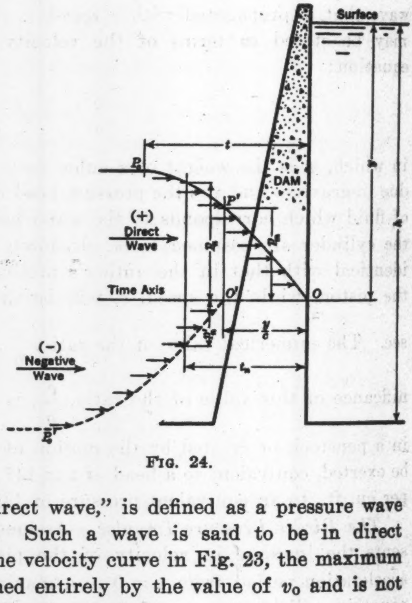

FIG. 24.

In this discussion, the term, "direct wave," is defined as a pressure wave caused by horizontal motion only. Such a wave is said to be in direct phase. Regardless of the form of the velocity curve in Fig. 23, the maximum pressure in direct phase is determined entirely by the value of v_0 and is not affected by the length, τ, of the acceleration period.

Effect of Free Surface; Indirect Phase.—On the other hand, the acceleration period (and, therefore, the manner in which the displacement is imparted to the dam) is decidedly important when one considers the effect of the free surface of the water, or when the phenomenon is in the "indirect" phase.

In the case of water-hammer, the increase in pressure characteristic of the direct phase, is counteracted by the effect of a negative wave reflected from the direct positive wave at the open end of the penstock. The condition in general is identical to that of sound waves at the open end of organ tubes. By way of analogy, the effect of the open surface of the water behind the dam may be visualized as creating a negative pressure impulse, identical in form and coincident in phase with the direct pressure wave, but of opposite sign. This negative impulse, which will account for the vertical displacement of the water layers, will be propagated downward with the accoustical velocity, c, and will reach a layer at a depth, y, in a period equal to,

$$t = \frac{y}{c} \text{ sec.} \qquad \text{(107)}$$

measured from the time the dam first began to move (see Fig. 24).

At the surface ($y = 0$), where the direct and the negative impulses are generated simultaneously and where their phases coincide, the resultant pressure will always be equal to zero. At a depth, y, conditions may be visualized as shown in Fig. 24. The pressure caused by the direct wave which is generated by the movement of the dam is represented by the curve, OP_0. The negative impulse, $O'P'_0$, is identical in shape with OP_0, but opposite in sign, and has a difference of phase, $OO' = \frac{y}{c}$. Obviously, while $t < \frac{y}{c}$, the effect of the surface yield has not had time to reach the layer at a depth, y, and the pressure increase is entirely due to the direct wave. For $t > \frac{y}{c}$, the resultant pressure is the difference between the ordinates of the direct and the negative wave. Thus, for $t = t_n$, the resultant pressure is $p_n - p'_n$.

If the shape of the velocity curve is as given in Fig. 23 (that is, if the acceleration is maximum at the beginning of the motion and then gradually becomes less), the maximum pressure at a layer, distant y from the surface, will be reached at the moment, $t = \frac{y}{c}$. This is the moment when the negative wave reaches the water layer under consideration. The effect of the acceleration period, τ, is now apparent: If it is small, the time, $\frac{y}{c}$, may be greater than τ, so that the negative impulse will not reach the layer in question in time to relieve the direct wave. In that case, the maximum pressure will attain its greatest possible value, $p_0 = 4.6\ v_0$, which corresponds to the direct impulse. A depth or an equivalent height of a dam may be determined for each value of τ by the equation,

$$h_0 = c\tau \qquad \text{(108)}$$

beyond which the increased pressure during the initial acceleration period will not be affected by the surface yield and the maximum pressure will be fully determined by direct impulse. If $c = 4\,715$ ft. per sec., the values of h_0 for corresponding values of τ are as follows:

Values of τ, in seconds	Values of h_0, in feet
0.01	47
0.05	235
0.10	471
0.20	942

For sinusoidal motion, with $\tau = \frac{T}{4}$ and $T = \frac{4}{3}$ sec., $h_0 = 4\,715 \times \frac{1}{4} \times \frac{4}{3} = 1\,570$ ft. This is in excess of the height of any dam thus far built. Therefore, it may be concluded that in actual structures the pressure never reaches the maximum value corresponding to the direct pressure impulse. This conclusion, however, will obtain only if the movement of the dam appears as represented in Fig. 25, in which the displacement begins at $t = 0$ from the extreme position and the velocity reaches its maximum over a period, $\tau = \frac{T}{4}$. On the other hand, conditions would be decidedly different if the motion was generated as shown in Fig. 26 by a sudden impact, such as in a ballistic pendulum, and in which the maximum velocity is reached over a short initial impact period, which is brief in comparison with T, the period of the subsequent oscillations. At least some seismographic records seem to indicate movement of this character.[32]

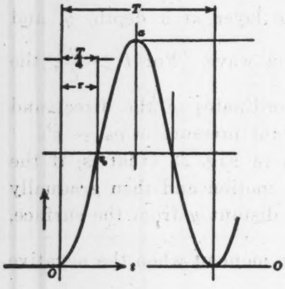

FIG. 25

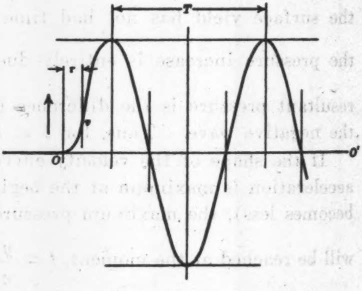

FIG. 26

Case of Sinusoidal Movement Shown in Fig. 25.— To compare data obtained by approximate reasoning outlined in the foregoing discussion, with the results of the exact method introduced by Professor Westergaard, assume the motion to be as in Fig. 25 with $T = \frac{4}{3}$ and $v_0 = 0.68$ ft. per sec., which corresponds to a maximum acceleration of 0.1 g. Assume that the maximum pressure, $P_m\ (y)$, at a depth, y, will correspond to the direct impulse at the moment, $t = \frac{y}{c}$; and that further in view of Equation (108), $\frac{T}{4} = \frac{h_o}{c}$; then,

---

[32] See, for example, the article on "Earthquakes," in the Encyclopedia Brittanica.

$$P_{m(y)} = P_o \sin 2\pi \, \frac{\frac{y}{c}}{T} = P_o \sin \frac{\pi}{2} \times \frac{y}{h_o} \quad \ldots\ldots\ldots\ldots (109)$$

If $P_o = 3.13$ tons per sq. ft., and $h_o = 1\,570$ ft., the value of the maximum pressure, P_m, for different heights of the dam, h, is as shown in Table 4.

TABLE 4.—VALUES OF MAXIMUM PRESSURE, P_m, FOR DIFFERENT VALUES OF h.

h, in feet (1)	$\frac{h}{h_o}$ (2)	$\frac{\pi}{2} \times \frac{h}{h_o}$ (3)	$\sin \frac{\pi}{2} \times \frac{h}{h_o}$ (4)	P_m, in tons per square foot (5)	P_w, in tons per square foot (6)
200	0.127	0.200	0.197	0.62	0.47
600	0.382	0.600	0.565	1.77	1.51
800	0.510	0.800	0.718	2.24	2.18

Column (6), in Table 4, contains the values obtained by Professor Westergaard's equations for comparison. The pressures computed from Equation (109) are somewhat larger, particularly for small values of h. For high dams the difference is small.

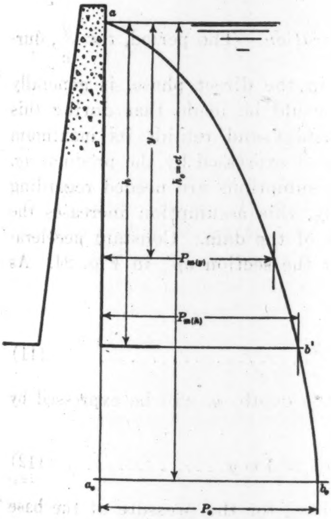

FIG. 27.

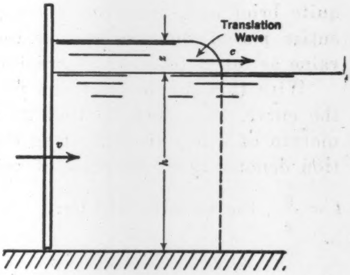

FIG. 28.

Maximum Shear at Bottom.—In computing the total shear, Q, at the base of a dam, the effect of the negative impulse beyond the point, o', in Fig. 24 may be neglected, and instead the simple assumption may be made that the shear is the sum of the pressures as determined for each depth layer by Equation (109). In this case (see Fig. 27):

$$Q = \int_0^h P_{m(y)}\,dy = \int_0^h P_0 \sin\left(\frac{\pi}{2} \times \frac{y}{h_0}\right) dy$$

$$= (p_0 h)\,\frac{2\,h_0}{\pi h}\left[1 - \cos\frac{\pi}{2} \times \frac{h}{h_0}\right] = \beta'\,(P_0 h) \dots\dots\dots\dots (110)$$

Let $h_0 = 1\ 570$ ft. and $P_0 = 3.13$ tons per sq. ft., then values of Q are as listed in Table 5.

TABLE 5.—COMPARATIVE VALUES OF Q

h (1)	$\cos\frac{\pi}{2} \times \frac{h}{h_0}$ (2)	β (3)	$P_0 h$, in tons (4)	Q, in tons (5)	Q_w, in tons (6)
200	0.980	0.100	626	62.6	68.4
600	0.825	0.292	1 878	550	658.3
800	0.697	0.379	2 504	950	1 253

The shears in Column (5), of Table 5, obtained from Equation (110), are somewhat less than those computed by Professor Westergaard, which are given in Column (6).

Simplified Solution with Constant Acceleration.—The period, $t = \frac{y}{c}$, during which the pressure impulse is applied in the direct phase, is generally quite brief and, therefore, the assumption could be made that during this entire period the acceleration remains constant and retains its maximum value as taken from seismographic records and expressed by the product, αg.

With this simple condition no further assumptions are needed regarding the curve, $v = f(t)$, in Fig. 23. Obviously, this assumption increases the margin of safety in computing the stability of the dam. Constant acceleration denotes linear increase of velocity over the section *op'*, in Fig. 24. As $t = \frac{y}{c}$, the velocity will be:

$$v = \alpha g\,\frac{y}{c} \dots\dots\dots\dots\dots\dots\dots\dots (111)$$

and thus the maximum pressure, $P_{m(y)}$, at the depth, y, will be expressed by the equation:

$$P_{m(y)} = v\,\left(\frac{c}{g} \times w\right) = \alpha\,w\,y \dots\dots\dots\dots\dots (112)$$

which, with $w = 0.03125$ tons per cu. ft., gives, for the pressure at the base of the dam,

$$P_h = 0.031\ \alpha\,h\,\frac{\text{ton}}{\text{ft.}^2} \dots\dots\dots\dots\dots\dots\dots (113)$$

The shear, in tons, at the base of the dam, is expressed by,

$$Q = \frac{P_h \times h}{2} = \frac{w}{2}\,\alpha\,h^2 = 0.016\,\alpha\,h^2 \dots\dots\dots\dots (114)$$

and the moment, in foot-tons, is expressed by,

$$M = Q \times \frac{h}{3} = \frac{w}{6}\,\alpha\, h^3 = 0.0052\,\alpha\, h^3 \text{.............} (115)$$

Let $\alpha = 0.1$, then representative values of shear and moment are indicated in Table 6.

TABLE 6.—VALUES OF SHEAR AND MOMENT FROM EQUATIONS (110) AND (111)

h	P_h, in tons per square foot	Q, in tons	M, in foot-tons
200	0.62	64	41.6 × 10^3
600	1.83	575	1 123 × 10^3
800	2.48	1 022	2 662 × 10^3

The numerical coefficients in Equations (113), (114), and (115), should be compared with Items 9 and 10 in Table 2 of Professor Westergaard's paper.

The comparison of values computed by the approximate method and by equations presented by the author are, as follows:

	Approximate solution	Westergaard solution
$\frac{P_h}{\alpha h}$	0.031	0.0255 — 0.0296
$\frac{Q}{\alpha h^2}$	0.016	0.017 — 0.0198
$\frac{M}{\alpha h^3}$	0.0052	0.0068 — 0.0079

The Surface Surge.—It might be desirable to examine the nature of the phenomenon that occurs at the surface behind the dam. If a water-tight barrier (see Fig. 28), formerly at rest in a rectangular canal, were to be set in motion with a uniform velocity, v, a surge or a wave of translation would be formed with a speed,[33]

$$c = \sqrt{gh}\,\sqrt{1 + \frac{3}{2} \times \frac{z}{h} + \frac{1}{2}\,\frac{z^2}{h^2}} \text{.............} (116)$$

The height of this wave when v is not too large compared with c, will be:

$$z = h\,\frac{v}{c}\left(\frac{1}{1 - \frac{v}{c}}\right) \text{....................} (117)$$

For small values of $\frac{v}{c}$ and $\frac{z}{h}$, it is permissible to assume that $c = \sqrt{gh}$ and $z = h\,\frac{v}{c}$, in which, c is the Lagrange velocity of propagation of waves

---

[33] St. Venant, Comptes rendus de l'Academie des Sciences, 1870; see, also, Bakhmeteff, "Hydraulics of Open Channels," 1932, p. 255.

of small height in a deep channel. For various depths, *h*, the values of c are, as follows:

h, in feet.	$c = \sqrt{gh}$, in feet per second.
200	80
600	139
800	160

In other words, for a dam 600 ft. high the surge created by an earthquake on the surface of the reservoir will travel with a speed of approximately 95 miles per hour. The velocity of the dam body itself, $v_o = 0.68$ ft. per sec., in the preceding examples, is insignificant by comparison. For a velocity $v_o = 0.68$ ft. per sec., the height, z, of the surge wave would be as follows (from Equation (117):

h, in feet	$\frac{v_o}{c}$	$z = h\,\frac{v_o}{c}$, in feet.
200	0.85×10^{-2}	1.70
600	0.49×10^{-2}	2.94
800	0.425×10^{-2}	3.40

This indicates the height of the surface wave that would be generated if the acceleration of the dam were slow and the velocity, $v_0 = 0.68$, was attained over a comparatively long period of time. The additional pressures in this case, caused by the rise of the water surface, would be the increase in hydrostatic pressure corresponding to the surge height, z. These additional pressures are quite insignificant when compared with the effect of the compression impulse considered in the foregoing analysis. The conclusion to be drawn is, that even with comparatively slow oscillations, $(T = \frac{4}{3})$, the pressures caused by earthquakes on dams are principally the result of elastic impulses within the water, and that the effect of the actual bodily displacement of the fluid is of secondary importance.

N. MONONOBE,[34] M. AM. SOC. C. E. (by letter).—The writer has read this paper with the greatest interest, and the following comments are made in connection with it.

That the solutions obtained by Professor Westergaard have a singularity at the point, $x = 0$, $y = 0$, may be attributed to his Condition (1) that $\sigma = 0$ at $y = 0$. The writer derives a different system of solutions, in which the singularity in question does not occur, by specifying the following boundary condition:

$$\left[\frac{\partial^2 \phi}{\partial t^2} - g\,\frac{\partial \phi}{\partial y}\right]_{y=o} = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (118)$$

in which, ϕ is the velocity potential. This condition, which is well known in hydrodynamics, stands for an incompressible fluid, but may be applied to a compressible fluid if y is small.

---

[34] **Director, Experiment Station of Public Works, Home Dept., Japanese Govt.; Prof., Civ. Eng. Dept., Tokyo Univ., Tokyo, Japan.**

Let y_0 denote the elevation of the wave above the undisturbed free surface, and p_0, the pressure intensity on the wall. Then, the solutions are:

$$y_0 = -2\delta \sum_{r=1}^{\infty} \frac{1}{n_r \sqrt{1 - \frac{w p^2 h^2}{\kappa g n_r^2}}} \times \frac{1}{1 - \frac{g}{p^2 h} + \left(\frac{g}{p^2 h} n_r\right)^2} e^{-q_r} \cos pt \quad ..(119a)$$

and,

$$p_0 = \frac{w}{g} p^2 \sum_{r=1}^{\infty} \left(\frac{g n_r}{p^2 h} \cos \frac{n_r}{h} y - \sin \frac{n_r}{h} y\right) \frac{2\delta}{n_r^2} \times \frac{h}{1 - \frac{g}{p^2 h} + \left(\frac{g}{p^2 h} n_r\right)^2}$$

$$\times \frac{1}{\sqrt{1 - \frac{w p^2 h^2}{\kappa g n_r^2}}} - \cos pt \quad \ldots\ldots\ldots\ldots\ldots\ldots (119b)$$

in which, $q_r = \frac{n_r x}{h} \sqrt{1 - \frac{w p^2 h^2}{\kappa g n_r^2}}$; $p = \frac{2\pi}{T}$; δ is the amplitude of the motion; and n_r denotes the roots of the following equation:

$$\frac{g}{p^2 h} n_r \sin n_r + \cos n_r = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots (120)$$

Inspection of Equation (119a) will show clearly that the series converges at $x = 0$. With data as supplied by the author, $\frac{g}{p^2 h}$ is approximately equal to 1.64×10^{-2} and $\frac{\rho_0 p^2 h^2}{\kappa}$ is approximately equal to 1.8×10^{-3}. Therefore, it is seen that the answers in Equations (119) are nearly the same as those given by the author when r is small, while there is an appreciable difference when h, the height of the dam, is small. The elevation of the wave is found to be $-$ 0.47 ft.

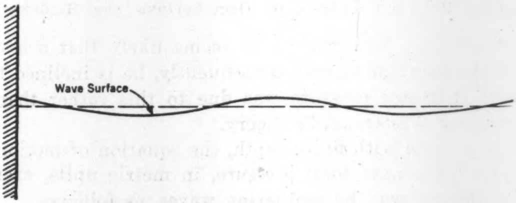

FIG. 29.—WAVES OBSERVED IN TANK.

The writer has investigated the wave motion of water contained in a rectangular tank, 17.9 ft. by 5.97 ft. by 5.97 ft. deep, produced by simple harmonic motions with periods of 0.86 and 1.68 sec. For each period the number of standing waves observed (Fig. 29) was the same as the number of oscillating waves. The period was nearly the same as that of the external force. For the two periods of harmonic motion, 1.68 and 0.86 sec., $1\frac{1}{2}$ waves and $4\frac{1}{2}$ waves, respectively, were observed. According to a theoretical calculation, for $1\frac{1}{2}$ waves the periods of oscillation of the water were found to be 1.59 sec. and 1.53 sec. for depths of 2.9 ft. and 4.5 ft., respectively; and for $4\frac{1}{2}$ waves the period of oscillation was found to be 0.87 sec., nearly independent of the depth.

It is not a simple matter to find a definite relation between the number of oscillations and the heights of waves. Although Fig. 30 suggests that the heights may have a tendency to increase with successive oscillations the reverse tendency was also observed.

It has been stated[35] that experiments by Professor Lydik S. Jacobsen are in fair agreement with the formulas by the author. Because Professor Jacobsen's experimental apparatus was not described in detail the writer hesitates to pass final judgment. Nevertheless, it seems likely that a standing wave was observed in the experiment and, consequently, he is inclined to the belief that the increase in water pressure was due to this rather than to factors involved in Professor Westergaard's theory.

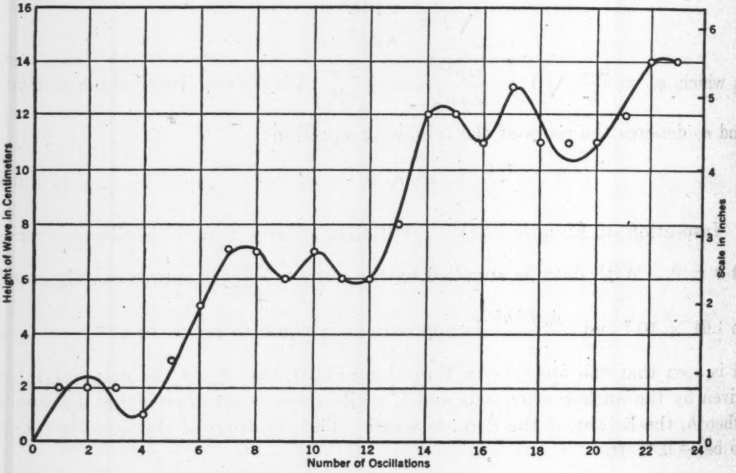

FIG. 30.—RELATION BETWEEN NUMBER OF OSCILLATIONS AND HEIGHTS OF WAVES.

In the case of a basin with finite depth, the equation of motion derived by Flamant gives the maximum total pressure, in metric units, exerted upon a unit width of a vertical wall by oscillating waves, as follows:

$$P = \frac{H^2}{2} + \frac{h_0^2}{2}\left[ln \cosh \frac{\pi H}{L} - \frac{1}{2} \tanh^2 \frac{\pi H}{L} \right] + \frac{h_0 L}{\pi}\left[\frac{\cosh \frac{\pi H}{L} - 1}{\cosh \frac{\pi H}{L} \sinh \frac{\pi H}{L}} \right] \quad ..(121)$$

in which, $2\ L$ is the length and h_0 is the height of the waves. With data obtained experimentally by the writer, $H = 4.53$ ft., $L = 1.97$ ft. and $h_0 = 0.66$ ft., Equation (121) gives $P = 0.3199 + 0.400 = 0.3599$ tons per ft. If the free water surface is assumed to rise only 0.33 ft., the hydrostatic pressure would become 0.3686 tons per ft., an increase of 0 0481 tons per ft. above the original value.

[35] "Earthquake Forces on Dams" by S. B. Morris, M. Am. Soc. C. E., and C. E. Pearce, Assoc. M. Am. Soc. C. E., *Bulletin*, Seismological Soc. of America, September, 1931.

It does not seem possible to obtain small enough periods of the wave-generating force by the apparatus referred to; moreover, it is evident that the results of experiments in a relatively small tank cannot be applied directly to a very large reservoir without causing considerable error. However, one does observe seiches on a lake during an earthquake and the writer believes that the systems of waves discussed here should be considered in most cases.

H. M. WESTERGAARD,[36] M. AM. SOC. C. E. (by letter).—It is gratifying that the experiments made by Professor Lydik S. Jacobsen (referred to by Mr. Pearce) showed a satisfactory agreement with the analysis. It was desirable that such tests should be made. A full account by Professor Mononobe of his tests and of his theories will be awaited with interest.

The discussions have thrown light on several different phases of the problem. Mr. Rowe, by his diagrams interpreting the theory, has made possible a clear visualization of the action of the whole body of water behind the dam. Mr. Bauman and, especially, Professor Bakhmeteff have connected the problem successfully with practical hydraulics. Messrs. Brahtz and Heilbron and Professor Mononobe have obtained information concerning the effects of certain modifications of the boundary conditions. It is noted that in a majority of important cases the effects of the modifications which they studied will be small.

Particular acknowledgment is expressed to Professor von Kármán on account of his simple approximate solution. It is often more difficult to devise a simple approximate solution than to develop a complete mathematical analysis. Since the results of Professor von Kármán's theory agree so well with those of the more complex analysis, and with Professor Jacobsen's tests, the suggestion is offered that Professor von Kármán's approximate method be applied to the following problem: To determine the influence of the shape of the cross-section of the canyon at the dam when the canyon is fairly narrow.

Let, y = the elevation measured from the bottom of the water, at the dam;

B = the width of the canyon at the elevation, y, at the dam;

$A = \int_0^y B\,dy$ = the area of the cross-section of the canyon between the elevations, 0 and y;

b (as before) = the dimension of the equivalent body of water considered to move with the dam, measured from the dam in the up-stream direction;

h = the maximum depth of the water.

Factors B, A, and b are functions of y only.

---

[36] Prof. of Theoretical and Applied Mechanics, Univ. of Illinois, Urbana, Ill.; Cons. Engr., U. S. Bureau of Reclamation.

With the variable width, B, introduced, Professor von Kármán's Equations (55) to (59), inclusive, will be written as follows:

$$A\,a_x = B\,b\,a_y \qquad (122)$$

$$p = \rho\,b\,a_x \text{ (unchanged)} \qquad (123)$$

$$\frac{d}{dy}(\rho\,B\,b) = -\rho\,B\,b\,a_y \qquad (124)$$

$$\frac{d}{dy}(\rho\,B\,b^2\,a_x) = -\rho\,A\,a_x \qquad (125)$$

and,

$$B\,b^2 = \int_y^h A\,dy \qquad (126)$$

The last quantity, Equation (126), may be interpreted, if one wishes, as the bending moment at the elevation, y, in a vertical simple beam with supports at $y = \pm h$ and with a symmetrical load equal to B per unit of length at any elevation, $\pm y$.

Equation (126) gives,

$$B\,b = \sqrt{B\int_y^h A\,dy} \qquad (127)$$

from which, in any given case, the total volume of water which is considered to move with the dam may be computed as,

$$V = \int_0^h B\,b\,dy \qquad (128)$$

As an example, assume,

$$B = \frac{h}{2} + y \qquad (129)$$

This equation applies roughly to the canyon at the Hoover Dam. By Equation (126) one finds, then,

$$B\,b^2 = \frac{1}{12}\,(5\,h^3 - 3\,h\,y^2 - 2\,y^3) \qquad (130)$$

which gives, at the bottom, $b = h\sqrt{\frac{5}{6}} = 0.913h$. Professor von Kármán found $b = 0.707h$ corresponding to a constant, B. Further computations by Equations (127) to (129) give $V = 0.496h^2$, while a constant width equal to the average width, $B = h$, according to Professor von Kármán's Equation (65), gives $V = 0.555h^2$. Thus, with the variable width, the pressure at the bottom, $a\,w\,b$, is greater, but the total horizontal force, $a\,w\,V$, is less than the corresponding values in case of a constant width, $B = h$. By assuming values of b according to Equation (53), $b = \frac{7}{8}\sqrt{h\,y}$, with y denoting the depth of any point and h denoting the maximum depth of the water, one finds in the example of variable width, $V = 0.525h^2$, while with $B = h$, one finds $V = 0.583h^2$. It is concluded that, in the case of a narrow canyon, Equation (53), used as just indicated, leads to a value of V slightly on the side of safety.

Paper No. 1836

WESTERN HIGHWAY PRACTICE, WITH SPECIAL REFERENCE TO CALIFORNIA[1]

By C. S. POPE,[2] M. Am. Soc. C. E.

With Discussion by Messrs. J. S. Bright, R. D. Rader, H. S. Kerr, E. Q. Sullivan, T. A. Corry, Charles T. Leeds, G. S. Paxson, and C. S. Pope

Synopsis

The field of Western highway construction is so widespread and each locality offers so many varied problems that it is only possible to cover a small part of it. The writer, therefore, does not propose to cumber the already voluminous literature of highway engineering with repetitive descriptions of problems or the methods used in the solution of problems already common to highway engineers from their own experience or reading. The paper contains an outline of the methods used in solving certain construction problems of a nature unusual to Eastern terrain and to indicate some of the controls which have been applied in the Western States to those forces of Nature which, unless properly curbed, are destructive to the works of Man.

While the general theme of this paper is devoted to construction designed to insure protection against stream erosion and floods, cloudbursts, and the destructive action of the sea, the writer has also presumed to touch briefly upon the subjects of highway financing and of clearing right of way previous to construction.

Finance

Of all problems facing the Western States, that of finance is probably the most serious. The large areas of public lands, the scant population in many locations, the long stretches of country on which no local need of business or political weight urges the expenditure of funds, and the expensive grading and bridge construction which are often necessary for even the most elemental road construction, place upon Western highway engineers a serious construction problem. Competition in high ideals in road design and construction has necessitated an orderly procedure in the use of such funds as may become available.

---

[1] Presented at the meeting of the Highway Division, Sacramento, Calif., April 24, 1930.

[2] Chf. Constr. Engr., California Div. of Highways, Sacramento, Calif.

Western highway engineers now realize that no highway system will ever be entirely completed, but that it will be added to, rebuilt, changed, and improved to the advancing needs of traffic farther into the future than any man can predict. Through the gasoline tax a source of steady income, automatically adjusting itself to the finances required, has been set up, thus enabling construction programs projected from 10 to 50 years into the future to be outlined with a moderate assurance that they will be carried forward. Whether a gasoline tax imposing a moderate tariff on motor vehicle owners will furnish sufficient funds to meet the demands of highway users, without the assistance of bond issues, is a question which time will answer.

The application of the budget plan of expenditure, however, and the assertion of the principle of preferential road construction founded on a study of the economic and engineering justification of each road under consideration has done much to clarify the allotments of funds in a rational manner.

In 1930, California began planning its road expenditures on the basis of the needs of the succeeding ten years, in actual definite projects, and the State authorities have been looking ahead very much farther than that in its prospective highway plans.

Clearing the Right of Way

Present-day highway engineering literature devotes itself quite completely to problems such as soil studies, drainage, paving design, and similar subjects relating possibly more to the highway already graded and constructed under average conditions than to the highway in process of construction. Many Western highways present additional interesting construction problems which have possibly not been given so much attention. Among the first of these is the clearing of the right of way previous to construction.

The problem of clearing brush and trees of medium size and thickness of growth is not unusual in many States. Such conditions as those encountered in the Northern coastal highway construction are, however, somewhat unique. Not only does dense undergrowth occur, but trees of very large size, both standing and prone, which must be felled or cleared away. Normal clearing costs where moderate sized trees and scattered underbrush are to be removed, may be stated as about $250 per acre. In the heavily timbered country of the Northern California coast, the clearing may be as high as $1 200 to $3 000 per acre.

Clearing may include grubbing and the removal of all stumps in the case of trees prone to rotting, but in many cases redwood stumps are not removed because of their known long life. Where stumps are removed, the allowance which must be made in excavation computations for filling stump-holes is often a matter of considerable moment.

Trees of moderate size are pulled over with tractors, but in handling trees up to 18 ft. in diameter, other methods are used. The organization for such

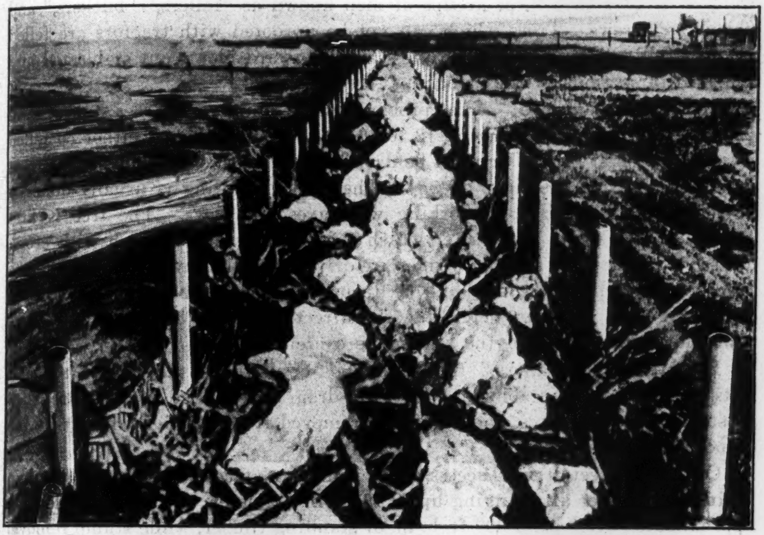

FIG. 1.—PIPE, WIRE MESH, AND BRUSH FENCING FOR BANK PROTECTION

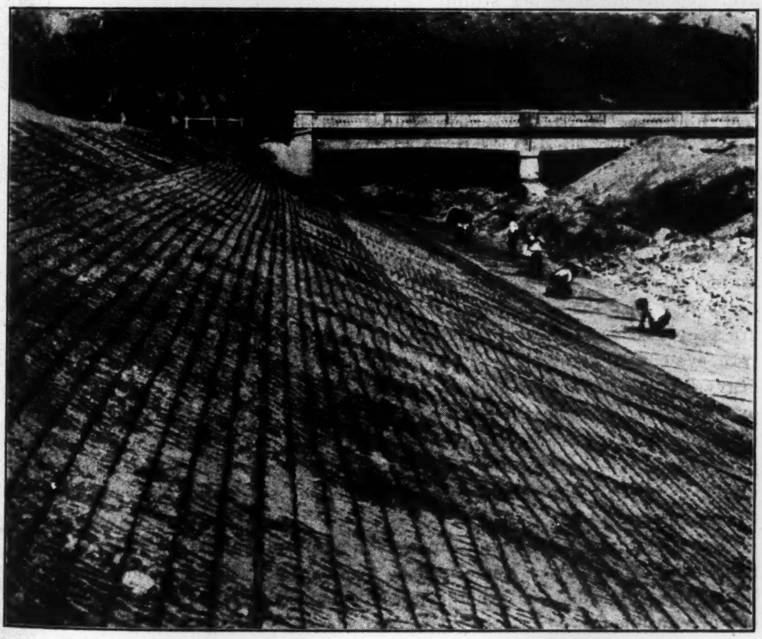

FIG. 2.—WIRE MESH MATS FILLED WITH GRAVEL FOR BANK PROTECTION.

work is divided into three groups of men known as "fallers," "buckers," and "blocking" crews. Trees which can not be uprooted with tractors are felled by the "falling" crew and the stumps are afterward blown out or blasted and removed in sections by the "blocking" crew.

Falling is somewhat of a problem when numerous trees more than 200 ft. in height and averaging 12 to 16 ft. in diameter must either be felled in a 100-ft. right of way or must be dropped so that they will not injure trees which are outside the right of way. The work of falling is usually done by two "fallers" to each tree, working with axes and saws. The tree is first heavily notched with axes, after which the trunk is cut through with crosscut saws. During the sawing, wedges are driven into the saw-cut to prevent the tree from pinching the saw and to insure falling in the proper direction. The final cuts, however, determine the direction of the fall, and it is here that the ultimate skill of the "faller" is exercised.

Following the "fallers," the "bucking" crew trims the felled tree and cuts it into merchantable lengths with drag saws. The stumps are then blasted and logs, stumps, and débris are removed from the right of way by the "blocking" crews.

On one project it was necessary to remove about 1 800 trees larger than 12 in. in diameter and ranging up to 18 ft. in diameter. The cost of clearing approximated $7.00 per 1 000 ft. b. m. of standing timber, while stump removal averaged about $6.50 per stump.

PROTECTION FROM ELEMENTS

Some of the more unusual elements against which it is necessary to protect highways in the Western States are floods, cloudbursts, sea waves, moving sand dunes, and earthquakes.

Floods may be either those caused by the rise of large rivers, or by the sudden flow of water, in otherwise normally dry stream channels, due to cloudbursts.

Structures to furnish protection against cloudbursts consist either of a system of "dips" or depressions in pavements, which permit a temporary overflow across the pavement. By means of these structures the pavements are protected from scouring by means of overflow aprons and cut-off walls; or a system of channels and deflecting dikes which pick up the broad but heavy flow occasioned by cloudbursts and conduct it through control channels over which trestles have been constructed.

Protective structures for sea waves take the form of booms anchored to piles, heavy random rip-rap, hand-placed rip-rap, sheet-piling of wood or concrete, or other bulkheads, groynes of wood or steel, jetties, wave breakers, slope paving, and sea walls.

Protection against moving dunes is generally obtained by a study of their habits and movements. Some may be avoided by a change of location, others by a raise of grade, and others may be removed by wind action or with the use of equipment.

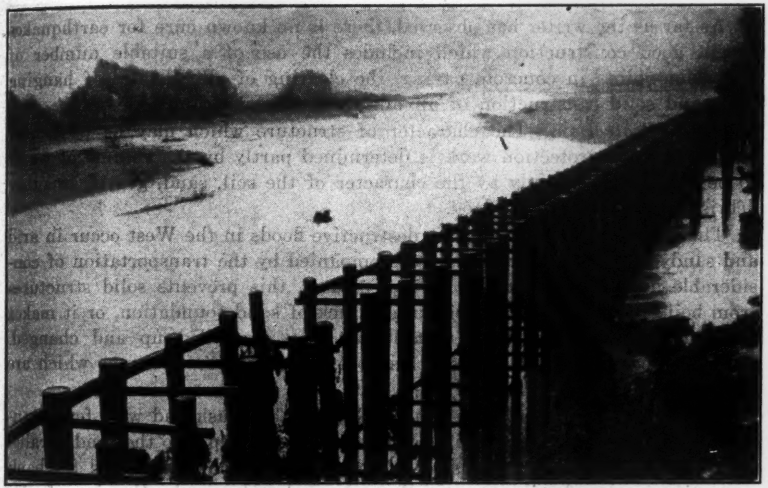

Fig. 3.—Piles and Barbed Wire for Bank Protection on Hard-Bottom Rivers in Timbered Country.

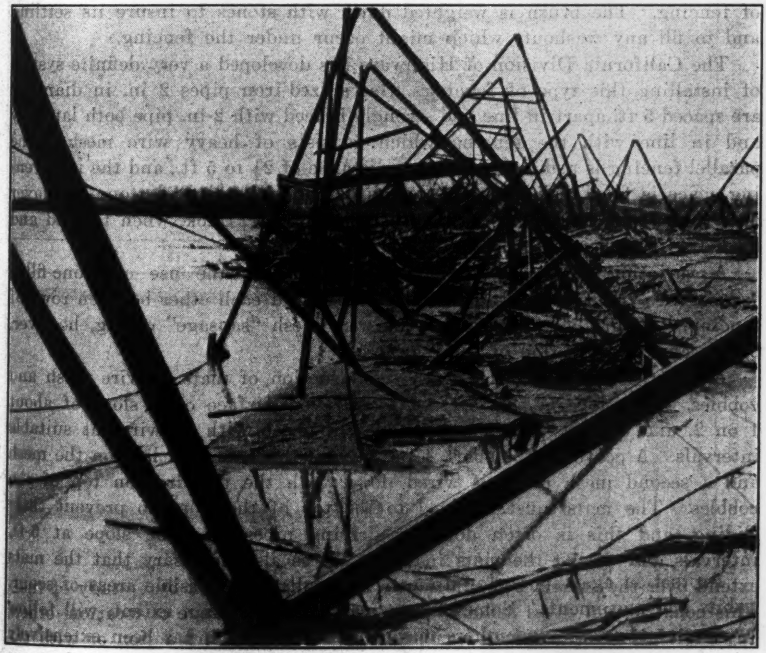

Fig. 4.—Tetrahedrons Fabricated from Steel Rails for Shore Protection.

As far as the writer has observed, there is no known cure for earthquakes except good construction which includes the use of a suitable number of expansion joints in concrete paving, the clearing of all hillsides of hanging rock, and solid construction of all fills in earthquake country.

Flood Protection.—The character of structure which may be used with success in flood-protection work is determined partly by the volume of water to be handled and partly by the character of the soil, sand, gravel, or other débris transported by the flood.

The more common of the most destructive floods in the West occur in arid and sandy regions and are usually accompanied by the transportation of considerable quantities of sand. In many cases, this prevents solid structures from being used successfully because of lack of solid foundation, or it makes them useless for the reason that stream beds are filled up and changed. There has been considerable use, therefore, of structures of a type which are flexible or which may be easily replaced.

Brush and Wire Fencing.--Among these is the brush and wire fence constructed of two rows of galvanized-iron pipe driven deep into the sand parallel with the stream. This type is shown in Fig. 1, which is designed for bank protection in slow-flowing streams through sand and gravel. Fencing of wire mesh is fixed to the pipe to retain the brush which is placed between the rows of fencing. The brush is weighted down with stones to insure its settling and to fill any washouts which might occur under the fencing.

The California Division of Highways has developed a very definite system of installing this type of fencing. Galvanized-iron pipes 2 in. in diameter are spaced 5 ft. apart in line and strongly braced with 2-in. pipe both laterally and in line with the fencing which consists of heavy wire mesh. The parallel fencing is usually placed at a distance of 2½ to 5 ft., and the intervening space is filled with alternate layers of willow brush and stone. A layer of brush, 2½ ft. thick, will compact to a layer, 1 ft. thick, when tamped and loaded with sufficient stone to hold it down.

A variation of the willow and stone filler is the use of stone-filled "sausages" of wire mesh, which are laid on top of each other between rows of fencing. Naturally any break in the wire mesh "sausage" casing, however, brings about destruction of the "sausage."

Another common practice is the construction of mats of wire mesh and cobbles. The slope is first dressed to an even surface on a slope of about 1 on 2, and on it is laid a section of wire mesh with tie-wires at suitable intervals. A coating of cobbles, 4 in. or 8 in. thick, is then laid on the mesh and a second mesh panel is wired down with the tie-wires on top of the cobbles. The mats must be fixed to the top of the slope to prevent their sliding, and this is often done by driving pipes into the slope at 6-ft. intervals and wiring the mats in place. It is also necessary that the mats extend over the stream bed sufficiently to blanket any possible areas of scour. This construction gives a flexible mat which, to a certain extent, will follow any undulations which may occur due to washouts. It has been extensively used in storm-protection work in Los Angeles County, California, but not

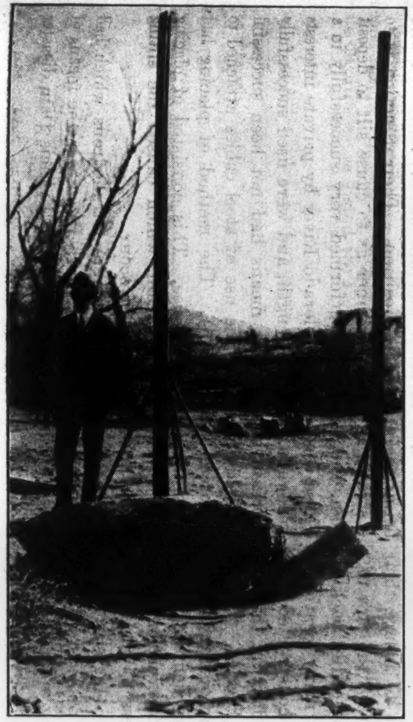

FIG. 5.—CONCRETE MUSHROOM ANCHORS TO HOLD RAIL TETRAHEDRONS IN PLACE.

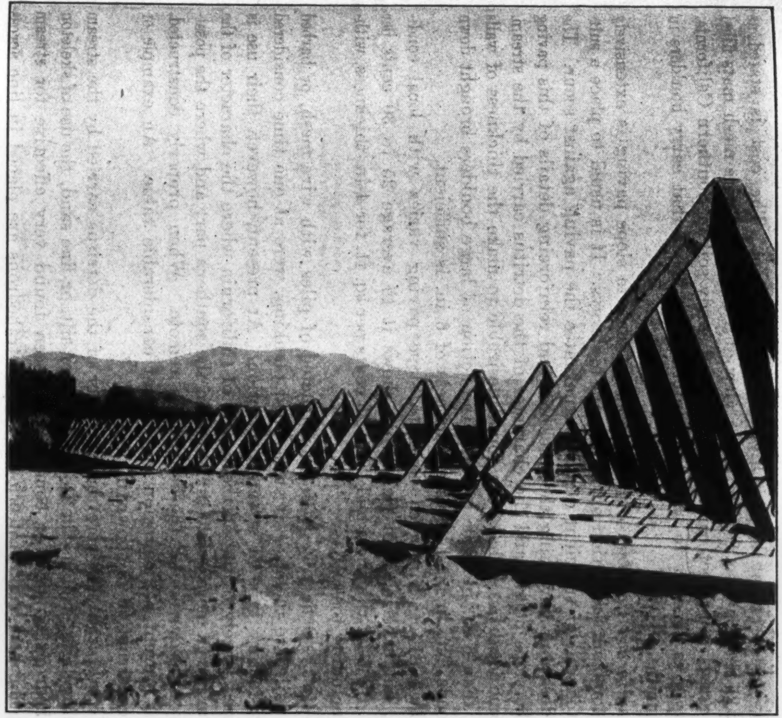

FIG. 6.—REINFORCED CONCRETE TETRAHEDRONS FOR BANK PROTECTION IN A STREAM WITH A WINDING CHANNEL.

to any great extent by the highway organization. The cost is stated as about 25 cents per sq. ft. Fig. 2 is a view of a section of wire-mesh mats filled with gravel to protect banks of gravel and sandy soil in Southern California. The type is effective to withstand intermittent floods that carry boulders in their paths.

Reinforced Concrete Slope Paving.—Concrete slope paving is extensively used for bank protection on California highways. It is usual to place a suitable toe-wall of sufficient depth to guarantee the paving against scour. The considerations governing the thickness and reinforcing details of this paving are the slope height and the character of the detritus carried by the stream. In some localities it has been found desirable to make the thickness of walls more than 6 in. in order to resist the action of large boulders brought down by floods, but in most cases a thickness of 6 in. is sufficient.

The cost of reinforced concrete slope paving varies with local conditions, but experience in California shows it to average 25 to 30 cents per sq. ft. for 6-in. thickness and 20 to 25 cents per sq. ft. for 4-in. thickness, without including toe-walls.

Jetties.—Deflecting jetties constructed of piles with wire mesh, or barbed wire nailed to them, or of stone-filled planking, were at one time considered a satisfactory type of stream protection. At present, however, their use is confined largely to the northern part of California where the character of the stream bed is more stable than that in the southern part and where the possibility of scour under the fencing is remote. When properly constructed, jetties prevent bank erosion and are of considerable value. An example of this construction is shown in Fig. 3.

Tetrahedrons.—Where the character of the detritus carried by the stream is rather light, such as the Colorado River silt, or fine sand, the use of skeleton tetrahedrons of steel or concrete has been found very effective for stream deflection and bank protection. These tetrahedrons are placed in line across a point that is giving trouble due to scour and are usually anchored with cables to insure their being maintained in position. Their function is to interrupt the flow of the stream in such a manner as to cause silt to deposit in the eddies back of them, and they have performed very successfully in a great many locations. Those used on the Colorado River by private interests were constructed from steel rails, 30 ft. in length, and were used successfully in deflecting this large stream where other means had not been successful (see Fig. 4). They were held in line by the use of steel cables attached to mushroom anchors of concrete (see Fig. 5). The method of placing had a very definite influence on their successful use. This consisted of placing the obstructions one after another down stream, which caused the silting process to begin at once and prevented further scour.

On highway work, a row of reinforced concrete tetrahedrons which had been placed to deflect the stream on the Santa Clara River was the means of saving a considerable section of highway during the St. Francis Dam disaster (see Fig. 6).

Stone-Filled Steel Wire Baskets.—In one location, a mountain river in heavily timbered country, metal baskets, 7 ft. square, and of varying depths, filled with stone, were installed under plans made by the U. S. Bureau of Public Roads. A typical plan and elevation are given in Fig. 7 and approximate quantities are listed in Table 1.

Slope paving of hand-placed stone with appropriate toe-walls has been extensively constructed in a number of suitable locations. On many streams the use of random rip-rap of considerable weight has been advantageous as a method of protection. Fig. 8 shows two types of slope protection suited to canyons that are subject to boulder-carrying floods.

CLOUDBURSTS

One of the most unusual problems in California is the protection required against cloudbursts. It is the opinion of many engineers that these occur in approximately the same areas within a reasonable range of time. Since in many localities the hills and mountains are entirely denuded of any verdure which would retard the flow of water, the volumes of water to be handled are very large and the run-off is very rapid. The water often appears without previous intimation that a cloudburst has occurred. The first knowledge which the observer has of the approaching danger is the appearance of a wall of water and mud sweeping down the canyon. The method pursued in the past was to construct paved "dips" across all locations where the profile indicated that storm or cloudburst run-offs were usual. This, however, proved unsatisfactory in many cases because of extreme scour which occurred at the overflow aprons, and also the great expense of cleaning débris from the dips and roadway after each storm. It seemed practically impossible to check the velocity of the water after it had crossed the pavement, either by cut-off walls or by the use of water cushions.

A usual formation in sections where cloudbursts are frequent shows the presence of flat débris cones issuing from the canyons (or other sources from which the water comes) and spreading out fan-wise into the lower lands. Taking advantage of this condition, the State has adopted the system, formerly used by the Atchison, Topeka and Santa Fé Railway Company, of constructing pick-up channels or dikes across the drainage lines of the débris cones in such a manner as to secure greater velocity in the channels than is afforded by the general slope of the cones (see Fig. 9). The channels, of course, must be located close enough to the highway to prevent any considerable quantities of water falling between the intercepting system and the highway. The results thus far obtained have been extremely satisfactory in restraining all the water from crossing the highways, except at certain designated points, known as controls, where wooden trestles are constructed along the highway for the passage of streams. The system of drainage thus developed has given rise to a nomenclature for its various parts. The source of the water is usually designated as the "cone," the main drainage channels as "ditches," feeder channels as "sub-ditches," and the outlets at which water is concentrated and carried across the highway as "controls."

In Fig. 10 the highway location is parallel to a desert valley. The main drainage is through a series of dry lakes or sinks. Tributary drainage is shown emerging from the mountains to be intercepted by one or two main channels that break up into interlacing overflow channels. The storm-protection ditches are located so as to obtain the maximum fall. Associated with the channels is often a system of dikes for directing the flow. In other places where large open valleys are encountered in desert locations, and storm flow occurs as broad sheets of water, it has been necessary to construct extensive dike systems and to conduct the water under the highway by means of wooden bridges or trestle structures, as before stated.

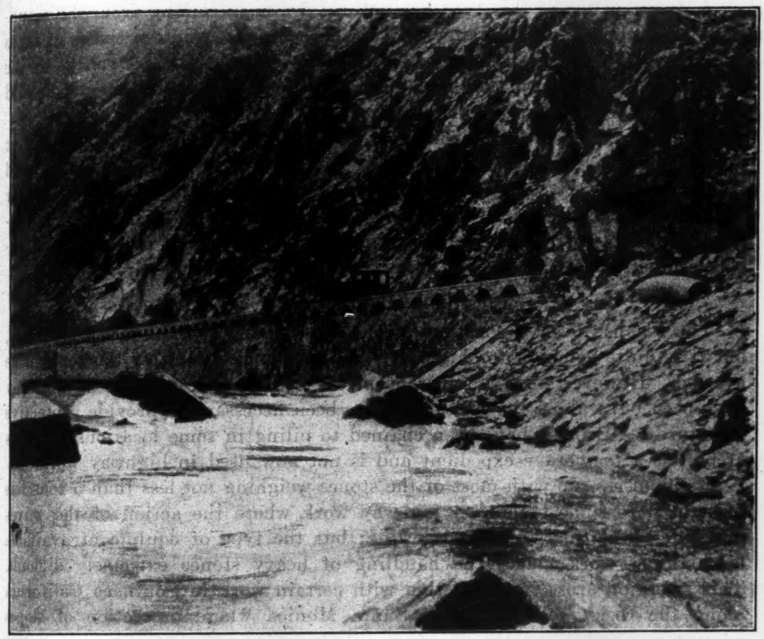

FIG. 8.—RUBBLE WALL AND HAND-LAID DRY SLOPE PAVING.

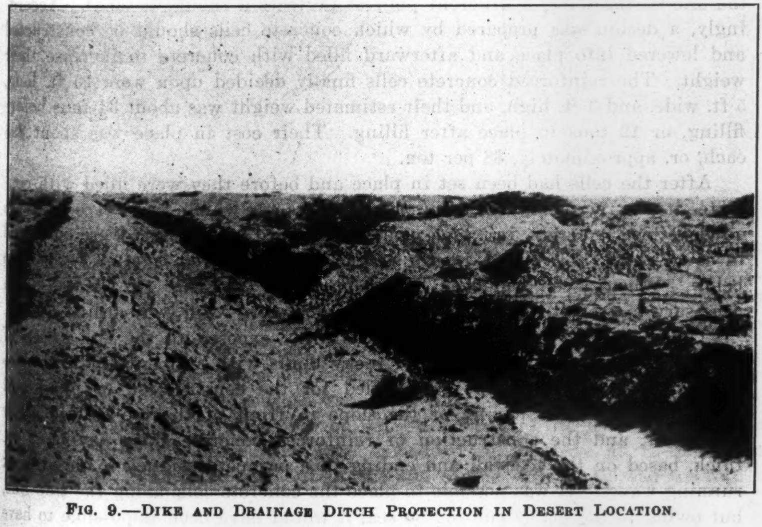

FIG. 9.—DIKE AND DRAINAGE DITCH PROTECTION IN DESERT LOCATION.

A desert valley of this type has natural drainage coming from the mountains on each side of the valley and discharges usually into a series of lakes and sinks. These sinks or dry lakes are formed in most desert valleys by the débris deposits from major side-tributary drainage which has cut off and backed up the main valley drainage.

The cost of ditching for the type of work done on débris cones is about \$1 500 per mile. The cost of the wider ditches with dikes, such as are used in the wide desert valleys, is about \$2 500 per mile. The cost of timber bridges and trestles of 20 to 24-ft. creosoted piles and of redwood superstructure of 24-ft. roadway, varies from \$100 to \$125 per ft. of length. Highway protection by this system costs from \$3 000 to \$3 800 per mile.

Sea Protection

The sea has been a constant menace to construction in many localities, but it is quite common for highways to be located where this danger can be averted. However, in a number of places considerable lengths of highway have been built along the sea, and it has been necessary to provide protective structures. "Booms" have been chained to piling in some locations, but this at best is a temporary expedient and is not now used in highway work.

Random rip-rap with most of the stones weighing not less than 5 tons has been used to some extent on highway work where the action of the waves and tides is normal to the coast line; but the type of equipment available on highway work makes the handling of heavy stones extremely difficult. This situation arose in connection with certain work in Southern California along the rocky coast north of Santa Monica where protection of slopes against sea action became necessary. It was decided that, since large rock suitable for both rip-rap and blanketing the slopes could not be handled at the site of the work, a different plan of protection should be used. Accordingly, a design was prepared by which concrete cells should be constructed and lowered into place and afterward filled with concrete to increase their weight. The reinforced concrete cells finally decided upon were 10 ft. long, 5 ft. wide, and 3 ft. high, and their estimated weight was about 3½ tons before filling, or 12 tons in place after filling. Their cost in place was about \$95 each, or, approximately, \$8 per ton.

After the cells had been set in place and before they were filled with concrete, it was necessary to grout the boulders on which they were set with quick-setting concrete, in which cement and hard wall plaster were combined in equal parts, in order to insure sealing of the concrete against wash from below. When a cell had been filled completely (see Fig. 11), it was again necessary to protect the fresh concrete against wave wash by boarding the top.

The shore line at this location is entirely exposed to the full sweep of the Pacific Ocean and consisted of rocky bluffs with a steep slope into deep water. The design in this case called for the construction of a toe-wall below high tide, the paving of the slope in front of the toe-wall to below low water, and the construction of reinforced concrete slope paving, 9 in. thick, based on the toe-wall and ending in a parapet designed to throw back running waves. It was possible to place the concrete cells along the tide line, but owing to the heavy run of the sea, it would have been impossible to have built the toe-wall or the slope walls without some protection. Accordingly, such leveling and removal of boulders as was possible was done at low tide and the concrete cells were then sunk into line on the roughly prepared foundation and were filled with concrete and heavy stone between tides.

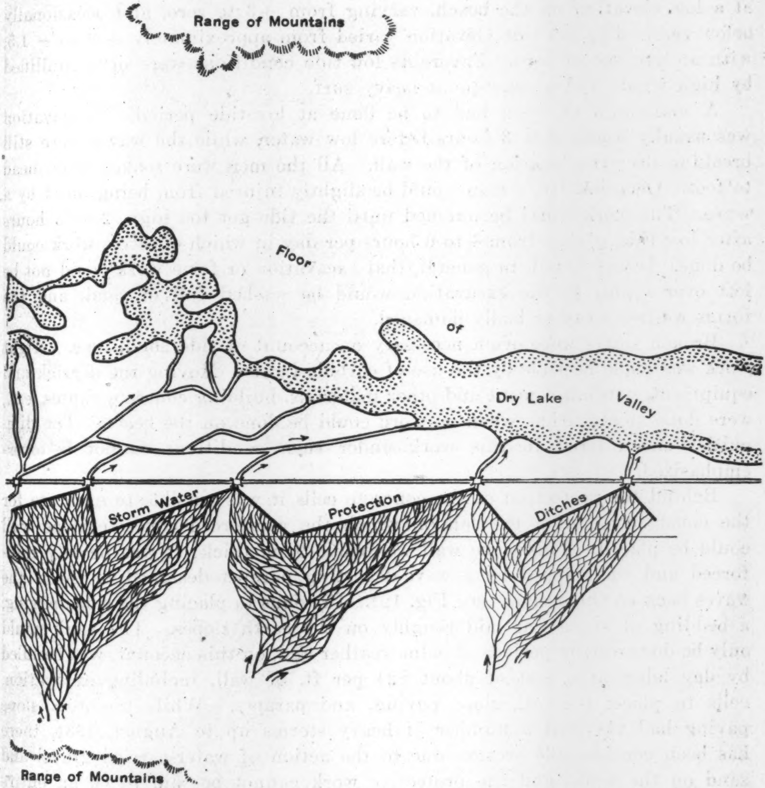

FIG. 10.—TYPICAL HIGHWAY LOCATION, WITH STORM-PROTECTION DITCHES.

When the cells had been poured and the beach boulders grouted, enough protection was afforded so that sufficient time was allowed in spite of the rising tide, to pour the base of the toe-wall to a height of 1½ to 2 ft., leaving from 1½ to 2½ ft. to construct on top of the base, the cells acting as a form on the outside. After the section of base was constructed, the top section was poured into the forms built on the base poured previously. These forms were built while the other work was proceeding. The toe-wall was poured with Class C concrete, 4.2 sacks per cu. yd. Steel bars, ½ in. by 4 ft., were used in the toe-wall. These bars were embedded in the base at 12-in. centers extending up through and out of the top of the wall to tie the toe-wall to the slope paving.

To give a better understanding of the aforementioned procedure, it is necessary to call attention to the great difficulty created by the tides. This work had to be carried on during the winter months, the most unfavorable time of the year, in order not to delay the slope paving. All the work was at a low elevation on the beach, varying from +3 to zero, and occasionally below zero. The low-tide elevation varied from approximately + 2 to − 1.5, with an average of zero. Favorable low-tide conditions were often nullified by high winds and a consequent heavy surf.

A maximum of work had to be done at low-tide periods. Excavation was usually begun 2 to 3 hours before low water, while the waves were still breaking over the location of the wall. All the men were soaked from head to foot. Occasionally, a man would be slightly injured from being upset by a wave. The work could be pursued until the tide got too high, 2 to 3 hours after low tide, giving from 4 to 6 hours per day in which effective work could be done. It was found, in general, that excavation or form work could not be left over night, as the excavation would be washed full of sand, and the forms washed away or badly damaged.

Broken shifts were often necessary on account of tide conditions. Night work was made possible by the use of carbide lights. Moving the derrick and equipment, hauling cement and other materials, building concrete chutes, etc., were done at high tide, when no work could be done on the beach. The difficulties encountered in this work under such conditions cannot be overemphasized.

Behind the protection of the concrete cells it was possible to excavate for the construction of a toe-wall on which the reinforced concrete slope wall could be placed. This slope wall was made 9 in. thick; it was heavily reinforced and was capped by a wave-deflecting parapet designed to throw the waves back on themselves (see Fig. 12). Previous to placing the slope paving, a bedding of stone was laid roughly on the earth slopes. The work could only be done during periods of calm weather and, on this account, was handled by day labor at a cost of about $24 per ft. of wall, including excavation, cells in place, toe-wall, slope paving, and parapet. While the 9-in. slope paving had survived a number of heavy storms up to August, 1931, there has been considerable erosion due to the action of water-carried gravel and sand on the slabs, and the protective work cannot be said to be an entire success.

The use of sheet-piling of either wood, steel, or concrete, on State work in California has never met with much success, and it has not been used extensively in sea protection.

In locations where the run of the tide is parallel to the shore line and where sandy beaches alternately form and depart during storms, groynes have been used extensively along the south coast and in many locations the beach has been restored by their use. Fig. 13 shows a beach immediately after groynes were constructed and Fig. 14 shows their effect some time afterward. The State construction usually contemplates the use of wooden structures, but some of the private beach owners have used steel sheet-piling with considerable success. The usual State construction contemplates the

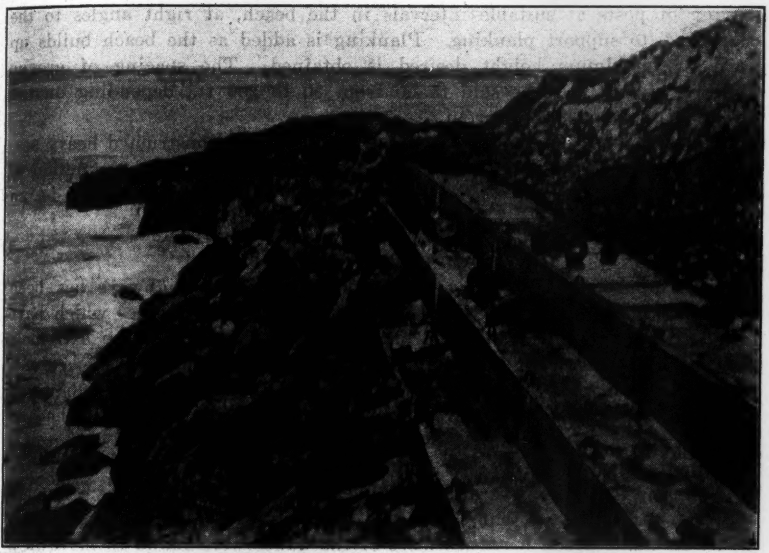

FIG. 11.—REINFORCED CONCRETE CELLS FILLED WITH CONCRETE FOR SHORE PROTECTION.

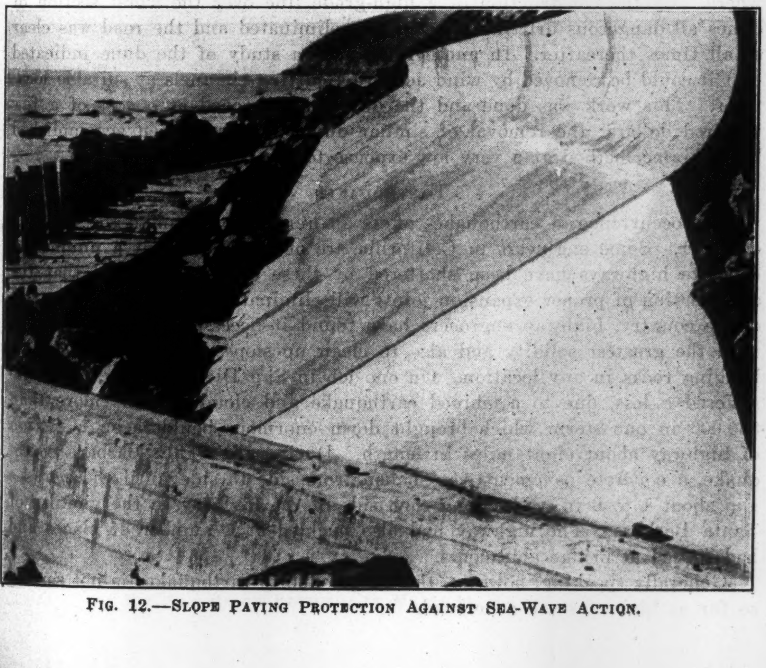

FIG. 12.—SLOPE PAVING PROTECTION AGAINST SEA-WAVE ACTION.

driving of posts at suitable intervals in the beach, at right angles to the coast line, to support planking. Planking is added as the beach builds up until the maximum height desired is obtained. The spacing of groyne lines varies, but may be said to be from 50 to 200 ft., depending on the direction of the coastal current.

Sea-Walls.—In one or two locations, the State has constructed heavy sea-walls of monolithic concrete of sufficient strength to withstand the action of the heaviest waves. These have been built with the usual throw-back design of top which has proved effective wherever tried.

SAND DUNES

In a number of places the California Division of Highways has been faced with the problem of control or elimination of sand dunes which have formed not only a serious burden on maintenance, but have been extremely dangerous to traffic. It is quite usual for a sand storm to place a dune, within a few hours, across the highway, several feet in depth, which would require constant labor to remove. On one particular dune the State had an annual expense of about $7 000 for keeping the road clear over a section of a few hundred feet.

A study of the habits of dunes and their movements, made over a number of years, demonstrated that they could be conquered if proper means were used. In many given localities most of the dunes were found to move in a certain direction and then attain a height which was seldom exceeded elsewhere. By the construction of a high-grade line over the worst section of dunes all dangerous drifting was entirely eliminated and the road was clear at all times thereafter. In another location, a study of the dune indicated that it could be removed by wind action by cutting channels at suitable locations. This work was done and the dune was removed at a cost of a few hundred dollars; the removal of similar dunes has since been accomplished by the same method at a very low expense to the State.

EARTHQUAKES

The occurrence of earthquakes offers an unusual problem to the highway engineer. Some engineers in California are of the belief that a number of concrete highways have been shattered by these disturbances and that the construction of proper expansion joints will eliminate this danger. In earthquake country, highway engineers have found it necessary to construct fills with the greatest solidity and also to clean up slopes so that there are no hanging rocks in any location. On one job in San Diego County, the State suffered a loss, due to combined earthquake and cloudburst, of more than $30 000 in one storm which brought down enormous boulders on a section of highway about eight miles in length. During the Santa Barbara earthquake, a concrete pavement was shaken from side to side until there was a gap about 4 to 6 in. wide along each side of the highway in the vicinity of Santa Barbara. The highway had also buckled at a number of places and had settled at bridge abutments.

Generally speaking, however, the danger due to earthquakes is not serious so far as highways are concerned.

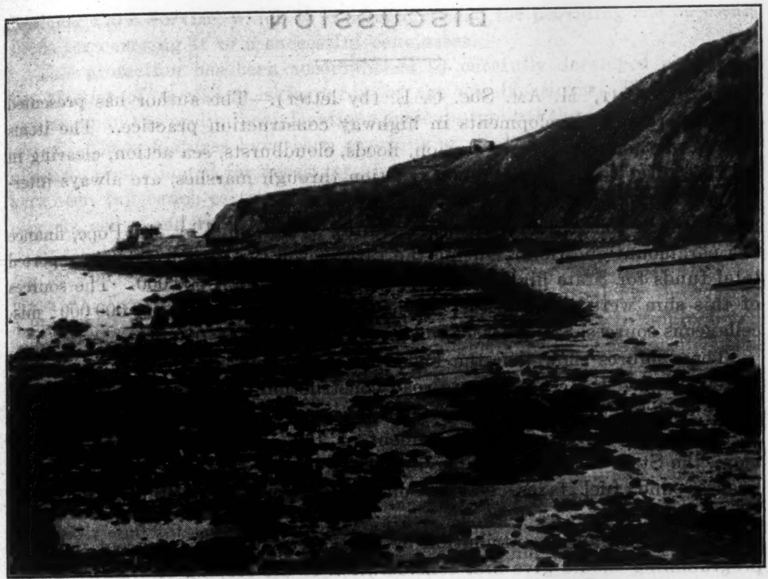

FIG. 13.—WOODEN GROYNES PLACED TO RESTORE A BEACH.

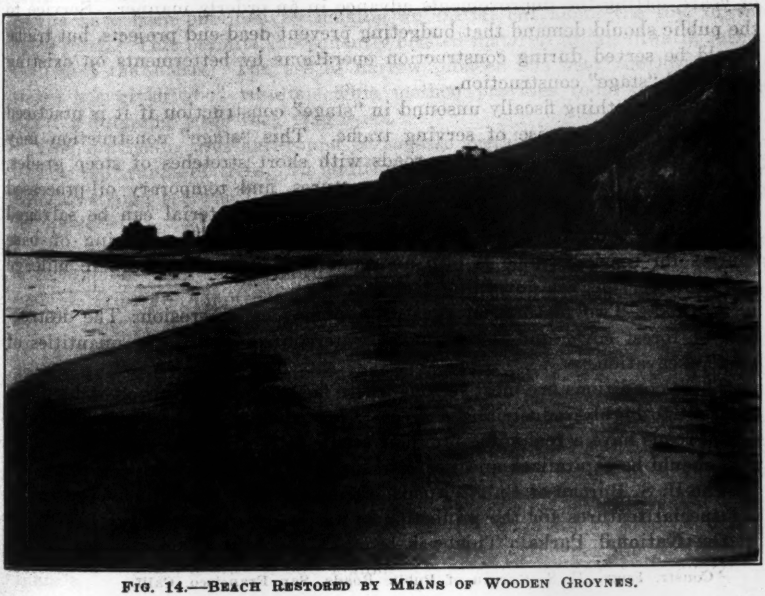

FIG. 14.—BEACH RESTORED BY MEANS OF WOODEN GROYNES.

DISCUSSION

J. S. BRIGHT,[3] M. AM. SOC. C. E. (by letter).—The author has presented some interesting developments in highway construction practice.. The items of highway finance, stream erosion, floods, cloudbursts, sea action, clearing in advance of construction, and construction through marshes, are always interesting due to their general application.

Finance.—In the eleven Western States, as indicated by Mr. Pope, finance is a paramount question. During the 1928 season the Western States reported total funds for State highway purposes aggregating $91 500 000. The sources of this sum were: Motor fuel tax, $40 000 000; plate tax, $18 000 000; miscellaneous sources, $18 500 000; and Federal aid, $15 000 000.

These figures show that the Federal Government is contributing approximately 16% of the cost of State road construction in this area; or, taking it in the reverse order, the State systems are being united into a Federal system at a cost to the National Government of 16% of the programs. Furthermore, the State road users are paying about 76% of the State's share, through licenses and fuel taxes, leaving only 24% for other State interests to contribute.

With such a large contribution by the road users, it is apparent that road programming should give first consideration to the serving of traffic. A well-planned budget is paramount for good administration. It should cover a series of years, letting the improvements advance in an orderly manner. Service to the public should demand that budgeting prevent dead-end projects, but traffic should be served during construction operations by betterments on existing roads and "stage" construction.

There is nothing fiscally unsound in "stage" construction if it is practiced with the major purpose of serving traffic. This "stage" construction may involve narrow surfaces, pioneer roads with short stretches of steep grades, concrete fords in lieu of expensive structures, and temporary oil-processed surfaces on old county roads. Such oil-processed material can be salvaged readily and transported to the final location. The oil-processing of base courses for serving traffic is also an economical expenditure where mileage and short seasons are governing factors.

Erosion.—Two features of construction may cause erosion: The destruction of forest cover and the filling of watercourses with large quantities of waste excavation.

These conditions are most serious where flashy storms occur on water-sheds adjacent to highly industrialized areas. Nevertheless, the borders of all California roads have a real value for their scenic attractiveness. This attractiveness should be capitalized and not disregarded in construction operations.

The U. S. Bureau of Public Roads, during the 1931 season, has been adopting special features for the protection of forest cover on highway operations in the National Parks. This was brought about at the insistence of the

---

[3] Constr. Engr., U. S. Bureau of Public Roads, San Francisco, Calif.

National Park Service, which is to be commended for providing the necessary funds for carrying it to a successful conclusion.

This protection has been accomplished by carefully developed plans, and the placing of necessary safeguards in the specifications. The landscape engineers, on the preliminary locations, have designated the features to be preserved. These features have been carefully studied during the location, and measures then adopted for necessary protection. The best protection measures have been full bench sections, balancing fills, tunnels, hand-laid embankment, concrete cribs, and retaining walls.

Specifications for construction in the National Parks have provided clearing by stages, leaving a screen of timber on the lower side until after the heavy shooting has been finished. Prior approval is required for the plan of drilling and loading. It is contemplated that the engineer will approve this plan on its successful demonstration over a small area. The specifications give the engineer, as a last resort, authority to limit the spacing of holes to 2-ft. centers, and a minimum charge of ½ lb. of 40% dynamite per cu. yd. of material. Mats may also be required as a last resort. Penalties consist of gathering the scattered material, the removal and trimming of injured trees, or, in extreme cases, closing down the work. Six contracts under these specifications show an increase of 57% in cost for 25% of the total excavation. The additional total cost, therefore, has been nominal.

The preventive measures adopted by contractors have been mostly in blasting. Quarrying the rock at the end faces of the cuts accomplishes the desired results, but is not adapted to an efficient program for drilling. Better results have been obtained by making an initial cut along the line of the upper ditch. This permits subsequently blasted material to fall inward, rather than over the slopes. The use of narrow pioneer fills near the lower slope stakes has given good results. This method provides room on the upper side for dumping large rock fragments.

One contractor uses half-round corrugated metal culvert sections for protecting the trunks of trees. In addition, the use of heavy woven-wire, guard fencing, strung between the first line of trees, has been proposed for checking rolling rocks.

Hand-laid embankments have proved satisfactory and have involved a cost of $1.40 to $2.00 per cu. yd. more than the cost of rock excavation. Reinforced concrete cribs are adapted to the same purpose, and have cost from $2.00 to $6.00 per sq. ft. of exposed face.

In cliffs, the tunnel is an ideal design to prevent destruction of forest cover below, and also to prevent waste material from falling. The West has become "tunnel minded"; although many projects have been designed with short tunnels, the tendency seems to be for greater lengths. No trouble has been experienced from engine gases on lengths of about 1 500 ft. The ventilation problem in the Western canyons is quite different from that encountered in river tunnels, where the dipping grades generally produce pockets. Tunneling has proved economical, the prices varying from $55 to $100 per ft. for a 23-ft. unlined roadway section, and from $80 to $130 per lin. ft. for lined tunnels.

Advance Clearing.—The author has opened the question of clearing in advance of construction. This practice accomplishes several desirable objects, among which, first and foremost, is the desirability of burning when the conditions of fire hazard are the least. It also allows the slope stakes to be placed well in advance of construction operations and provides sunlight for the early melting of snows with resulting lengthening of the construction season.

Construction Through Marshes.—The problem of construction through muskeg or marsh is a live question in Alaska, and is there solved by ditching and corduroy road building. Logs for corduroy construction should be from 4 to 8 in. in diameter, and should provide a ridged platform. A 6-in. seal of fine roadside material is placed over the corduroy before the gravel sub-base is applied. The seal excludes the air, which causes decomposition. Examined after ten years corduroy roads show no signs of decay where such a seal has been applied, but where gravel has been used directly on the logs the roadway has broken badly in a few years.

A planking to carry construction traffic, even over the completed gravel surface, has been found necessary. This affords time for the adjustment to take place uniformly, while the ditches are drawing down seepage to a constant flow. The ditches should be at least 10 ft. beyond the line of the shoulders, and of generous depth. Through some areas it has been found advisable to construct the ditches well in advance. In general, planking will permit traffic immediately upon the roadway.

Conclusions.—A financial budget for highway construction is absolutely necessary, but the questions of what methods to adopt on problems of erosion, clearing, or wet foundations, are not so well defined. These problems must be considered separately, under existing physical and financial conditions. It is certain, however, that where scientific principles are applied with patience the correct solutions will appear.

R. D. RADER,[4] M. AM. SOC. C. E. (by letter).—This excellent paper covers a number of the problems with which highway engineers are confronted, some of them being peculiar to the Western States.

The eastern half of Montana is a plateau from 3 000 to 4 000 ft. above sea level and is especially subject to so-called "cloudbursts." These occur during the hot summer months, and often cover only a few square miles, but as much as 2 in. of rainfall may occur in less than an hour. Mr. Pope states that it is the opinion of many engineers that cloudbursts occur in approximately the same areas within a reasonable range of time. Eleven years of observation of this phenomenon in Montana leads the writer to believe that there is no possibility of anticipating where cloudbursts will occur except in a general way. Of course, certain large areas are more subject to these torrential rains than others, but it is only occasionally that they are found to cover the same acreage, or that the run-off crosses the highways at exactly the same place. Some of the alluvial "fans" or "cones" spread out several miles in width and unless the highway is located along the foothills so as to bridge across the main channels where they are well defined, it is difficult to control the flow so as to confine it to bridges of reasonable length.

---

[4] State Highway Engr., Helena, Mont.

In Montana, such an elaborate system of ditches and dikes as that described by Mr. Pope has not been attempted. The first rush of water, sand, boulders, and débris will fill any ordinary intercepting ditch, and these ditches have not served the desired purpose of directing the flow under the bridges. However, such flow is usually of short duration, and passes over the highway in a broad flat sheet which does little damage, except the scouring and gullying of the shoulder on the down-stream side of the highway. The cost of repairing this damage is less than the interest charge on an adequate system of ditches and bridges. The method followed in Montana, therefore, is to build bridges over the natural channels, designed so as to carry the normal run-off from the usual rains or melting snow. No attempt is made to design and build bridges for the cloudbursts which may not occur more than once in a long period of years. Occasionally, the grade line of the highway is depressed for a few stations so as to allow exceptional floods to flow over, and, where the grade is well compacted, the loss of embankment is found to be small, even if there is no protecting wall or rip-rap.

FIG. 15.—PILE AND PLANK JETTIES ALONG THE BIG HORN RIVER, NEAR CUSTER, MONT.

For bank protection of rivers flowing through soil subject to scour, the method of driving double rows of piling parallel to the stream has been used successfully in Montana. Brush and rock are placed between the piling, and are retained by planking or wire mesh attached to it. In such cases, if possible, the piling is driven deep enough to be below the probability of scour. Pile jetties, also, are sometimes used. Fig. 15 shows a layout of pile and plank jetties installed to protect a scouring bank on the up-stream side of a bridge over the Big Horn River, near Custer, Mont. This river carries a large volume of silt in its flood stages, and it is expected that the partly planked, piling jetties will retard the current at flood stage so as to cause the deposition of this silt and thus restore the bank. If this occurs, willows will be planted between the jetties in order further to protect the newly restored bank. The rip-rap is for the purpose of protecting the jetties from scour if a tree or other large drift should lodge against them, and also to prevent damage from floating ice.

H. S. KERR,[5] M. AM. SOC. C. E. (by letter).—While reading the part of this paper relative to protection from the elements, the writer was reminded of the success achieved by the Utah Highway Department in keeping all important highways open throughout the four winters from 1927–28 to 1930–31. As a matter of fact, the snowfall was below the average during these years, but even had the average been exceeded the organization could successfully have maintained continuity of traffic on all Utah interstate highways with perhaps short minor delays due to high winds. On one of the through highways, elevations range between 6 500 and 8 000 ft. for a distance of 70 miles. The snowfall is heavy and drifting is of frequent occurrence. The design of the highway was for a grade line well above the valley level, wherever possible, giving the wind a chance to help remove the snow.

Over portions of this section, when it was not possible to raise the grade, and in the few cases where cuts were necessary, snow fencing has proved advantageous. Fencing of this kind is used in numerous other parts of the State, Fig. 16 being a view of a section of the Bingham Highway, 15 miles southwest of Salt Lake City. This is the common slat fence consisting of laths about 2 in. apart, held together with wire. The posts are old railroad boiler tubes cut to the desired length. The fence is not wired tightly to posts, thus enabling it to be raised as drifts form and to be removed in the spring.

Protection from Floods.—Fig. 17 is a view of the crossing of "West Water" Wash, in Grand County, near the Colorado-Utah State line. This wash is typical of those encountered on the desert of Eastern Utah, across which U. S. Highway No. 50 is located for a distance of 130 miles. Aside from the crossing of the Green River and a small stream—Price River—there are no rivers or creeks for this entire distance; yet there are numerous washes—dry except at times of heavy run-off from the Book Cliff Range—parallel to and north of the highway. Regularly every summer and in the early autumn there are times when some of these washes carry streams as large as from 2 000 to 3 000 sec-ft. for a short time. These are flash floods from mountain lands that are generally devoid of vegetation, continually eroding, and precipitous. Where the land is not bare, it is usually over-grazed.

The State of Utah endeavors to protect its highway bridges from these erroneously termed "cloudbursts," by creosoted piles driven on 5-ft. centers, to which are bolted 4 by 12-in. creosoted planks. Normally, the piles are 25 ft. long, driven 20 ft. into the stream bed. The cost varies from $5 to $8 per ft. of revetment.

A form of basket somewhat different from that described by Mr. Pope has also been used to good advantage. These baskets consist of cedar posts and wire mesh frames, 6 by 6 ft., filled with rock and located along the toe of the slope. Native cedar posts resist decay very well, and the rock gives

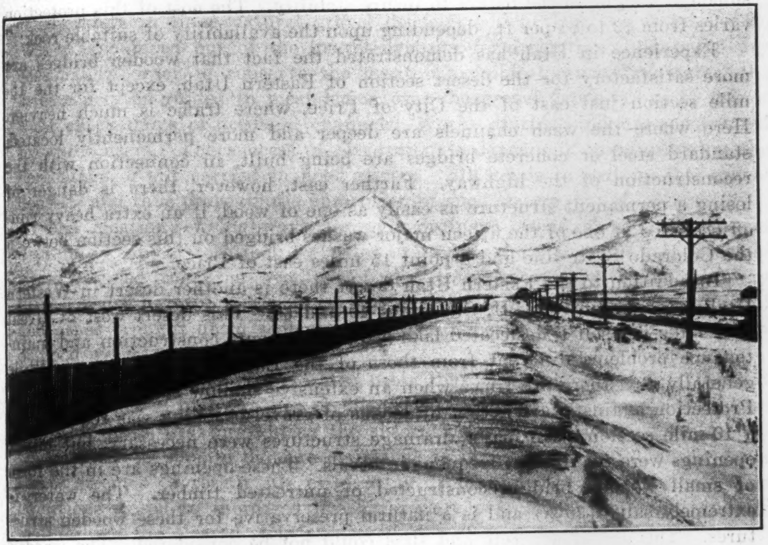

FIG. 16.—FORMATION OF DRIFTS AT SNOW FENCE ALONG BINGHAM HIGHWAY, IN UTAH.

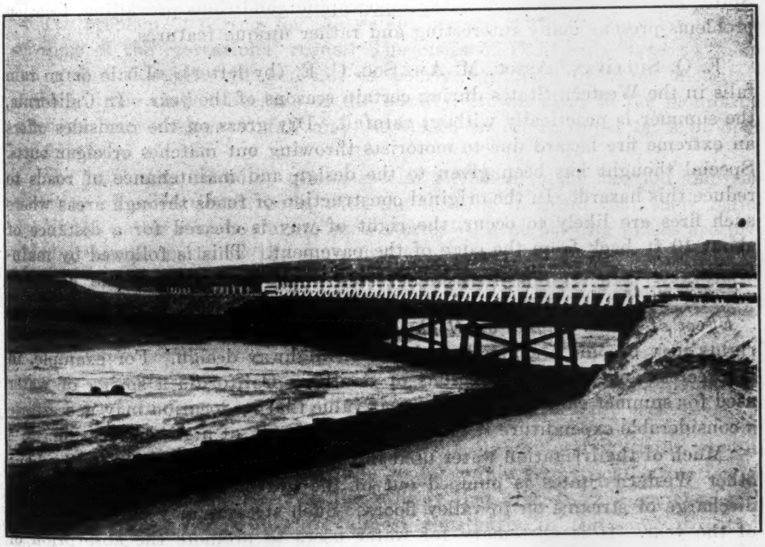

FIG. 17.—BRIDGE OVER COTTONWOOD WASH, IN UTAH.

sufficient weight to the basket to insure stability. The cost of this protection varies from $2 to $4 per ft., depending upon the availability of suitable rock.

Experience in Utah has demonstrated the fact that wooden bridges are more satisfactory for the desert section of Eastern Utah, except for the 15-mile section just east of the City of Price, where traffic is much heavier. Here where the wash channels are deeper and more permanently located, standard steel or concrete bridges are being built, in connection with the reconstruction of the highway. Farther east, however, there is danger of losing a permanent structure as easily as one of wood, if an extra heavy run-off occurred at one of the fifteen major washes bridged on this section between the Colorado State line and a point 15 miles east of Price.

In addition to the Eastern Utah desert there is another desert in Western Utah crossed jointly by U. S. Routes 40 and 50. This desert west of Great Salt Lake is itself a desiccated lake bed and presents construction and maintenance problems different from those of the Eastern Utah desert. While generally dry, there are times when an extensive shallow salt lake is formed. Protection against wave action by means of gravel beaching was required for a 10-mile section. No major drainage structures were necessary, but minor openings were required at frequent intervals. These openings are in the form of small wooden bridges constructed of untreated timber. The water is extremely salty (25%) and is a natural preservative for these wooden structures. The use of concrete and steel could not be considered. The wooden structures were built by the use of wooden pegs in lieu of spikes.

Aside from those noted herein, there are no special problems in this State; however, on account of the topographic conditions prevailing, location problems present many interesting and rather unique features.

E. Q. SULLIVAN,[6] ASSOC. M. AM. SOC. C. E. (by letter).—Little or no rain falls in the Western States during certain seasons of the year. In California, the summer is practically without rainfall. Dry grass on the roadsides offers an extreme fire hazard due to motorists throwing out matches or cigar butts. Special thought has been given to the design and maintenance of roads to reduce this hazard. In the original construction of roads through areas where such fires are likely to occur, the right of way is cleared for a distance of about 10 ft. back from the edge of the pavement. This is followed by maintenance operations, consisting of clearing away all dry grass and brush in advance of the dry season.

Effect of Water Rights on Highway Design.—In the semi-arid West water rights may become a controlling factor in highway design. For example, in the recreational mountain regions of Southern California a spring of water used for summer cabins is of such great value that its location may necessitate a considerable expenditure if it is found in the path of highway location.

Much of the irrigation water used in the valleys of California and in some other Western States is pumped out of the gravel deposits formed by the discharge of streams on to valley floors. Such streams may be dry for most of the year. It is customary for water users to promote the absorption of flood waters in these natural gravel deposits which then act as reservoirs. Water is pumped out of the gravel deposits for irrigation during the dry season. In order to conserve the greatest possible quantity of water, the stream may be guided in meandering over the gravel deposits by the use of light check dams or artificial channels. Works of this kind are constructed by water users. The success of absorption is dependent on minimizing the percentage of silt carried in flood waters. Silt tends to seal up the gravel deposits and thus prevents the absorption of such waters.

---

[6] Dist. Engr., State Div. of Highways, San Bernardino, Calif.

The location of highways through drainage areas above such gravel deposits is subject to attack by water users on several grounds. It is sometimes claimed that the opening of the drainage area with the highway increases fire hazard; in the event, the drainage area is burned over, the soil and ashes brought down seal up the gravel deposits and prevent absorption of flood waters.

Claims are also made by water users that earth and rock dust exposed to the weather in highway cuts or fills are washed down the streams to seal up gravel deposits, thus preventing the absorption of flood waters.

In order to obviate damage claims, it is necessary to build check dams across streams to retain silt originating from highway construction. The objections raised to increased fire hazard are overcome by clearing and by maintaining the cleared strip as described.

Control of Snow on Recreational Roads.—The use of recreational roads during and following heavy snowfall has become increasingly popular. This has affected design and maintenance.

The problem of caring for the public is very acute during snow storms on some of the recreational roads. The cities of California have no snowfall and the public, in general, is poorly equipped to enter mountain regions in the snow. Because of the novelty, crowds rush to the mountains whenever snow begins to fall and the roads, therefore, must be kept open continuously.

The problem is solved by giving special attention to the location and construction of recreational roads, with the thought in mind that their major use by the public may be during snow storms. Large parking places are provided at elevations below the snow line where cars can be stopped to put on chains. The highway is located so as to avoid snow slides and it is also built, as far as possible, on southern exposures. Drifting snow is taken care of by snow fences and other devices.

The more popular recreational roads are kept open during snow storms by the continuous use of snow plows, and traffic is aided and controlled to allow the maximum use of the roads by the crowds of pleasure seekers.

T. A. Corry,[7] M. Am. Soc. C. E. (by letter).—Referring to the part of this paper headed "Sand Dunes," the writer would like to call attention to similar problems encountered on the railway that crosses La Joya Desert in Southern Peru. The winds are almost constantly in the same direction and rarely exceed more than 20 miles per hour.

---

[7] Los Angeles, Calif.

The sand dunes are all shaped in the form of crescents and they move from 40 to 50 ft. annually, depending on their relative sizes. Their derivation is from the decomposition of granitic rocks.

In Southern Peru the practice is to control this movement by burying the dunes under a thin layer of gravel. Section gangs can cover a dune large enough to be included in a circumscribed square, say 100 by 100 ft., at a cost of about $7.00.

To adapt the same process to California conditions, where the winds are higher, would probably require the use of very coarse gravel.

CHARLES T. LEEDS,[8] M. AM. SOC. C. E. (by letter).—The problems of Western highway construction, particularly in the State of California, and the Southwest, are in many ways so different from those in other parts of the United States that this paper is extremely interesting. The California Division of Highways has much excellent work to its credit in the handling of difficulties such as those described.

Stream Erosion.—The problems of stream erosion, particularly those due to floods and cloudbursts, differ materially in California from those in the central and eastern sections of the country, because of the difference in climate. Many streams may be merely dry beds of sand in summer; and in winter they may become raging torrents. In desert sections of the country, as the author has stated, the water often appears without previous intimation that a cloudburst has occurred. The first knowledge that the observer has of approaching danger is the appearance of a wall of water and mud sweeping down the canyon. The writer cannot agree, however, with "the opinion of many engineers that these [cloudbursts] occur in approximately the same areas within a reasonable range of time." The writer has seen canyons from which no serious flood run-off is known to have occurred within historic times, and yet from which, within the last few years, sudden cloudbursts have brought down a literal wall of water, mud, and gravel, filling up the old channels and creating new ones, and spreading great fans of débris over the highway and the country below.

A serious difficulty of engineers in this Western country has been the paucity of records of rainfall and run-off upon which to base a reasonable estimate of probable flood flow for which provision should be made. In many cases it has been necessary to do as the railroad engineers were forced to do in early years when no records were available; namely, to make a personal inspection of the ground, determine the tributary area, guess at the probable maximum rainfall, and from that deduce a possible value for run-off. If the next flood proved the culvert or bridge inadequate, a larger one was built. This was not slipshod engineering, because no better fundamental data were available. It was the best possible under the circumstances. Now, however, the State Engineer's office maintains careful legal supervision of design and construction of all dams in California, and a painstaking study is being made of the rainfall and probable run-off in all the principal streams. Such data are of great value wherever it is necessary to erect a structure across or over any stream.

---

[8] Maj., Corps of Engrs., U. S. A. (*Retired*); Cons. Engr. (Quinton, Code and Hill-Leeds and Barnard), Los Angeles, Calif.

It is probably not out of place here to caution engineers against taking data from one stream or locality and carelessly applying them to another stream where actual run-off records are lacking. At first, the topographic conditions may seem similar in the two cases. Careful study, however, must be given to all available data on topography, wind direction, storm movement, elevation, and temperature, and their influence on precipitation.

Careful study of the geology of a section will often give valuable indication of the magnitude of past floods, and the débris of sand, cobbles, and boulders brought down thereby. The magnitude of a flood as it debouches from a canyon mouth may be very different from the magnitude of the same flood as it passes farther over the débris cone, or as it later reaches more level ground. In the first case, it is not merely a body of flowing water, but a moving mass of combined water, gravel, and sand, the larger and heavier portions of which will be deposited progressively as the flood proceeds downward, until, finally, there remains only the flowing water carrying fine sediment or silt.

Highway Location.—The problem of highway location through a desert region is not always a simple one. The closer to the mountains the location, the easier it will be to determine where the floods shall be carried across the highway, but the greater the mass of débris that will be brought thereto. On the other hand, if the highway is located farther away from the canyon mouths, the bridges or culverts may possibly be smaller, but the length of diversion dikes necessary to concentrate the broad sheets of water at control points may be greater.

An example of the difficulties experienced from wind and sand is that of the California State Highway passing through the Coachella Valley. The old county highway followed along the foot of the mountains on the southern border of the desert. This road was, of necessity, winding and crossed all the canyon mouths, but, at the same time, it was well sheltered from the severe windstorms which are not uncommon in that region. The new State Highway location, which passes down through the center of the valley, permits a much straighter road on a more even grade and requires fewer stream crossings. A saving of approximately five miles in distance and the elimination of practically all dips was effected thereby. Although the number of bridges was unchanged, the general drainage conditions were greatly improved. On the other hand, in time of severe wind and consequent sandstorms, it is sometimes necessary to divert traffic from the main highway and cause it to pass along the old county road at the foot of the mountain where it is well sheltered. This is not so much because of drifting sand as because of wind velocity and sand-blast effect on automobiles.

Earthquakes.—The writer had the good (or bad) fortune to be in Santa Barbara at the time of the earthquake mentioned by the author, and can corroborate his statements that the concrete pavement was shaken from side to side until there was a gap of from 4 to 6 in. wide along each side of the highway. It had also buckled at a number of places and had settled at the bridge abutments. This action took place where the highway had been constructed on filled soft ground. He does not recall seeing any such evidence where the highway had been constructed on solid original ground. The very fact that the highway settled away from the bridge abutments to a distance of from 4 to 8 in. would seem to demonstrate that such settlement does not occur except where there is soft material underneath, and that, therefore, the highway fills should be constructed with the greatest solidity that is economically feasible. Even then some settlement is practically certain to occur.

The size and number of expansion joints in the pavement to prevent damage by earthquake must depend very largely upon the direction in which the probable earthquake wave will be propagated. If it is propagated longitudinally with the highway, expansion joints might take up this motion. On the other hand, if the direction of vibration is at right angles to the highway, it is not seen how expansion joints would be of any advantage. This, again, would seem to be evident from the observations in the Santa Barbara earthquake. Expansion joints would not have taken care of the kind of damage cited by the author, and no serious harm was done. If this earthquake wave (which apparently may have had an amplitude of vibration of from 8 to 12 in. at right angles to the highway axis) had progressed longitudinally of the highway, it is interesting to inquire what width of expansion joints should be inserted in the pavement and at what intervals to resist such action.

The entire question is well summed up by the author in the statement that "generally speaking, however, the danger due to earthquakes is not serious so far as highways are concerned." In view of the probable long intervals between earthquakes in California, it is not believed advisable or economically justifiable, to take undue measures to protect against their occurrence on highway construction.

Foundations.—One phase of the subject upon which the author has not touched is that of foundations for highway structures crossing streams. This phase is particularly important in a country such as California, subject to heavy floods, where stream beds may be composed of sand or silt to a very considerable depth. In the case of pile bridges it is not always adequate simply to drive the piling to a depth sufficient to secure adequate carrying capacity because, in time of flood, the bed of sand in the river may become so saturated with water that the entire stream bed is moving down stream. This has been observed in floods in both the Los Angeles and San Gabriel Rivers. In the flood of 1889–90, the pile trestle bridge that carried the Southern Pacific Railroad across the San Gabriel River moved bodily down stream several feet without breaking or turning over, the entire railroad being simply carried down stream laterally that distance.

It is very common in some streams, as in the Colorado River, for the bed to scour to extreme depth in time of flood and then to refill as the flood peak passes, so that the actual depth of the stream at the time of maximum flood is far greater than any measurements after the flood may indicate. The failure of the highway toll bridge across the Colorado River, from Blythe, Calif., to Ehrenberg, Ariz., in 1928, was largely due to inadequate precaution against scour around the bridge piers, which scour occurred to much greater depth than had been anticipated.

River Crossings.—Because many streams in California, particularly in their higher sections, are to some extent "riding on a ridge," it is very necessary, in designing a river crossing, that study should be made not only of the immediate locality, but of the entire river higher up, in order that adequate measures may be taken to assure that the river shall always pass under the bridge to be erected. In 1906, two bridges were constructed across parallel channels of the San Gabriel River on its débris cone, not far from the mouth of the canyon. They had ample flood capacity, but the flood of 1914 instead of passing under them as had been anticipated, cut new channels for itself, still farther apart, tearing out the outer approaches and thus leaving the bridges "high and dry." Since then these bridges have been replaced by a modern concrete bridge and adequate precautions have been taken to protect the banks thoroughly above the bridge, and a repetition of such a disaster has been prevented.

Bank Protection.—The author has referred to the flood in the Santa Clara River, caused by the breaking of the St. Francis Dam. This was, of course, comparable to a cloudburst and of far greater dimensions. As a result, much damage was done in the Santa Clara Valley and considerable bank protection previously constructed was either damaged or destroyed. As an aftermath, the City of Los Angeles, which had constructed this dam, not only paid for all damages which had resulted, but also appointed a consulting board to work with a similar engineering board, representing Ventura County, in preparing plans for bank protection which should afford to all owners of abutting property the same measure of protection which they had prior to the flood.

In the case of pre-existing protection works, the aim was to repair them to their former efficiency where the protection was not wholly destroyed and, where it was entirely destroyed, to construct new works of similar character to those which existed before the flood, or works of an equivalent efficiency. In the case of new work the problem resolved itself into: (1) The construction of levees to keep the river within reasonable limits of width, the levees to be protected by a system of spurs of different types of construction, depending on the conditions encountered; and (2) where no levees were required, the construction of spurs to protect the existing banks. Wherever levees were constructed, it was required that, in order to prevent the formation of a channel along the toe of the levee, the borrow-pit should not be continuous along the levee. A bar was left between the protecting spurs not less than 20 ft. wide. Where no spurs were required, the bar was to be left at intervals no greater than 200 ft. apart.

Three types of protection for levees or banks were proposed, designated as Types *A*, *B*, and *C*.

Type *A* (see Fig. 18) composed of creosoted timber piles, was used as a replacement for similar protection which had been destroyed. It consisted of timber piles driven in two rows 8 ft. apart, 10 ft., center to center, in rows, and braced between with a 6 by 6-in. by 7 ft. 6-in. timber near the top.

These piles were not less than 12 in. in diameter at the butt, 6 in. in diameter at the tip, 30 ft. long, and were driven to a penetration of not less than 16 ft. and where possible to such penetration that their tops extended 9 ft. above scour grade of the river. This dimension was governed, of course, by the cross-section of the river. The piles were of Douglas fir and creosoted by the 8-lb. empty-cell process. Three 1-in, wire ropes were used in each row to tie the piles together. These ropes were stretched taut against the piles and tied thereto with an independent short piece of wire rope. Each row of piles was also faced on the river side with an 8-ft. width of 6-in. square, electrically-welded, galvanized wire mesh of No. 6 wire, fastened to the piles by heavy staples at each horizontal wire. To hold the piles from spreading at the top, a loop of ⅝-in. wire rope was taken around opposite piles and twisted together tightly.

FIG. 19.—BANK PROTECTION TYPE *B*.

on the Santa Clara River in the form of spurs to protect a levee or bank. They were constructed in unit lengths of 100 ft. and extended out from the levee or bank at an angle of 60° down stream. Except as otherwise specified, the spaces between the spurs were invariably 200 ft. This type of protection is shown in Fig. 19. Each unit consists of five tetrahedrons set 20 ft. apart, center to center, tied together with five $\frac{3}{4}$-in. to 1-in. wire ropes and anchored to "dead men" at both ends. Each tetrahedron is made up of six 60-lb. rails from 15 ft. to 16.5 ft. long, connected together at the ends to form a four-sided figure each side of which is an equilateral triangle. The center of each leg of the triangle which rests on the ground, is braced with a piece of rail approximately 12 ft. long to the center of the opposite sloping leg. Second-hand rails were used for this work and were found amply satisfactory. The wire ropes were also second-hand and were securely tied to the rails at proper intervals with $\frac{3}{4}$-in. **U**-bolts.

It is believed that this tying together of the tetrahedrons with four cables, 1 ft. apart, on the face and another at the back, is a distinct improvement over the protection as used on the Colorado River. Each spur unit was anchored at each end. The anchor at the levee end of the spur consisted of a sound log or two logs of a combined minimum cross-section of 1.5 sq. ft. and not less than 12 ft. long, buried 6 ft. in the ground. The ends of the wire rope tying the tetrahedrons together were looped around the anchor and fastened back on the rope with bull-dog wire-rope clips, two to each rope. The anchor at the river end of the spur consisted of a rubble concrete block, 5 cu. yd. in volume. The block was set 12 ft. in the ground and properly anchored in it was a 12-ft. length of 60-lb. rail, to the upper end of which the wire rope tying the tetrahedrons together was fastened.

This type of protection was used in lieu of Types *A* and *C* where the required pile penetration could not be secured.

Type *C*, a system of iron-pipe piling, was used in a manner similar to Type *B* to protect levees and banks and, as in Type *B*, was used in the form of spurs, with one exception. This exception, for protection work opposite the City of Santa Paula, was a location where the river bank and levee on the edge thereof, were protected for a distance of 3 000 ft. by a continuous row of Type *B* construction in addition to spurs.

As in Type *B*, the spurs were each 100 ft. long and extended from the protected levee or bank at an angle of 60° down stream and were spaced 200 ft. apart (see Fig. 20). Each spur is 100 ft. long and consists of a double row of pipe piling, driven 10 ft. on centers in rows 8 ft. apart. The piles used in the lower half or river end of the spur are 6 in. in diameter, while those for the upper half, or levee end, are 4 in. in diameter.

The 6-in. pipe piling, constituting the river end of the spur, was driven to a minimum penetration of 16 ft., or to a penetration of 18 ft. if refusal was not reached before that depth. The tops of the piles were on a straight line sloping downward toward the river on a 2% grade. The 4-in. pipe piling, constituting the levee end of the spur, was driven to a minimum penetration of 14 ft. For economy, second-hand pipe was used throughout the job, subject to inspection and approval.

Between rows the piles were braced by welding a piece of pipe between opposite piles, 2 ft. from the top. The two piles on each end of the spur were also braced longitudinally to the second pile from the end by welding pipe horizontally between them, 2 ft. from the top.

FIG. 20.—BANK PROTECTION, TYPE *C*.

For greater rigidity the last four piles on the end were tied together diagonally by $\frac{5}{8}$-in. wire rope twisted tightly between the second pile from the end, 2 ft. from the top, and the end piles, 8 ft. from the top. The rows of piling on the up-stream side of the spur were tied together longitudinally with two second-hand wire ropes of $\frac{3}{4}$ in. to 1 in. in diameter, well tied to the piles with No. 6, annealed, galvanized wire.

Each row of piling on the up-stream side was faced with an 8-ft. width of 6-in. square, electrically welded, wire mesh of No. 6 galvanized wire, stretched taut and securely tied to the piles with a double loop of No. 6 annealed galvanized wire at all horizontal wires. The top of the wire mesh was flush with the tops of the piles. The wire mesh on the up-stream row of piles was extended around the river end of the spur, and securely tied to the first pile of the back row. The wire mesh was also tied with No. 6 galvanized wire, at 12-in. intervals, to the wire ropes on the up-stream row of piling.

For greater rigidity the piling was braced diagonally between rows with a double line of $\frac{5}{8}$-in. wire rope, twisted tight, extending from the point of the brace weld 2 ft. from the tops of the piles to a point 8 ft. from the tops of the opposite piles.

Where it was found impracticable to secure the prescribed pile penetration, namely, 16 ft. for 6-in. piles and 14 ft. for 4-in. piles, Type *B* spurs were used instead of Type *C*. This was found necessary in some cases because of underlying layers of heavy cobbles or boulders.

In this work, brush and rock-fill spur-dikes were considered, but were not adopted for the reason that in this climate all brush becomes thoroughly dried in the summer season and hence it constitutes a fire menace and also loses its effectiveness. This is not true in a region where it can be kept wet almost constantly. The same argument holds true for any willow mattress work in bank protection, which, while extremely effective on rivers such as the Mississippi and its tributaries, is entirely unsuitable on streams, such as those of Southern California or Arizona, which are almost if not entirely dry during a large part of the year.

The reinforced concrete tetrahedrons, shown in the author's Fig. 6, which had been previously installed on the Santa Clara River, have been entirely effective, as he has stated. This type, however, is more expensive than the rail tetrahedron type, and no more efficient.

It should be noted that in all these types of spur-dike protection, an essential feature of merit is provided by cables and wire netting which are stretched along the up-stream side. The function of a spur-dike, when used for bank protection, is to deflect currents and also to retard the velocity of the water and thereby produce a deposition of silt behind the spur. It is, therefore, highly essential that these spurs should be constructed so as to catch drift and thereby increase the resistance to flow of the river. Where the river does not carry any appreciable drift, therefore, such spurs will not be as effective as where considerable floating brush and leaves will lodge against the spurs and thereby increase their effectiveness. It is also highly essential as the author intimates under "Jetties," that the spur be constructed so as to prevent possibility of scouring under the fencing. Such action, if it occurs, may be more injurious than if no spurs had been constructed, for the undercut spur concentrates the scour.

Protection by Sea-Walls.—The writer had occasion to observe the protection work of reinforced concrete cells, so well described by the author, while they were under construction by the California Highway Division, and he desires to register his commendation of this excellent device in a difficult situation.

The sea-walls constructed by the State of California of monolithic concrete appear to be of sufficient strength to withstand the action of the heaviest storm waves thus far encountered. The writer believes, however, that the profile adopted has had a tendency, in some instances, to erode the beach, and that with a different design a considerably greater effective beach width could have been secured.

It is true, as the author states, that the use of sheet-piling, of either wood, steel, or concrete, on State work in California has never met with much success, and that it has not been used extensively in sea protection. Except in rare cases, it should not be so used. When a vertical wall is built to offer resistance to the onrush of the waves, the inevitable result is a downward deflection of part of the wave and a throwing into the air of a mass of water which, dropping again with great force, scours out the sand at the toe of the wall. The profile of the wall should be so designed, with slope and curve, as to deliver the return wash of the wave parallel to the beach slope, or still better, to provide a means of breaking up the force of the wave, as with riprap, or with a step-faced sea-wall of adequate design.

Shore Protection by Groynes.—Groynes for the protection or improvement of the beach line are extremely effective where properly used. Groynes of steel sheet-piling or of interlocking concrete blocks have usually been more effective than those of wood, however. Wood groynes, too, are subject to damage by storms. It is often difficult to secure sufficient penetration for the vertical wood piling to prevent their being worked loose in severe storms. Horizontal planking is often torn loose and is quite likely to have the beach eroded below the level of the lowest plank under severe storm conditions. If any opening occurs below the bottom plank, the force of the water flowing under it produces a severe jet action which scours out the beach to a much greater depth than if the groyne had not been in existence. With steel sheet-piling or concrete blocks that can settle into place, there is no danger of this.

In the location of groynes the simplest rule (and the one most generally followed) is to construct them at right angles to the shore line. This, however, is not the scientific procedure, and the groynes will be found to function more effectively if their orientation is carefully determined from a study of the prevalent direction of wave action on the shore. The height, length, and profile of the groyne are also important elements which can only be determined from a careful study of local conditions.

At the present time (1932) the California Division of Highways, and the California Division of State Lands are co-operating in planning a system of steel sheet-pile groyne protection for a section of the State Highway where there has been severe erosion. In this study, the inter-related effects of adjacent parts of the shore line and previous construction thereon have been carefully considered, and the future results will be noted.

This entire problem of shore protection and beach improvement is an intricate one in which no isolated problem can be adequately solved without consideration of adjoining section of the coast. It is probable that in the past adequate attention and study have not been given to this problem in many sections of the country. Much can be done, however, by thoroughly co-ordinating all efforts of State, municipal, and private agencies. This is particularly important in connection with highway construction, as a large measure of the usefulness of the highways is as a means of access to and along the beach and ocean by people of the hinterland.

G. S. Paxson,[9] Assoc. M. Am. Soc. C. E. (by letter).—Except the works designed to withstand earthquake shocks, the problems discussed by Mr. Pope are common to all the Western States. Several interesting and successful structures, designed to protect highways from stream erosion and from the encroachment of sand dunes, have been built in Oregon in recent years.

The State has several rivers of medium size (approximately 10 000 sec-ft. maximum discharge) that flow through flat alluvial plains. The banks of these rivers are composed of sand and gravel and are eroded easily. The rivers are fed by smaller streams flowing on steep gradients and carrying large quantities of sediment. On joining the main river the rate of flow becomes less and the stream contains more sediment than can be carried at the lower velocity. Under these conditions bars are formed that often change the direction of the current causing serious erosion along the banks. To control the current before it reaches the stream bank is usually more economical than to reinforce the banks themselves. A cheap and efficient current-directing structure is shown in Fig. 21. It is built of rock enclosed in wire mesh, and is most easily constructed during the low-water period when the site is dry. A width of wire mesh is laid in position on the stream bed and rock is piled on it to form a dike the section of which is an equilateral triangle. Other sections of mesh are laced to the edges of the bottom section, folded over the sides of the dike, and laced together at the top. The dike is thus completely enclosed by mesh and will not break up even if it is undermined. Dikes of this type have rolled completely over without damage. The crest is built to about the ordinary winter water elevation. During flood periods the current is checked enough to cause sediment to become deposited behind the dike. In a few years an elevated plain is built up, that acts as a buffer between the stream and the threatened bank. This type of current retarder built 5 ft. high, costs about $4 per lin. ft.

This treatment has not been applied to streams that have a rise of more than 8 or 10 ft. during flood periods. For such streams the usual treatment has been a bank protection consisting of piling, brush fascines, and rock. Fig. 22 shows a revetment on the bank of the Willamette River near Harrisburg, Ore. The piles in the front row are spaced at 4 ft. 0-in. centers. The back row is 8 ft. 0 in. from the front row, and the piles are at 8 ft. 0-in. centers. The space between the rows of piles is filled with willows tied in bundles 8 ft. long and 2 ft. in diameter. These fascines are weighted with large blocks of stone. Where the revetment is in contact with the bank many of the willows take root and grow. In a short time a compact and resistant barrier is formed.

In many places, highways have been built through or beside sand dunes that shift on to the roadway during storms. The removal of this sand is a continuous and costly maintenance operation and many attempts have been made to control it. The most successful has been the planting of grass or shrubs. For example, "Holland grass," which grows wild along the Oregon Coast, is planted in bunches of three or four stalks at 2-ft. centers. It has an extensive root system which holds the sand in place and the tops act as

a wind-break. This grass is quite hardy and survives the dry summer months with little damage. Successful plantings have also been made with maritime pine, an importation from France, and with native shrubs, such as rhododendron, huckleberry, and salal.

C. S. Pope,[10] M. Am. Soc. C. E. (by letter).—It has been a source of gratification to the writer that a paper on a practical subject of this kind should evoke such interesting discussion and cause such a concentration of experience records. A study of the comments of the various discussers will yield much of benefit to those in search of solutions of similar problems.

Mr. Bright calls attention to the wise policy of the U. S. Bureau of Public Roads in requiring that expenditures shall not be made on dead-end projects, but only on highways that are at least a part of a through traffic road.

In the West, the measures taken for the protection of the forests and the maintenance of scenic beauties are most timely and are receiving the co-operation of the various State departments.

will be studied with great interest as to the manner in which traffic is handled through it.

In Mr. Rader's opinion there seems little probability that the location of cloudbursts can be anticipated with any degree of certainty, and the writer is inclined to agree with this view, but he makes the mental reservation that studies should be inaugurated to determine, if possible, any laws that may govern the location of cloudbursts. For some years, in California at least, it was held that sand dunes could not be controlled, and that their formation and actions were erratic and could not be predicted. However, a study of the dunes in the Imperial Valley indicated that they conform to very definite laws within certain limits and that it was entirely possible to eliminate some of their disadvantages.

As to drainage structures of the extent used in some of the desert work, Mr. Rader very properly points out that there is some question as to whether such expensive drainage systems are justified by the traffic. An analysis of construction that cost about $3 000 000, in the desert section of California, indicates that nearly $1 000 000 was used in the construction of drainage channels and trestles, which, in view of a traffic running from, say, 200 to 1 200 vehicles for the different routes, might give some room for argument. The drainage structures undoubtedly permit of uninterrupted traffic over these highways, whereas the construction of dips, which is the other alternative, introduces, at times, the problem of rather severe maintenance and also a less safe road. The record of five or six years in one district shows twenty-eight deaths to have occurred due to traffic accidents in dips, so that, from this point of view, there is much to be said for the more expensive construction.

Colonel Leeds points out the problem brought about by moving bridge foundations in alluvial soils, such as are found in Imperial Valley, due to the movement of the entire mass of the stream bed down stream. An attempted cure for this condition was the construction of a submerged dam down stream from one of the bridges, but the method proved unsatisfactory, and it has since been the custom to drive pile trestles and replace them when serious movement occurs.

Colonel Leeds comments on the sea-wall section used by the Division of Highways on some of the work in California. The original section (Fig. 23, Section *A*), used on a wall of considerable length south of Santa Barbara, showed a throw-back section that gave no interruption to the flow of waves, and, in cases of high winds, the sheet of water was thrown over on the highway. This wall was of massive section, about $\frac{3}{4}$ mile in length, and was founded on hard shale. An unfortunate feature of design was the lack of sufficient expansion provision in the coping section of the wall which formed the throw-back, and, as a consequence, a considerable part of this coping has been shattered through pressure due to moisture and temperature (see Fig. 24). The main body of the wall, however, has shown only slight deterioration, due to the action of the sea water.

Along the rocky coast south of Section *A*, Fig. 23, a type of wall founded on heavy riprap already in place and having a vertical face (Section *B*), and a throw-back section projecting at an angle, was constructed over a considerable length of shore, but, later, the front face (Section *C*), was given a batter to break up the direct impact and scouring action of the waves. In one section, also (Section *D*), an effort was made to induce turbulence at the moment the wave struck the throw-back section so that each succeeding wave would be met by a wall of falling water which would tend to break its force. These latter walls have been quite successful in protecting the highway and in preventing spray sheets from being blown over it.

Groynes of steel sheet-piling (Fig. 25) were constructed to a considerable extent during 1931-32, in order to build up shore protection north of Santa Monica, and the technique of building these groynes has shown some advance over past practice. Each groyne was constructed at a pre-determined angle to the shore line, in order to secure the most rapid and stable accumulation of sand, and the grade line was also fixed in such a way as to increase and maintain the deposit. In some cases, certain sections of sheet-piling were made shorter than the adjoining sections (see Fig. 25), leaving openings through the sheet-piling wall through which the water could pour, and this greatly facilitated the depositing of sand in front of the piling. The durability of this type of piling has been questioned, but it has been stated that experience in Germany indicates that a satisfactory economic life may be expected.

Mr. Paxson calls attention to the use of gravel sausages in Oregon, and also to the use of Holland grass for stabilizing sand dunes. Both these methods are valuable in the proper locations. A variation of the gravel sausage enclosed in wire mesh has been developed by F. A. Kittredge, M. Am. Soc. C. E., Chief Engineer of the National Park Service. The method requires the construction of a smaller sausage of gravel enclosed in wire mesh, which is laid beside the larger protective sausage that is subject to scour. In case of a washout, the smaller sausage sags into the depression and supports the larger structure.

LOW-COST BITUMINOUS ROADS [1]

BY WALTER N. FRICKSTAD,[2] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. H. J. SPELMAN, J. T. L. MCNEW, ROGER M. LEE, E. Q. SULLIVAN, HUGH W. SKIDMORE, A. H. HINKLE, CLAUDE P. OWENS, CARLTON N. CONNER, HAROLD L. TILTON, AND L. I. HEWES

SYNOPSIS

In the development of modern highway systems there is a serious need for a low-cost secondary road that will accommodate a limited heavy traffic and an unlimited light traffic. In the western part of the United States a light type of asphaltic binder known as fuel oil has been successfully used to treat crushed aggregate. Whether mixed at a central pug-mill plant, or on the road itself, the costs are about the same, and the result has proved economical in first cost and maintenance charges.

After summarizing the status of this field up to October, 1928, the writer discusses the advances from that time to date (1931), describing construction methods, specifications for materials, and necessary equipment.

INTRODUCTION

Two types of highway work, involving treatment of fine crushed aggregate with a light grade of asphaltic binder known as fuel oil, may be classified as surface treatment and oil-mixing treatment, respectively. In an unpublished paper,[3] entitled "Bituminous Treatment of Fine Crushed Rock and Gravel Roads," Thomas E. Stanton, Jr., M. Am. Soc. C. E., has described these treatments and the extent of their application in the Western United States up to October, 1928. Mr. Stanton's paper is summarized briefly herein.

Surface Treatment.—This is sometimes called penetrative treatment because the binder is absorbed into the upper strata of aggregate. The first step in construction is to prepare the base and this implies repairs, thorough compaction, and thorough cleaning. Approximately, $\frac{1}{4}$ or $\frac{3}{10}$ gal. of asphaltic fuel oil per sq. yd. is spread on this prepared base. The oil should contain 60 to 70% of 80-penetration asphalt having a specific viscosity (Engler) at 50° cent. of 10 to 25. The oil is allowed to penetrate the upper strata of the metal; sometimes stone chips are spread to protect traffic. After a suitable interval another application of asphaltic oil is spread. This may be of the same nature as the primer, or it may be of slightly higher viscosity; it may be much heavier, approaching pure asphalt.

[2] City Engr., Oakland, Calif.

[3] Presented at the meeting of the Highway Division, San Diego, Calif., October 4, 1928.

The next step is to spread stone chips in sufficient quantity to absorb the oil and then the road is rolled. Details vary considerably, particularly in the quantity of oil and stone chips added, which is greater for the heavier oil. Sometimes the second application of oil is kept to a minimum, usually $\frac{1}{6}$ to $\frac{1}{4}$ gal. per sq. yd.; the stone chips are relatively large, as, for example, $\frac{5}{8}$ to $\frac{7}{8}$ in., and a third spread of oil of approximately the same quantity is applied, and followed by still finer stone chips. Heavy oil, applied hot or emulsified, is considered more durable than fuel oil, particularly against weather damage.

Oil-Mixing Treatment.—In this process the asphalt oil binder is thoroughly mixed with the upper 2, 3, or even 4 in. of surfacing material. The first construction operation is to provide the desired quantity of loose mineral aggregate on top of a firmly compacted base. All the aggregate should pass a 1-in. screen and one-third to one-half of it should pass a 10-mesh sieve. It may be obtained by scarifying if a sufficient supply is already on the road, or it may be added for treatment. The oil is usually spread in three applications, aggregating 1.25 to 2 gal., or more, per sq. yd. After each application the materials are mixed by means of a disk or spring-tooth harrow, or by both. After all the oil is applied, the mixing operation is completed by casting the material into a windrow with a blade grader and moving the windrow back and forth over the road, turning the mass at each move. The oil commonly used contains from 60 to 70% of 80-penetration asphalt. The viscosity is variously specified, generally 25 to 45 (Engler specific) at 50° cent., or 45 to 80.

The quantity of oil varies according to the grading and other characteristics of the aggregate. As in the case of asphaltic concrete the higher proportion of oil is required for the finer material. C. L. McKesson, M. Am. Soc. C. E. has suggested[4] the following equation for estimating the quantity of oil required:

$$P = 0.015a + 0.03b + 0.17c \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (1)$$

in which, P = percentage of oil required; a = percentage of aggregate retained on the 10-mesh sieve; b = percentage passing the 10-mesh and retained on the 200-mesh sieve; and c = percentage passing the 200-mesh sieve. The quantity of oil is sometimes estimated by Equation (1) and sometimes by appearances, but quite commonly by a modification of the stain test so long used in sheet-asphalt practice. After the mixing operation is completed the material is carefully spread with a blade grader to uniform thickness, and is compacted by traffic. During the compacting period, ruts and other irregularities are eliminated by a drag or blade grader until traffic makes no impression and until the road is as smooth as the most carefully constructed of the higher types of pavement.

---

[4] "Light Asphaltic Oil Road Surfaces," by C. L. McKesson and W. N. Frickstad, *Public Roads*, September, 1927, p. 150.

In addition to the foregoing, a method of plant-mixing, first introduced in California in 1928, should be mentioned, in which the aggregate and the oil are mixed at the source in the ordinary type of pug-mill. The aggregate is not heated, but the oil is warmed enough to facilitate pumping. When the mixed material is placed on the road it is spread by a blade grader and compacted in the same manner as the road mixture. It has been found that the cost of pre-mixing when the surfacing material must be brought to the road is little, if any, greater than road mixing under the same conditions. To those acquainted with the price of asphaltic concrete the low cost of fuel-oil mixture may seem surprising, but the explanation lies in the elimination of heating operations at the plant and the simplicity of handling cold material on the road.

At the end of the 1928 working season approximately 3 600 miles of State highways in Washington, Oregon, California, Nevada, Arizona, New Mexico, Colorado, Utah, Idaho, Montana, and Wyoming had been oil-treated. Of this mileage, 2 330 was surface treated, 1 170 was mixed, and 100 was of miscellaneous types. Some of that classified as miscellaneous was in the nature of penetration macadam. During 1929, 730 miles were surface treated, 1 640 miles were mixed, and 130 miles had miscellaneous treatments. Hence, about 2 500 miles were treated in 1929, making the grand total up to that time, 6 100 miles. Statistics for 1930 and 1931 are not available, but at least 3 000 miles were added each year, giving a total at the end of this (1931) season of more than 12 000 miles. The foregoing figures do not include county roads and small town streets, which aggregate a considerable but unknown mileage.

DEVELOPMENT IN SURFACE TREATMENT

The trend of surface treatment practice is now (1931) very definitely toward the use of heavy oils, with an asphalt content of 90%, or more. Fuel oil is used principally as a primer or as a dust palliative. A few of the less traveled roads are being surface treated with fuel oil alone, but generally this application is followed with heavy oil and coarse stone chips. Thus, there is a reversion to the methods by which macadam roads have been treated successfully since about 1910. Although the process has been satisfactory on macadam, it has not heretofore been commonly successful on gravel or fine-crushed rock. The introduction of a primer seems to have overcome the difficulty.

Some authorities have a strong preference for tar rather than oil, reporting better penetration into the road and more careful curing with less annoyance to traffic. The Highway Department of Oregon has used a light tar for this purpose and reports marked success.

Details of the surface-treatment process are far from being standardized. One of the California State Highway methods is among the most elaborate and may be outlined, as follows:

(1) Clean, repair, and compact the base thoroughly;
(2) Spread ⅓ gal. per sq. yd. of 50 to 60 asphaltic fuel oil (Specific viscosity (Engler), 10 to 25 at 50° cent.);
(3) Allow the first application to penetrate and add a small quantity of fine stone chips if necessary to protect the traffic and to absorb oil that may settle in depressions;
(4) Spread ¼ gal. per sq. yd. of 94 + asphaltic oil at a temperature of approximately 350° Fahr.;
(5) Spread sufficient ½ to ¾-in. stone chips to cover the oil. (120 tons per mile of 18-ft. road is the estimated quantity, but this includes considerable waste due to the effort to save labor);
(6) Roll;
(7) Spread ¼ gal. of 94 + asphaltic oil as before;
(8) Cover with ⅛ to ½-in. stone chips. (80 tons per mile is estimated, which includes waste as before); and,
(9) Roll.

The Oregon Highway Department has a similar specification, using slightly smaller quantities of oil. This Department also has a modified method, omitting the third application of oil, but spreading the two sizes of stone chips separately. The Oregon estimate for stone chips is about two-thirds that of California.

The surface-treatment process has made some headway in Washington and in Idaho, in addition to California and Oregon, but the other Western States have not generally adopted this type. The State of Washington, like California, has treated many roads as a temporary expedient, realizing that elimination of dust and conservation of road metal will compensate for a considerable proportion of inevitable failure.

PLANT MIXING

Plant-mixed oil and aggregate presents one of the most interesting possibilities among the developments concerning the oil mixtures. It has spread in an experimental way to several other States, and California is firmly committed to this type of treatment for new construction. When the surfacing material had to be brought to the road, the cost of the earliest project was little, if any, more than road mixing. Plant mixing, of course, permits more complete control than road mixing. Some find that the plant mixture lacks the ideal riding qualities of the road mixture, but if this is true the fault can be corrected by a moderate amount of manipulation while spreading.

To be economical, the mixing must be performed without any extra handling of the material except its passage through the mixing box. Elimination of the need for heating the aggregate and the consequent opportunity for spreading and compacting, without consideration of loss of heat, keeps the mixing cost surprisingly low. It is reported, however, that the power required to operate the mixer is about one-half more than that required for the same quantity of heated aggregate and asphalt.

EQUIPMENT FOR FIELD MIXING

The machinery used for road mixing continues to vary in type. Most of the States are equipped with tractors and blades for snow-fighting and ordinary maintenance, and have simply transferred this equipment to oiling operations during the appropriate season. Use for these other purposes has influenced the purchase of equipment for oil mixing. One State, however, has equipped itself primarily for oil mixing, and has adopted the tractor or dual-drive type of self-propelled blade. A group of four of these motor graders is extremely efficient. The best work is done with blades 10 or 12 ft. long.

Regardless of the type of machinery, workmanship has steadily improved. The first thought was to regard mixing as a rather haphazard process, and too often it was so in fact. Since the beginning of 1929 neatness and system have been notable. Partly oiled material is picked cleanly from the base and turned over and over in accurately lined windrows; during the final turnings, a small quantity is allowed to remain on the base, and the final mixing takes place without the incorporation of uncoated particles. It is then spread quite accurately to uniform thickness (see Fig. 1). Even where the grading of the aggregate varies from station to station, with a consequent necessity of adjusting the quantity of aggregate drawn into the mixture, the windrows become remarkably uniform in color before spreading when properly manipulated. Observing the work of a skillful crew, road mixing can no longer be regarded as haphazard. One step in this process is shown in Fig. 2, which illustrates work on a Nevada project.

Grading of Aggregate

The grading of aggregate has not tended to become standardized, which confirms the opinion that a wide range is acceptable for oil mixing. First experiments indicated that the mixture should conform to that of asphalt concrete. Since the maximum size was fixed at ¾ in., or 1 in., it followed that the proportion of material passing a 10-mesh sieve would approximate 40 to 50%, of which perhaps one-fifth would pass the 200-mesh sieve. However, successful oil-mix projects have been constructed with as much as 80%, or even more, passing the 10-mesh sieve. In fact, there is record of many miles of natural soil mixtures of which practically all the material passed the 10-mesh sieve, and a few in which the greater part passed the 80-mesh sieve. On the other hand, successful oil-mixed projects have been constructed with only 25% passing the 10-mesh sieve. There is good reason, therefore, to believe that gradings which correspond not only to asphaltic concrete, but to Topeka mixture and sheet asphalt, may be successfully mixed with fuel oil.

The proportion passing the 200-mesh sieve is an important element. This has been as low as 3 or 4%, and higher than 20 per cent. Apparently, the 200-mesh material should fill the spaces between the larger particles sufficiently to reduce the size of voids to the minimum and increase their number to the maximum. Studies of the fundamental physical characteristics of asphaltic concrete and sheet-asphalt mixtures have been made and the results have also "shed light" on the subject of oil mixtures.

In particular, it is hoped that further research pertaining to the characteristics of fillers may disclose the quantity and quality of the 200-mesh material desirable for oil as well as asphalt mixtures.

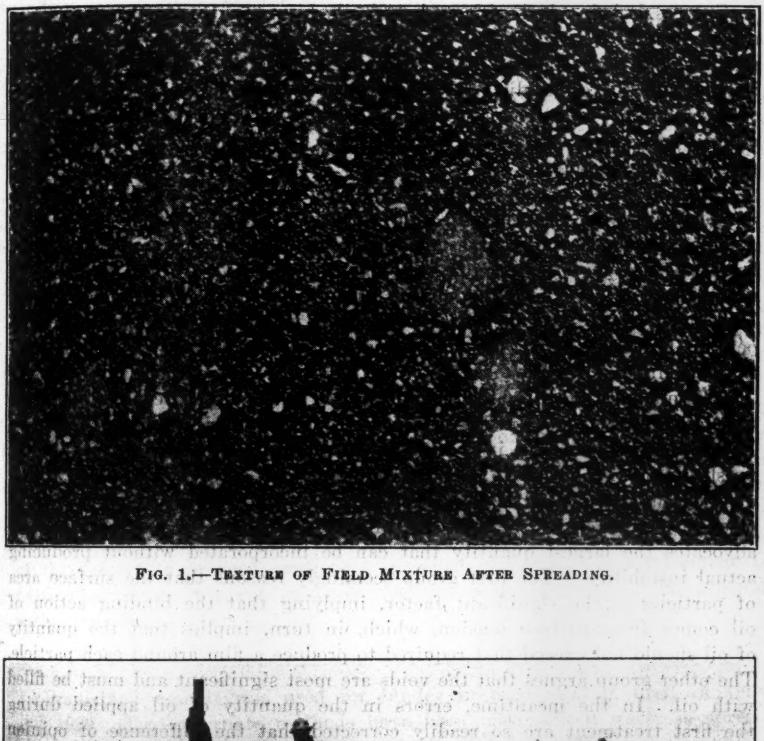

FIG. 1.—TEXTURE OF FIELD MIXTURE AFTER SPREADING.

FIG. 2.—FIELD MIXING, MOVING MATERIAL FROM ONE WINDROW TO ANOTHER.

Quality and Proportion of Oil

Success is being had with asphaltic oils from the Rocky Mountain area, although their characteristics are somewhat different from the California product. So many factors affect the success or failure of mixtures that the influence of the oil is difficult to segregate. Plant mixtures offer a better opportunity to study the effect of oil than road mixtures. Undoubtedly, oils differ in their suitability, and a strong effort should be undertaken to ascertain the reason.

After the first season of oil mixing the medium grade of fuel oil with an Engler specific viscosity of 25 to 45 at 50° Fahr., carrying 60 to 70% of 80-penetration asphalt, was generally recommended. Subsequently, there has been a marked tendency to raise the viscosity to 55 to 85, which is the grade generally used for plant mixing, and the asphalt content to 65 per cent. The higher viscosity generally carries with it higher specific gravity, and perhaps higher ductility, but adds somewhat to the difficulty of mixing, particularly in cool weather.

The quantity of oil which should be used is much debated for the reason that aggregates vary widely in grading and in their absorptive qualities. For estimating purposes it is common to allow ½ gal. per sq. yd. per in. of finished thickness, with 15 to 30% allowance for extra requirements. The quantity used generally falls within the range of the estimate. One group of engineers advocates the least quantity that will coat the particles; another advocates the largest quantity that can be incorporated without producing actual instability. The first group seemingly reasons that the surface area of particles is the significant factor, implying that the binding action of oil comes from surface tension, which, in turn, implies that the quantity of oil should not exceed that required to produce a film around each particle. The other group argues that the voids are most significant and must be filled with oil. In the meantime, errors in the quantity of oil applied during the first treatment are so readily corrected that the difference of opinion is not serious. However, it is obvious that the less oil used, the cheaper will be the construction cost, a statement which applies with particular force to projects distant from the source of oil supply.

Width, Thickness, and Cost

The tendency to use a minimum width of 20 ft. became marked during 1929. Likewise, a compacted thickness of 3 in. is becoming established. Few projects are being constructed less than 2½ in. thick. There is some tendency to use a greater thickness than 3 in., especially on plant-mixed projects.

Cost of treatment exclusive of road metal continues to range rather widely from about $1 200 to as much as $2 000 per mile. The foregoing applies to averages. Individual projects within a State will vary even more widely, depending upon local conditions. The cost of oil is the largest variant. The cost of actual mixing, omitting the cost of oil and the application thereof, shows quite remarkable uniformity at $500, or less, per mile of 18-ft. road.

FAILURES

It is safe to state that the principal failures continue to arise from faulty support. Support may be deficient in thickness of metal or stability of sub-grade. As frequently stated, an impervious oil surface aggravates the effect of moisture in the sub-grade. Since many oil-treated projects are being undertaken upon metal insufficient for untreated conditions, it may be expected they will be found deficient when oil-treated, regardless of the method used. Emulsification of the light fuel oils in the presence of moisture and traffic is frequently reported. If the moisture comes from rainfall, the mixture can be protected by the application of a seal coat of heavy asphaltic oil and stone chips. Even a light application of the fuel oil used in the mixture, approximately $\frac{1}{8}$ gal. per sq. yd., covered with coarse sand, is commonly an effective protection against moisture and a preventative of raveling. Investigation shows that most cases are accompanied by a third condition, namely, the presence of an excessive amount of 200-mesh material, usually clay. Possibly the trouble may be avoided by eliminating clay from the mixture, which, however, is not always practical.

Rain during construction is a source of much annoyance. The immediate effect of free moisture is very similar to that of excess of oil, giving a deceiving appearance of richness and causing the material to gather in lumps while being mixed. If the moisture is retained after spreading, it produces waving and bleeding. The effect of moisture on the mixture during construction and afterward makes it advisable at the present stage of knowledge of the subject to proceed cautiously in moist climates. This statement is particularly true of plant mixtures, because a wet pit cannot be utilized without drying.

EMULSIFIED AND CUT-BACK BINDER

Emulsified asphalt was used for binder in road mixing, first, in 1928 and 1929. Two alternate methods have been used: First, water is spread upon the aggregate prior to and during the mixing to prevent the emulsion from breaking until mixed; and, second, a preliminary application of $\frac{1}{4}$ to $\frac{1}{2}$ gal. per sq. yd. of fuel oil is incorporated into the dry aggregate, improving the mixing qualities of the emulsion. A seal coat of about $\frac{1}{4}$ gal. of emulsion per sq. yd., covered with fine stone chips, is found advantageous to complete either method. Emulsified asphalt has been used in surface treatment with marked success. Cut-backs have also been used, although not extensively in the West.

Following experience with emulsions, it was suggested that cut-back asphalt or heavy road oil would be a suitable binder for a mixing treatment. This type of binder is accepted in California as having passed the experimental stage.

In using emulsions or cut-backs in road mixtures, it is hoped, of course, to produce a harder and more stable surface than can be attained with fuel oil. Engineers and highway authorities are not quite prepared to believe that an asphalt commonly designated "fuel oil" has sufficient binding properties to make a really successful pavement. Oil mixtures admittedly are soft and easily disturbed when first laid, whereas asphaltic concrete hardens at once; hence, it is reasoned that the early hardening of asphalt applied as an emulsion or a cut-back is highly desirable. The truth or error of this reasoning will not be known until a number of projects have been subjected to several years of service, after which a study of their construction and maintenance costs should furnish the answer.

In this connection, much should be learned from a test road in the Truckee River Canyon constructed in 1929 by the California Division of Highways. Thirteen road-mixed sections were built, which were followed in the spring of 1930 by a number of surface-treated sections. In the mixed sections two grades of fuel oil, two of cut-back, and two of emulsified asphalt were used, in combination with crushed gravel and crushed rock of varied grading. Accurate material and cost data were recorded. Although the combinations constitute only a few of the many possibilities, their behavoir and the records of maintenance costs should be very informative.

NEW CONSTRUCTION

First undertaken as a maintenance measure, oil treatments of both types are beginning to have a profound effect upon design and new construction in the Western States. Few Western State highways carrying as many as 500 vehicles per day of summer traffic are being built without a definite program for oiling, and, in many States, the traffic limit is even less.

Approaching the use of oil from the construction standpoint, surface treatment has the disadvantage of requiring a well-compacted base, which ordinarily cannot be had without a tedious wait, or by using an undesirable clay binder. Road mixing requires special equipment that, ordinarily, contractors do not have, and surfacing is quite commonly finished during the season when oiling is impractical. Consequently, many States are restricting oil mixing to their own forces, even on new construction, but are adjusting the grading requirements of new surfacing material to the needs of oiling. Plant mixing has the advantage of being suitable for contract operations, which, perhaps, is one reason for its general adoption upon new projects in California.

The introduction of oiling has brought about a new examination of specifications for low and intermediate types of surfacing. Much material formerly considered too fine has become available. Binder, or filler, is being scrutinized more carefully. On the other hand, the possibilities of penetration macadam and the elimination of fine crushing are attracting attention. Thus far, the facility with which fine-crushed material may be manipulated with machinery, as contrasted with hand labor and other expensive operations for macadam, shows the oil mixture to be much the lower in price.

Oil treatments have never been seriously proposed as a substitute for standard higher types of pavements, but they are actually encroaching upon that field to some degree where freedom from dust and convenience to traffic dominate the selection of type. Heretofore, for lack of a satisfactory or cheap intermediate type, roads carrying from 500 to 1 000 vehicles per day have frequently been paved, but oil treatment is now being found sufficient for at least immediate purposes. Thus, oil treatment is finding its place, mainly at the expense of the lower types, but to some degree as a substitute for the higher types.

DISCUSSION

H. J. SPELMAN,[5] M. AM. SOC. C. E. (by letter).—This paper is an interesting and valuable review of present practice in the Western States in the bituminizing of crushed rock and other traffic-bound surfacings. Mr. Frickstad discusses three classes of such treatments, namely, surface treatments, road mixes, and plant mixes. The total of 12 000 miles completed in those States indicates the importance of the subject.

There would appear to be no reason why the road-mix and plant-mix types should not approach in wearing qualities the asphaltic concrete, Topeka, or sheet asphalt surfaces, the characteristics of which they approach more or less closely.

There are two points in particular, which it is believed should be specially stressed. The first is the importance of sufficient manipulation or spreading, both in plant mixes and road mixes, to insure smooth riding qualities. If plant mixes are to be used more and more, as indicated in the paper, this is particularly important if this type is to give general public satisfaction. The second point is that failures are due principally to lack of sufficient base. It is an old, old story that most failures of pavement or surfacing are due to that cause, and it is well to emphasize that these new types will not take the place of bases of adequate thicknesses.

No mention is made in the paper of the so-called retreads which have been developed quite extensively in some of the States east of the Mississippi River during the time that these oil mixes have been developed in the Western States. As the types covered by Mr. Frickstad compare in characteristics with the older sheet and asphaltic concrete, so do these retreads compare in characteristics with the so-called, mixed bituminous macadams of 20 to 25 years ago, or with the "cold-patch mixtures" used so long for patching almost all kinds of pavements.

These retreads require no material less than $\frac{1}{4}$ in. in size, and the usual size is from $\frac{1}{2}$ in. to $1\frac{1}{2}$ in. Like the oil-mixed surfaces discussed by Mr. Frickstad they are constructed either by the road-mix or plant-mix method. Their increased cost over the Western oil mix is probably due only to the cost of the coarse aggregate which is hauled in and placed on the road just in advance of operations. Cut-back asphalts and tars have both been used successfully in their construction and more recently the development of a slower setting emulsion has enabled that material to be used with excellent results.

This type of construction has proved of great value in the East in the smoothing of old rough macadams, as well as in providing low-cost, dustless, wearing surfaces for the traffic-bound types. It is probable that its development was largely brought about because of the larger number of commercial plants ready to furnish the needed coarse aggregate of crushed stone, slag, or gravel. As in the Western types the riding qualities of this road-mix type are equal to those of any pavement. Failures have been generally attributable to the base, and plant mixes have not produced as smooth surfaces as road mixes. The smooth riding qualities of this type of construction are due primarily to the use of heavy road machines and heavy drags, which has been made possible by the development of tractors of the heavy, crawler type. If plant mixes are to compare favorably in riding qualities with road mixes, the use of similar methods of manipulation is essential.

---

[5] Senior Highway Engr., U. S. Dept. of Agriculture, Bureau of Public Roads, Washington, D. C.

The dividing line between surface treatments and retreads is not particularly well defined; nor is the term, "retread," a particularly satisfactory one for this type of construction. The term, "road mix," is a better one. The class of road mix used in the Western States might be called "fine aggregate road mix," and that used in the Eastern States, "coarse aggregate road mix."

Certainly, the dragging of all surface treatments is highly desirable, in order to obtain smooth riding surfaces. A suitable method of differentiation between retreads or road mixes and surface treatments might be to name as "retreads" or road mixes those jobs that involve the use of road machines, harrows, or other mixing equipment; and to call those surface treatments, that involve only dragging and rolling.

Mr. Frickstad's contribution is particularly important and timely because the increasing speeds of all classes of vehicles, as well as the increased number in use, have caused the road users everywhere to demand not merely a usable, all-year road, but a dustless, usable, all-year road.

J. T. L. McNew,[6] M. Am. Soc. C. E. (by letter).—Experiences of Western engineers with so-called "low-cost" bituminous roads have been summarized briefly in this paper. The term, "low cost," may be open to the objection that poor alignment, grade, and workmanship are to be permitted to accomplish "low cost." Invariably, the term is taken by the client to mean small outlay of money, and, in time, it may defeat the real purpose which engineers have had in mind as these surfaces for moderate traffic have been developed. Engineers are agreed that alignment, grade, and structures are probably the most permanent features of a highway; that safety to traffic demands that curves be flattened, widened, and superelevated; and that sight distance must be provided. They also recognize the importance of establishing grades to meet the demands for convenience of the motoring public. These demands must be met almost without regard to surface, and when so met they form a part of the permanent investment. "Low cost," therefore, is not to be applied to these appurtenances, except perhaps in the case of drainage structures themselves.

The term as applied to the surfaces then remains as the subject, and even yet it is somewhat misleading to the client. Much data are available to show both success and failure of so-called "low-cost" surfaces, and usually the promoter who reaches the client first uses the data most convenient to carry the question in favor of his particular product or type of surface.

---

[6] Prof. of Highway Eng., Agri. and Mech. Coll. of Texas, College Station, Tex.

Engineers must soon make public their intentions of recommending, designing, and constructing road surfaces to withstand present traffic requirements, plus the requirements of any increase in traffic that may reasonably be expected within a few years. Naturally, then, first cost, maintenance cost, amortization costs, transportation costs, and salvage value all must be considered in type selection to meet the needs of traffic in a locality. When, and only when, engineers accept and begin practicing these fundamental principles will the public begin to get the maximum possible mileage of serviceable roads, and only then will it recognize the fallacy of the idea so often expressed that "this or that surface is permanent." A highway is a structure that must be improved progressively as traffic and maintenance costs demand, and if roads continue to be needed for transportation purposes, they must be rebuilt time and time again in the future.

Bituminous surfaces have been brought to the attention of engineers rather forcibly in recent years and although several different methods are in use they are, in the final result, very similar. Much research has been reported, giving valuable information and guidance, and much more remains to be done.

The mention of the question of asphalt content invariably induces discussion. There are those who regulate the quantity by empirical rule; those who proportion by eye; those who insist that the stain test determines the quantity; and those who proportion the bitumen according to the voids in the aggregate. Naturally and logically the characteristics of the oil have a bearing upon the question as to how much bitumen the surface mixture must contain. Time (or perhaps it might be expressed as "age" of sample) also is a factor, because the light oils or topped crudes must certainly weather or volatilize more than the heavier grade oils. If, by bitumen content, is meant that content at the time the mixture is opened to traffic, and if any rule of proportioning is adopted for two mixtures containing different oils, then these two mixtures are alike in content at the beginning, after which they show variations in bitumen content dependent on the traffic using the surface and the climatic conditions as well. In general, the higher the percentage of asphalt of 80–100 penetration that an oil contains, the more stable it will be under atmospheric conditions and the more nearly true the given proportioning rule will be found.

The difference of opinion between the stain-test advocates and the devotees of the voids theory are not really as great as may appear, for each theory has its correct place in modern practice. Stability tests made on paving mixtures invariably indicate that, when bitumen in excess of that necessary to fill the voids in the compacted mineral aggregate is used, the stability as measured by resistance to shear is decreased. With these results the voids-theory enthusiast draws the conclusion that his theory is correct. On the other hand, the proponent of the stain test (which is no doubt a modification of the pat test as described by Mr. Clifford Richardson[7]), insists that the particles of aggregate should be coated with bituminous binder. Unfortunately, however, if the aggregate is proportioned for low voids in the compacted aggregate this coating of bituminous binder, as determined by the stain test, will prove to be an excess over that required to fill the voids, with the result that the stability test will indicate a weak mixture. If the aggregate contains more voids, then the stain test does not give an excess over that required for voids; hence, stability as affected by bituminous content will not be impaired. Of course, the voids theory must be limited for use with mixtures of aggregate that have sufficient voids to accommodate asphalt in an amount that will impart another property to the surface, which is perhaps more important than any other, namely, that which may be called "flexibility," or, perhaps, "resistance" to suddenly applied forces.

---

[7] "The Modern Asphalt Pavement", by Clifford Richardson.

The writer has conducted investigations in an attempt to find the critical bituminous content of certain paving mixtures below which excessive brittleness or lack of flexibility may be expected. The data accumulated from this work indicate that maximum resistance to displacement caused by suddenly applied loads invariably requires more bitumen content than is needed for maximum stability under static or gradually increasing load, as used in the various stability tests.

As the author has indicated, proportioning by empirical rule or formula has value only as a means of estimating bituminous content. In presenting the formula for the percentage of oil (Equation (1)),[8] C. L. McKesson, M. Am. Soc. C. E., stated: "It is not applicable to porous or absorbent materials, such as cinders or lava, but otherwise it appears to give results which are consistent with service obtained from various mixes." The writer wishes to emphasize also that, perhaps, Equation (1) will not apply to oils different in characteristics. Some oils contain fractions of highly volatile compounds, whereas others contain practically no very volatile fractions, and the different oils are absorbed in different quantities by a given aggregate. It must always be kept in mind that the term, "oiled road," may be applied alike to surfaces that may contain crude oil, topped crudes, fuel oil, residual oils, emulsions of any of the heavy residuals, or cut-backs, and that the determination of the proper bitumen content should be predicated upon one of the proper quantity of the particular oil to be used.

Mention has been made previously of the fact that, dependent upon the oil used, the bitumen content will decrease with the passage of time and will be influenced by both the climatic condition and amount of traffic the surface carries. Bituminous surfaces that carry light traffic usually show higher losses of the volatile oils than those under heavy traffic.

Incidentally, the intensity of the maintenance may affect the choice of bitumen content. If a surface is to receive a mixed-in-place treatment of a cut-back, or light topped crude, and provisions are made to maintain the surface continuously, one would be justified in using a slight excess of oil with the knowledge that more maintenance would be required to keep the surface smooth until the oil has reached a more stable condition upon exposure to traffic and weather. The engineer will probably recall instances where "shoves" have occurred in bituminous pavements soon after the surface was opened to traffic and that later these places are the most stable spots in the surface and seem to hold up under the more severe impacts. Not all engineers recognize the fact that a bituminous surface does move about under traffic and that a period of readjustment does take place. During this period the base itself may settle or heave, and careful maintenance in early life is essential to insure a smooth surface. It is also during this period of adjustment that "self-healing" is a desirable characteristic of the mixture. The ability of a surface to rise or fall with the subgrade, and to heal over the crack formed, is dependent upon the content of bitumen in the mixture, that has real binding properties. Experience has taught engineers to evaluate an oil on this score by its asphalt content of 80–120 penetration.

---

[8] "Light Asphaltic Oil Road Surfaces," *Public Roads*, September, 1927.

At times, one hears the statement made that the thinner the coating of the gluing agent the stronger will be the bond between two particles stuck together; and then the statement will be used as an argument for extremely lean mixtures. It is admitted that as bitumen content decreases to a given point, stability against shear as measured by static load increases, but the same law does not hold with the same quantities of bitumen if the stability is measured under impact loads. Bituminous surfaces do not have beam strength and no sacrifice of bitumen will impart sufficient strength to allow it to carry load as a beam.

If bituminous surfaces cannot be made to have slab strength sufficient to allow the surface to span soft spots when subjected to load, such facts should be admitted and a proper foundation prepared that will distribute the load over an area of such size that the subgrade will not be over-loaded. A sufficient quantity of oil should always be included, in order that the surface may follow the settlements of the subgrade or foundation course without cracking and subsequent disintegration.

The author calls attention to the fact that no standardized grading for aggregate for low-cost surfaces has been adopted. In the light of present knowledge of bituminous pavement practice perhaps no standard will be adopted. Surfaces falling naturally into the class of "low cost," for the most part, have been made of local materials on account of limited funds. Undoubtedly, the success of the methods of constructing these surfaces with various gradings of aggregate is evidence sufficient to disclose the fact that there are many satisfactory gradings. It is only within recent years that asphalt technicians in the field of hot-mix pavements have disclosed the fallacy in the assumption that any one grading is necessarily the best and that all others must be discarded. To standardize the practice and accept only one grading would defeat the element of "low cost" remaining. Concerning the theory of low-void aggregates there follows the fact that any number of combinations of mineral aggregate can be made with reasonably low total voids and minimum size of individual voids.

Mr. Frickstad states that the part of the aggregate passing the 200-mesh sieve is an important element, and the writer is fully agreed that such material of proper kind is beneficial. At the same time, attention should be called to the fact that this 200-mesh material must be controlled very carefully as to quality, such choice to be dependent upon the climatic conditions to which the surface is to be exposed.

Unfortunately, clay, the worst soil with which highway engineers must deal, passes the 200-mesh sieve. Certain classes of clay have the greatest attraction for water, the largest shrinkage factors, the poorest bearing values, and the highest absorptive properties of soils. Incidentally, some clays have greater affinity for water than for asphalt or tars. An aggregate containing appreciable quantities of such material is of doubtful value for districts where seasons of heavy rain exist. In some sections of the West and Southwest good results have been obtained with aggregates containing clay up to 25 per cent. The success of these surfaces has been due no doubt in part to good drainage for occasional rains and the absence of prolonged wet weather. Excess clay in oiled surfaces, in localities where rainy seasons are prevalent, usually makes its presence known as an extremely slippery surface and one in which the asphalt apparently emulsifies during the rain and immediately afterward.

The quantity of 200-mesh material, as well as the quantity of aggregate passing the 10-mesh, must be used somewhat as a guide as to the choice of oil. Aggregates containing "fines" similar in amount to the Topeka mixtures are much more difficult to mix uniformly with the heavier oils of 80 to 90% asphalt. Aggregates containing such quantities of oil are readily miscible with light oils, emulsions, and cut-backs, and are likely to require more care during the curing period. The writer has used the Topeka class of mixtures with some success on maintenance work by first introducing a distillate to moisten the aggregate in the mixer and then adding the heavier oil. As indicated previously, however, the mix does not reach good stability values until time enough has elapsed to allow a considerable quantity of the volatile fraction to evaporate. This method, therefore, requires careful maintenance until the surface has "set."

The writer feels confident that the experience of the Western and Southwestern States with these so-called "low-cost" surfaces has brought a means of extending the mileage of serviceable roads and has done much to focus the attention of taxpayers and engineers on the undisputable fact that highway-surface betterment is a problem to be solved by progressive improvement wherein each successive stage of development will realize the maximum salvage value of the last surface. It must be admitted, however, that there are yet many problems to be solved with these low-cost bituminous surfaces and that the acceptance of any set rule of mix design, bituminous content, or other construction method, without the proper care to see that such rules are acceptable for the case at hand, is open to numerous pitfalls to the disadvantage of the constructive work that Mr. Frickstad and his Western associates have so successfully carried to the present stage of development.

ROGER M. LEE,[9] ESQ. (by letter).—It is interesting to note that surface treatment of the type described by the author has been applied to more than 12 000 miles of roads in eleven Far Western States. Experience thus gained will be of very great value.

In Brant County, Ontario, Canada, on secondary roads tar and emulsified asphalts have been used, the latter being either plant-mixed or applied in the usual manner. Preferably, a little more money is spent to obtain a retread or, better still, a gravel asphalt is put through a standard asphalt plant and sealed with hot, mixed chips applied along with the remainder of the material so as to prevent the possibility of a slippery surface. With a reasonable base of gravel, 3 in of this surface would apparently provide fairly permanent results.

---

[9] County Engr. and Road Supt., Brant County, Brantford, Ont., Canada.

E. Q. SULLIVAN,[10] ASSOC. M. AM. SOC. C. E. (by letter.—One of the first road surfaces constructed by the California State Highway Department, by the oil-mixing treatment, was 44.3 miles between Victorville and Daggett, in San Bernardino County. This road was originally surfaced in 1927 with a 4-in. thickness of crushed gravel, with an average grading approximately as follows:

Sieve	Percentage passing	Sieve	Percentage passing
Fuel oil	3.7	20	45.9
200	10.6	10	56.4
100	19.1	3	72.4
80	22.8	½	82.6
50	28.9	¾	93.3
40	33.5	1	100.0
30	37.8		

The surface was not oiled originally. After this road had been under traffic for one year, there was considerable loss of surfacing material, the exact amount being unknown as the subgrade was sandy and gravelly and some of it had worked into the surfacing. The road surface had not started to fail when it was oiled, but was still in fairly good condition.

Oiling was undertaken by the oil-mixing treatment described by Mr. Frickstad. The cost per mile was, as follows:

Oil furnished and spread	$577.76
Mixing	498.84
Oil for seal coat	94.51
Labor, etc., for seal coat	60.95
Total cost per mile for oil-treating the completed road	$1 232.05

This road has been under an increasing volume of traffic, which has averaged, according to 1931 traffic counts, about 70 trucks per day, plus 850 automobiles, or a total traffic count of 920 vehicles for the 16-hour period between 6:00 A. M. and 10:00 P. M. The average maintenance cost has been as shown in Table 1.

The condition of this road surface has been kept continuously good, including the edges of the surfacing. Since the original gravel surface was only 18 ft. wide, the road is rather narrow for the increasing width of automobile stages and trucks using it. The increased cost of maintenance is due to increased expenditure on the edges of the road surface. Other maintenance has consisted of re-mixing a few short stretches of road surface that showed signs of being too rich in consistency, with resulting corrugations. Probably not more than 1% of the total road surface has been re-mixed as a maintenance measure.

---

[10] Dist. Engr., State Div. of Highways, San Bernardino, Calif.

A few broken places developed in this road surface during the first three years, perhaps an average of one such place per mile. These broken places were due, in general, to rodents that excavated burrows, thus causing failures 1 ft. or 2 ft. in diameter. The cost of such repairs is very small. The major maintenance work has been to hold the edges of the mixed surface from breaking.

TABLE 1.—SUMMARIZED COST PER MILE FOR MAINTAINING VICTORVILLE-DAGGETT ROAD

Year.	Road surface cost per mile.	Total cost per mile.
1927–28	$51.54*	$323.63
1928–29	92.46	174.05
1929–30	171.37	293.20

* Estimated; not accurately separated from total cost in this year.

Experience with this route indicates that with the present traffic it can be maintained indefinitely at about the cost indicated. Evidently, the cost of maintenance could be reduced materially if the road surface were widened to eliminate the tendency of wide vehicles to run off and on the edges, breaking them down.

Should the traffic increase on this road and more heavy trucking become established, it might be necessary to re-work the road at some future time, but it has been found by experiment that this road surface can be remixed to a greater thickness at small cost.

The road is constructed in a semi-arid country, on a well-drained sub-base of natural sand and gravel. In view of its success and the apparent permanent nature of the road surface, it was decided to extend the work across similar arid or semi-arid country where good, well-drained sub-base is available.

Alternate bids for field-mix *versus* plant-mix were called for in the first contracts. It was found that contractors bid approximately the same for either method of work, and subsequent calls for bids provided only for plant-mixing of the road surface.

The project provided for the construction of the subgrade by shaping, watering with a sprinkling truck, dragging, and then encouraging traffic to compact it for a period of two weeks. All contract work provided for a similar method of constructing the subgrade. This method is well suited to arid conditions; natural materials in arid regions usually cement and become very hard under this treatment. Exceptionally smooth riding qualities are attained in the profile by this subgrade construction when long drags are used.

The standard of work has been increased in later projects in view of the expectation of heavier traffic. The road constructed under the first contract has a thickness of from 2 to 3 in., but all contracts let have provided for a loose thickness of 5 in., which results in a compacted thickness of about 4 in.

The cost of the Victorville to Daggett project does not include that of crushing and spreading the original crushed gravel surface or the cost of the subgrade, but the cost of the subsequent projects in Table 2 includes that of crushing the gravel, plant-mixing the material, furnishing the oil, constructing the subgrade as outlined herein, spreading the material on the subgrade, windrowing the material, and spreading and laying it down for traffic to compact.

Table 2 is an analysis of the cost of seven typical projects covering 133 miles of road. These were all new roads, the surfacing being placed on new alignment on a newly completed grade. The cost of grading and structures is not included in this analysis. The cost of water used in sprinkling the subgrade has been separated from the remainder, because conditions vary so much in this respect in arid regions. The water for some of these projects was hauled in tank cars on the railroad for a distance of 60 miles. On other projects the contractor was able to develop water by drilling wells.

TABLE 2.—ANALYSIS OF COST OF SURFACING ON SEVEN TYPICAL CONTRACT JOBS COVERING 133 MILES OF ROAD

Location.	Miles.	Cost of Water for Sub-Grade.		Cost of Surfacing in Place, Including Oil and Seal Coat.		
		Total.	Per mile.	Total.	Per mile.	Per ton.
1½ miles northeast of Yermo to 1½ miles southwest of Dunn . .	20.78	$6 885.10	$331.33	$83 791.75	$3 998.04	$1.63
4 miles west of Hector to 2 miles west of Argos..............	14.00	4 232.00	302.29	63 810.50	4 557.89	1.72
Daggett to 4 miles west of Hector.	21.22	4 361.70	205.55	101 728.14	4 793.97	1.78
Barstow to 1 mile east of Yermo.	13.05	7 040.00	539.47	60 659.50	4 648.24	1.78
1½ miles west of Siberia to 6½ miles east of Amboy.........	22.38	17 500.00	782.30	130 437.60	5 830.92	2.19
9½ miles west of Hopkins Well to Black Butte................	22.10	8 542.90	386.56	133 375.78	6 035.10	2.36
2 miles west of Argos to 1½ miles west of Siberia.............	19.47	16 000.00	821.78	123 045.00	6 319.72	2.38
Averages for 133 miles of construction....................	18.998	$9 223.10	$481.32	$99 549.75	$5 169.12	$1.98

It has been found necessary in District VIII of the California State Highway Department, to surface-treat all projects with fuel oil and screenings. In general, it is most desirable to make the mix so dry that there is a tendency to ravel without this surface treatment. The desirable feature in requiring a dry mix lies in increased stability, resulting in elimination of any tendency of the road surface to creep or corrugate; the possibility of bleeding is also eliminated.

The treatment has been applied immediately after completion and compaction of the road surface. The cost of this treatment has averaged $155.46 per mile on day-labor work.

These roads, completed by plant-mixed methods, have given an opportunity to analyze reasons for best results. Experience in California to date indicates that there are three major points governing the attainment of best results, namely, workmanship, quality of oil, and quality of aggregate.

Workmanship.—It has been found that even when the quality of materials is not of the best, reasonably satisfactory results can be obtained if additional skill and effort are put into the workmanship. By this is meant, road-mixing and remixing, with careful adjustments in the quantity of oil.

Quality of Oil.—Plant-mixing has clearly brought to light the fact that, of several oils passing California State specifications, there is a marked difference in results.

Quality of Aggregate.—It has been found that the quality of aggregate influences results, not so much because of qualities of hardness of the particles as qualities of natural binding value in the aggregate. Clay in the aggregate, however, is found to be detrimental. In general, an aggregate having the best mechanical lock, will make the best aggregate for oil-mixing treatment.

It is believed that, if desired, the plant-mixed roads can also be remixed by field methods at any time, with any desired thickness of material added to increase the strength for possible increased stress of heavier traffic.

Conclusion.—The oil-mixing treatment for graveled roads is particularly suited to arid and semi-arid regions, where such roads are subjected to reasonable loads and to moderate traffic. Maintenance costs are low under these conditions. The traffic that these pavements can withstand is as yet undetermined since there is no sign of general failure. The strength can be increased to meet increased future demands.

There were two major developments in construction methods during 1931. The first was the discovery that heating the aggregate on plant-mixed jobs results in a saving in cost. The majority of contractors installed and used heating equipment at the plant, although this was not required under the specifications.

Two major savings are affected by heating the aggregate: (1) The power required to turn the pug-mill is greatly reduced; and (2) plant production is increased because the more rapid coating of the particles of the aggregate with oil reduces the time of mixing.

The second major development of 1931 was the marked improvement in riding qualities of plant-mixed surfaces. Previously, most engineers believed that it was impossible to secure, on plant-mixed jobs, the ideal riding qualities of the road-mixed jobs. It is now found that the same ideal riding qualities can be secured by requiring an appropriate amount of blading of the plant-mixed material. Contractors' bids indicate that there is no appreciable increase in cost in specifying a definite amount of blading with relation to plant output.

Hugh W. Skidmore,[11] Assoc. M. Am. Soc. C. E. (by letter).—Prime desiderata of low-cost road development are: Mileage, serviceability, and cost. The aim is to secure the most miles of the most serviceable road at the least possible cost. A logical development of this idea naturally lends itself to "stage" construction in accordance with the demands of traffic, and entails the utilization of local aggregate materials and, most generally, some one of a variety of bituminous binders.

---

[11] Pres., Chicago Paving Laboratory, Chicago, Ill.

Low-cost road construction has developed rapidly during the past few years due to recognition of the economic fallacy of expensive pavements on secondary roads and, as yet, rather sparsely traveled sections of trunk highways. A very great mileage of highway pavement, costing from $25 000 to $50 000 per mile, was unwisely built in many sections of the United States before low-cost road construction reached its present widespread application and before lack of funds forced economies in highway expenditures. One of the benefits of the present financial depression to the highway construction industry is the impetus it has imparted to low-cost road development mainly through the recognized necessity of securing greater road mileage per dollar spent.

The general scope of low-cost road construction is quite broad, both geographically and economically. Every section of the continent is deeply concerned in its application and a considerable number of localities have progressed to a quite well standardized procedure. With respect to cost, a wide variety of types and thicknesses, ranging from $1 000 to $15 000, or more, per mile, may quite properly be included, as compared with expenditures of from $25 000 to more than $50 000 per mile for so-called "permanent" types. In many instances the latter types are not living out the bond issues under which they were constructed, or they have reached a condition in which the maintenance cost is prohibitive. Resurfacing of these originally expensive pavements constitutes a separate field of application of low-cost surfaces which is likewise developing rapidly.

The exact nature of the composition used in low-cost road construction is entirely a matter of locality and the materials available therein, considered in the light of the traffic to be served. Thus, in certain sections of Nebraska, blow sands are the only locally available aggregates, while in other sections of the State a very finely graded gravel (almost a coarse sand, known as Platte River gravel), is the only aggregate available. Some States are blessed with an abundance of both gravel and durable stone, while in some instances very large districts are almost devoid of any kind of suitable aggregate. The Gulf States have available large quantities of oyster shells. Hence, it is clear that the development of pavement or treatment type is peculiarly a strictly local problem, and several varieties may be required within a given State.

A wide variation in aggregates entails a wide range in bituminous binders, from road oils, which in some cases are little more than topped crudes, to highly refined asphalts. Tars also include a wide range of consistencies from very light, volatile, priming tars to heavy, viscous, hot-application binders. Some binders, both tar and asphalt, are cut-back or diluted with a more or less volatile solvent (depending upon the nature and gradation of the aggregate) to enable the use of heavy, viscous binders at air temperatures, or slightly above, allowing the diluent to evaporate rapidly or slowly as the case may be. This evaporation begins during construction as soon as the bitumen is applied to the aggregate and continues for short or long intervals after construction, depending upon the volatility of the diluent used. Likewise, both tar and asphalt are emulsified with water which forms a non-adhesive, mobile liquid, enabling them to be used cold. Some time after application, the emulsion breaks, freeing the water and causing the composition to "set;" that is, the bitumen resumes its normal state of adhesiveness. By this means, quite viscous bitumens may also be utilized without using heat. Emulsions possess the added feature of being applicable to damp aggregate and, in fact, they often function best upon moist surfaces.

While a great variety of aggregates exists, there are also many types of binder available so that practically any aggregate condition may be met. The selection of the most suitable bitumen is not always immediately apparent except in a general way. Traffic, climate, and aggregates are the principal determining factors, but frequently considerable experimenting is required and some modification of existing binders is indicated. Naturally, intimate knowledge of bituminous materials is highly specialized and the application of such knowledge to the problem is essential to economic success.

The simple surface treatment of roads with some form of oil or tar will perhaps always be more or less common, solely as relief from the expensive dust nuisance. Most highway officials will freely state that such treatment is easily warranted for this reason alone, to say nothing of the preservation of road surface and metal afforded thereby. It is not at all uncommon to find gravel and stone road surfaces losing the equivalent of an inch of metal per year from wear, when untreated.

Surface applications are not permanent, however, and require more or less frequent renewals. This may become burdensome and then a more substantial pavement surface is indicated. Road mix or plant mix, utilizing some one of the several cold application binders, quite generally follows surface treatment when it becomes inadequate or too expensive. Conditions may justify even more substantial construction, such as bituminous concrete or sheet asphalt. It is certain, however, that the next decade will witness an increasingly vast mileage of simple, inexpensive, cold bituminous mixtures. Recognition of this fact has resulted in numerous patented types and processes, some of which have merit. Realization of the progress to come in this field has also encouraged manufacturers to apply their engineering skill to the development of equipment which will not only enable more miles to be built for less money, but will insure better pavement by eliminating the human element with respect to uniformity of mixture composition and smoothness of road surface.

Designers, builders, and users of pavements all desire smoothness of surface initially, and as long thereafter as possible. The engineer, aside from professional pride in his creation, realizes that smooth surfaces which retain their smoothness eliminate a costly source of maintenance; the builder, from a plain business point of view, knows that a superior surface is an important aid in securing additional work, and if he is in any degree responsible for maintenance, as is frequently the case for at least the early life of the pavement, he, too, appreciates the effect of initial smoothness upon subsequent expense; the user, obviously, is most intimately and frequently apprised of poor riding quality and he is seriously concerned as a taxpayer in both initial and ultimate cost. Of these three individuals, the engineer, in the main, must assume the burden of improvement and he is, therefore, especially interested in new methods, new materials, and new machinery that may offer possibilities of superior workmanship, greater durability, and reduced cost.

Any bituminous paving composition, regardless of hardness, will flow under pressure in proportion to the load applied and the length of time it is applied. Thus, resistance to distortion is mainly resident in ability to withstand shearing forces. In those compositions utilizing very soft binders, such as oils, very soft asphalts, and tars, stability is principally dependent upon close interlocking of aggregates since the binders are relatively fluid at normal temperatures. The more closely graded and better filled the mineral aggregate, the more effective, from the standpoint of stability, are very soft bitumens. This is another way of stating that as cements, they are more effective in thin films on closely packed particles than in thick films on aggregate masses containing large void spaces and relatively few contacting surfaces.

One of the major types of composition used in low-cost road construction is the rather open, coarse-graded type with mineral (either uncrushed gravel, crushed stone, slag, chatts, or gravel) coated with tar or asphalt, cut-back, or emulsified asphalt or tar, and sometimes a heavy asphaltic oil. There are numerous modifications of this general type, including variations in aggregate sizes from all coarse, large-sized particles; graded coarse particles exclusive of fines; graded stone or gravel plus moderate quantities of fines (sand or stone screenings), to rather well filled graduations, resembling graded bituminous concrete in texture. Binders requiring volatilization necessitate the use of fairly open mixtures with comparatively large void spaces; they are sealed with a surface application of liquid bitumen and chips, sand, or pea-gravel top dressing following an interval of time for evaporation of the diluent. When such binders are used in too dense a composition, volatilization is retarded or prevented to the extent that a crust forms at the surface, preventing complete volatilization in the lower portion of the mixture. Thus, cut-back binders and volatile oils are more or less restricted to open mixtures for the best results. Emulsions, however, can be successfully used in filled mixtures which develop ample stability to permit immediate compression and use by traffic. Suitable oils may be similarly used, but are limited as to the degree of stability developed in the mixture.

Mr. Frickstad confines his discussion to oil-mix and oil-surface treatment in the Far West, recognizing that there are many other similar and entirely dissimilar developments in other sections. Perhaps no section of the country has witnessed such extensive and varied application of low-cost road types as the Central States where practically the whole gamut of road mixes, plant mixes, and surface applications has been run, using such binders as light and heavy oils of asphaltic, semi-asphaltic, and non-asphaltic nature; tars, asphalts, cut-backs, and emulsions; and such aggregates as soils, sands, gravel, stone screenings, slag, chatts, and stone. Furthermore, a great number of proprietary formulas have been developed covering cold-mix, cold-lay; hot-mix, cold-lay; and cold-mix, hot-lay ideas, using all the various aggregates and bitumens. Some of these compositions depend upon the blending of hard, brittle asphalts with soft fluxes (oils) under the action of traffic. The real status of the matter is that this field of construction is just nicely started and outstanding developments, both with respect to cost and durability, may be counted upon during the next few years.

All engineers, and contractors as well, recognize that the greatest single influence in the direction of lower costs is the substantial increase in the production capacity of a given crew of workmen and quota of equipment. Obviously, then, real progress in this direction calls for the application of the inventive ability and mechanical ingenuity of equipment manufacturers. These men have not been slow to realize this fact and have wisely reaped the benefits of co-operation with engineers and contractors in developing machines of practical value. Every engineer realizes that improvements in methods and equipment are vital to real progress; therefore, it is surely proper that sincere recognition be given the designer and builder of machines which will give a better product at a lower cost.

During 1931 machines of the type shown in Fig. 3 have been developed. They have a wide application in the building of better compositions at substantially lower costs than have yet been possible. To the engineer or contractor who observes this equipment in operation, it is immediately apparent that plant mix of the very best quality can be manufactured, spread, and finished mechanically with much less effort and equipment, in greater quantities, and with positive assurance of far superior workmanship, than has been possible by road mix or plant mix to the present time.

The equipment comprises the application of well-known principles which eliminate the personal equation and insure uniformity of composition, perfect coating of aggregates, and a finished pavement of smooth surface and uniform denseness in all portions of the roadway. These very desirable characteristics may be obtained by the use of the full range of aggregates and binders, and upon any subgrade or base which is suitable to function in such capacity. The adaptability and flexibility of the equipment are two of its outstanding features.

The first unit consists of a large capacity, pick-up loader, with spiral feed, discharging into an overhead bin which, in turn, discharges upon a positive-feed, corrugated apron conveyor that has an adjustable, calibrated discharge which gauges, accurately, the continuous flow of aggregate. From the apron feeder, the aggregate drops through a baffled chamber where the bitumen is applied either hot or cold by means of two groups of high-pressure nozzles. One set of nozzles sprays the falling mineral as it leaves the apron, the other group as it leaves the baffles and just before it reaches the large-capacity, twin pug-mill mixer. These sprays are effective in coating at least two-thirds of the total surface.

The flow of bitumen is accurately controlled according to requirements by valves and a recording flow-meter. When the material reaches the mixer, it is already fairly well coated and by the time it has traveled the 8-ft. length of the twin pug-mill, it is thoroughly and uniformly coated. The machine has a capacity of 2½ cu. yd. of aggregate per min., operating at normal speed. The flow of mineral and bitumen is set according to the requirements of the mixture, and remains constant in this ratio until changed to accommodate a new condition. Thus, through continuity of flow of materials and synchronization of elements, exceptional uniformity of product is maintained.

With the loader mixer operating on the subgrade picking up the aggregate from windrows, the full benefit of sun and wind in drying the mineral is secured, thus eliminating costly mechanical drying which, if provided in sufficient capacity to supply the mixer adequately, would be prohibitive in many cases. Operating as a central plant at the source of aggregate, mechanical drying may be readily provided, but always with a substantial increase in cost of mixture.

The second unit is the spreader finisher, which also operates under its own power. Both machines are mounted on crawlers and are adequately powered to provide ample traction under the most adverse conditions. The finisher may operate directly behind the mixer with the mixture discharging directly into the spreader. The latter consists of two horizontal screw conveyors delivering mixture the full width of the road and in any finished depth up to 6 in. The screws operate independently so that the quantity may easily be controlled according to the condition of the subgrade.

Immediately back of the spreader trough is a double-faced tamper operating at 200 rev. per min., with a ¾-in. stroke. The tamper face is 1½ in. wide, divided into two steps of ¾ in., with a ¾-in. riser, with the shallower step forward. Immediately back of this is a screed shoe, 6 in. wide, operating on a half-cycle with the tamper. This ingenious arrangement nicely "tucks" the mixture under the screed and provides substantial compaction without any tearing or pulling effect. A 6 000-lb. force is applied directly upon the tamper, so that if those mixtures contain stable cements, including little or no volatiles, subsequent rolling may be eliminated, thus preventing the slightly "rippled" surface that always results from rolling even under the best of conditions. It has long been recognized that direct vertical compression of bituminous paving compositions is ideal if it can be applied uniformly and adequately.

The third outstanding feature of this unit is the application of a system of levers to smooth out humps and depressions in the subgrade. Long skid-shoes with lever-arm attachments to the main frame, extend ahead and behind the crawlers. The lever arrangement is such that a sharp bump of, say, 2-in. height in the subgrade will result in an imperceptible over-all rise of 1 in. in a distance 12 ft. in both directions therefrom. The principle upon which the subgrade equalizer works is demonstrated by Fig. 4, in which, *A* is a line drawn by straight-edge; *B* is an exaggerated, rough subgrade; *B′* is the same roughness transmitted to the pavement by the wheel; and *A′* shows the roughness removed by means of the equalizer. By this combination of crawlers and subgrade equalizer, the expensive item of forms is eliminated completely and a smooth riding surface is produced.

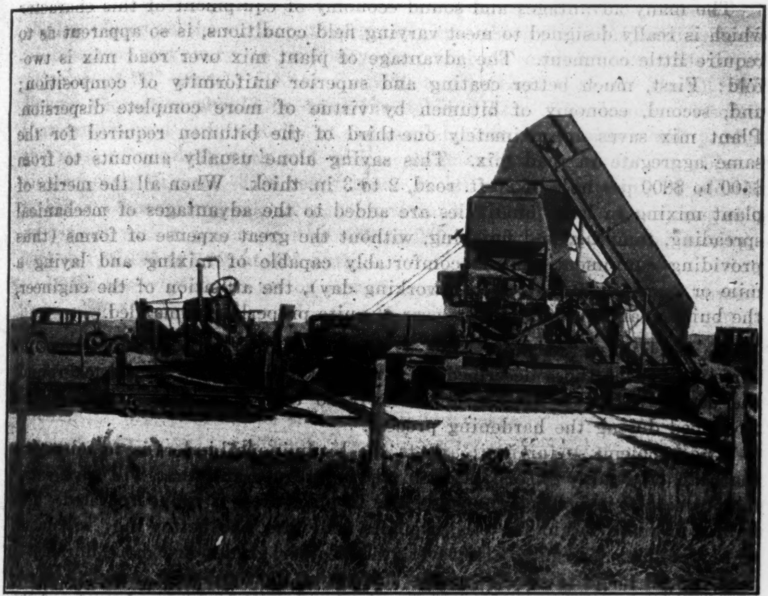

FIG. 3.—A MODERN TYPE OF ROAD-BUILDING EQUIPMENT.

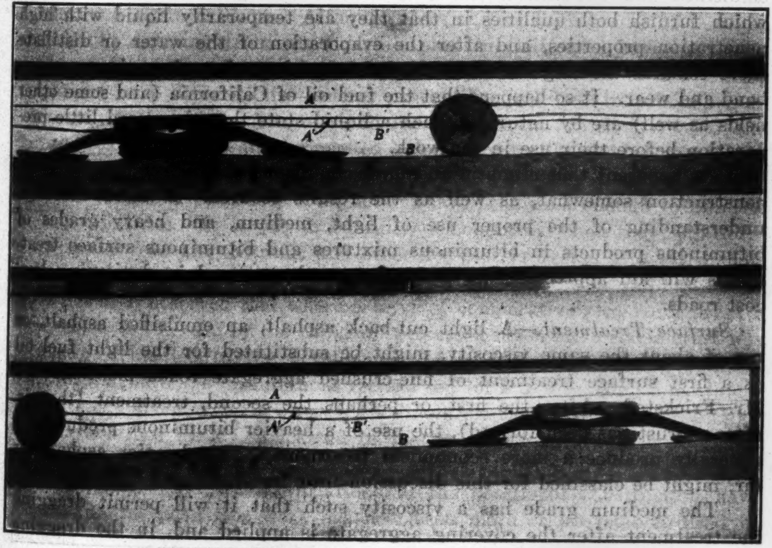

FIG. 4.—PRINCIPLES UPON WHICH A SUBGRADE EQUALIZER WORKS.

The many advantages and sound economy of equipment of this character which is really designed to meet varying field conditions, is so apparent as to require little comment. The advantage of plant mix over road mix is twofold: First, much better coating and superior uniformity of composition; and, second, economy of bitumen by virtue of more complete dispersion. Plant mix saves approximately one-third of the bitumen required for the same aggregate in road mix. This saving alone usually amounts to from $500 to $800 per mile of 20-ft. road, 2 to 3 in. thick. When all the merits of plant mixing in large quantities are added to the advantages of mechanical spreading, tamping, and finishing, without the great expense of forms (thus providing equipment that is comfortably capable of mixing and laying a mile or more of 20-ft. road per working day), the attention of the engineer, the builder, and the tax-paying user is quite properly commanded.

A. H. HINKLE,[12] M. AM. SOC. C. E. (by letter).—Bituminous types of surface, such as those described by Mr. Frickstad, require, as a background, the use of a binder that hardens slowly so that a smooth surface can be developed during the hardening process.

The problem, so far as it affects the bituminous binder, is to select one that can be readily incorporated in the aggregate and that will give satisfactory results in holding the aggregate in place after it is incorporated. The lighter or more liquid the oils, asphalts, and tars, the better they will penetrate the fine aggregate. However, the heavier grades are more durable if they can be made to "stick" to the surface of the aggregate, which is sometimes dirty. Thus, attention is at once brought to the use and study of the emulsified and cut-back asphalts, or similar acting bituminous materials, which furnish both qualities in that they are temporarily liquid with high penetration properties, and after the evaporation of the water or distillate there remains the original heavy, asphaltic product that gives the necessary bond and wear. It so happens that the fuel oil of California (and some other fields as well) are by nature, in such a liquid state that they need little preparation before their use in the work.

It is apparent that climatic and local conditions may affect the details of construction somewhat, as well as the results secured. A more thorough understanding of the proper use of light, medium, and heavy grades of bituminous products in bituminous mixtures and bituminous surface treatments will aid appreciably in the better results secured in developing low-cost roads.

Surface Treatment.—A light cut-back asphalt, an emulsified asphalt, or tar of about the same viscosity, might be substituted for the light fuel oil as a first surface treatment of fine-crushed aggregate roads mentioned by Mr. Frickstad. After the first, or perhaps the second, treatment (that is, after a crust has been formed), the use of a heavier bituminous product will generally produce a more economical treatment. This heavier asphalt, or tar, might be classified for this discussion into "medium" and "heavy."

The medium grade has a viscosity such that it will permit dragging the treatment after the covering aggregate is applied and, in the dragging operation, the aggregate coated with the tar or asphalt will be deposited in the low places on the surface, thus greatly smoothing it. This medium grade of bitumen may vary in viscosity for cut-back asphalt from 50 to 200 (Engler, at 50° cent.); for tar from 30 to 80 (Engler, at 40° cent.). The lighter viscosities should be used in cool weather. The heaviest viscosity that can be used satisfactorily at the available air temperatures will produce the most economical work and will be most satisfactory from the point of view of early drying. The heavy grade of bituminous material, in addition to being a heavy fuel oil, as mentioned in Mr. Frickstad's paper, might be an asphalt with a penetration of 175 to 250, at 25° cent., or a tar having a float test of 120 to 180, at 32° cent.

---

[12] Chf. Engr., Maintenance, Indiana State Highway Comm., Indianapolis, Ind.

If the heavy grade of tar or asphalt is used, it should be covered immediately with $\frac{3}{4}$-in. to 1-in. maximum size stone, slag, or gravel (80 to 110 lb. per gal.), and may then be immediately "traveled" without the inconvenience of splashing on machines. This heavy bituminous material, however, does not have the advantage possessed by the medium or lighter grades of permitting the dragging of the surface after treatment.

Most bituminous pavements are subject to slight distortions and wear under traffic which gradually roughens their surfaces. These slight irregularities frequently can be eliminated by proper dragging with a long base drag just after surface treatments with a medium grade of tar or asphalt; such treatments are applied periodically as regular maintenance operations.

Mixing Treatment.—The "mixing treatment" (sometimes called "mulch treatment"), involving a light cut-back asphalt or light tar (specific viscosity, Engler, 40° cent., of 10 to 20), has been used extensively in some of the Central and Eastern States. Although light and medium grades of tars and asphalt oils differing from the fuel oils used in California have been generally used in this work, and although some of the details of the mixing operations have differed, the general process has resulted in producing an intimate mixture of the bitumen and loose aggregate, which is leveled and spread over the surface and compacted by traffic, sometimes aided by a roller. In this work, California fuel and similar oils in climates subject to heavy moisture combined with deep frost action, have been used enough to indicate their possibilities. It is yet to be fully demonstrated that they will form a surface as resistant to traffic and other destructive agents as a tar or cut-back asphalt made from an asphalt base having a penetration of 70 to 110.

It has been observed that where a layer of comparatively coarse aggregate was treated on the road by the "mixing" process, a much more stable crust was produced. This led to the development of what is termed, for want of a better designation, a "bituminous retread top" of 2 to 3-in. compacted thickness of stone about 2 in. in size. This differs primarily from the oil-mixing method described by Mr. Frickstad in that a coarser aggregate is used and the bitumen consists of cut-back asphalt, an emulsified asphalt, or a medium grade of tar. While many variations in the details of construction have occurred in the past, this work has now been more or less standardized in Indiana, as follows.

Any time from one week to six weeks after the oil is applied to the old stone or gravel surface, crushed stone, slag, or gravel (preferably ranging in size from 1½ to 2½ in.), is spread on the surface from trucks to a depth of about 3½ in. This aggregate is leveled by a heavy grader and the edges are "trued up" by hand. To this loose aggregate is applied about 0.5 gal. per sq. yd. of the medium tar, cut-back asphalt, or emulsified asphalt. The aggregate is then harrowed with a spike-tooth harrow, struck off with a grader, and rolled once immediately thereafter; as soon as the bituminous material hardens sufficiently so that the aggregate will compact and remain compacted, it is again rolled. A second application of bituminous material of about 0.4 gal. is applied and, after curing, the surface is again thoroughly rolled. Just preceding the third application of bituminous material, the voids in the coarse aggregate are filled with ¾-in. to ⅜-in size aggregate leaving a uniform and slightly excess layer of covering on the surface. Fig. 5 shows the arrangement of a brush and an old carpet, pulled by a small truck, used for this purpose. This covering is not rolled until after the third application of about 0.35 gal. of bituminous material, after which the surface is planed or dragged and again thoroughly rolled. Equipment for dragging this covering material after the third application is shown in Fig. 6. This process rolls the coated stone chips around over the surface until they drop into the voids or fill the depressions in the surface. (This same process of dragging is used, after re-treatment, in future years, with a medium grade of bitumen to restore the smoothness of a surface that may have been roughened under traffic.) A fourth treatment of about 0.17 gal. per sq. yd. of the bituminous material covered by ½-in. size aggregate may be used if necessary. This process resembles the "mixing treatment" in its first stages (except for size of aggregate) and its finishing operations are like the bituminous (penetration) macadam method.

The work of smoothing and leveling is largely done mechanically, and experience has shown that generally a smoother surface is produced and at a much less cost than with an ordinary penetration macadam. In Indiana, the cost of this top course, 3 in., compacted, including the oiling of the old road, for a 20-ft. width, has been from $3 800 to $6 000 per mile. Experience has shown that where this top is built on a suitable base, it will carry any ordinary traffic that may be found on the average State highway. The surface is maintained the same way as the ordinary bituminous macadam. In this bituminous retread top a low percentage of bitumen is used, which is made possible by means of the coarse aggregate.

While this bituminous retread top has ordinarily been built on an old gravel or stone road, it has also been constructed on old brick and old bituminous concrete surfaces that have become very rough. When this top is built on such surfaces, in lieu of the first oil treatment for the gravel and stone roads, the old surface is given about 0.2 gal. of medium tar or cut-back asphalt and covered with stone chips to prevent the layer of coarse aggregate (to be applied later), from sliding and shoving on the old smooth surface while construction operations are under way.

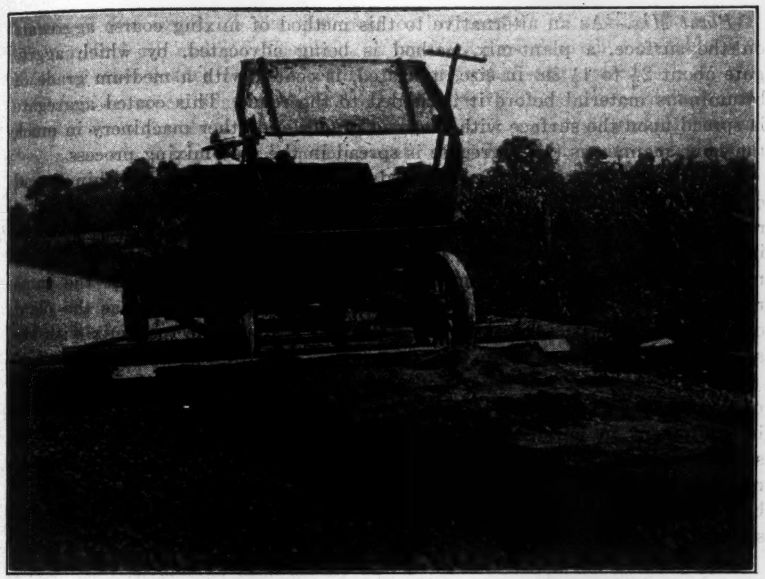

FIG. 5.—EQUIPMENT FOR BRUSHING THE COVERING MATERIAL INTO THE VOIDS OF THE STONE.

FIG. 6.—DRAGGING THE COVERING AFTER THE THIRD APPLICATION OF BITUMINOUS MATERIAL.

Plant Mix.—As an alternative to this method of mixing coarse aggregate on the surface, a plant-mix method is being advocated, by which aggregate about 2½ to 1½ in. in size, unheated, is coated with a medium grade of bituminous material before it is hauled to the road. This coated aggregate is spread upon the surface with the road grader and other machinery in much the same manner as the aggregate is spread in the road-mixing process.

This coated aggregate is compacted by rolling, after which a thin spread of ¾-in. coated aggregate is spread on the surface and the surface is again rolled. A system is now in use by which this aggregate is coated by immersing it in the asphalt or tar as it is unloaded by conveyors from the car. These methods of making a plant mix of coarse aggregate bear about the same relation to the bituminous retread described in this discussion, as the plant oil-mixing method described by Mr. Frickstad bears to the road mix with the same grade of fine aggregate.

Equipment.—Perhaps the use of a long-base heavy drag or planer described under "Surface Treatment" in this discussion, is the greatest development in equipment in building these cheaper types of bituminous roads. With such equipment a surface can be made even smoother than by any hand methods yet devised. This smoothing applies especially to the oil-treated base for the retreaded top where it is necessary to start producing a smooth surface if a smooth-riding, finished, top course is to be obtained.

Generally speaking, the equipment for this type of work may be that used in maintaining an ordinary traffic-bound gravel or stone road. While special machinery may be provided, as Mr. Frickstad states they are doing in some places, fortunately this is not necessary for counties and other smaller governmental units which will have occasion to build short stretches of this type of surface.

Grading of Aggregate.—The method described herein as "bituminous retread top," calls for the use of a comparatively coarse aggregate as compared with the fine aggregate used in methods described by Mr. Frickstad. With the coarser aggregate the question seems to be largely one of sufficient base in order to carry the loads rather than a question of sufficient durability of the top.

This coarse aggregate method has been used on some of the most heavily traveled roads in Indiana, and it can be said that, except for the necessity of treatments as a maintenance operation every year or so (which is some inconvenience to the traffic), the surface is holding satisfactorily.

Bituminous Materials.—It is fully demonstrated that cut-back asphalts, emulsified asphalts, and tars, are perfectly satisfactory for this work. When an asphalt product is used, the writer is inclined to think that best results will be secured by the use of an asphalt having a base with a penetration of about 80 to 120 and that it matters little whether this asphalt is put in a liquid form as a cut-back product, or as a suitable emulsified product.

While the fuel oil of California, and other oils, may not exactly comply with these requirements, they do not seriously depart therefrom; also the lower cost of the fuel oil and similar oils may more than justify their use even if they are not quite so satisfactory under certain conditions. With the use of fine aggregate the first coat of bitumen at least must be a very light tar, fuel oil, emulsified asphalt, or cut-back asphalt with a suitable distillate, as other grades will not readily penetrate such aggregate.

If further experiments with fuel oil mixed with aggregate containing an excess of fines proves successful in all climates, it will have great merit in those areas where much local fine aggregate is available, since, frequently, the local pits will supply this aggregate in about the proper proportions of fines that Mr. Frickstad describes as being used in California.

With the use of a coarse aggregate the percentage of bitumen is greatly reduced. For instance, the quantity used to coat the 1½ to 2½-in. stone will range from 2 to 3 per cent. With this coarser aggregate method there must, of course, be some finer aggregate used to seal the top and this requires a greater percentage of bitumen. Generally, however, the total in the coarse aggregate type, including the seal, is less than 4½ per cent. The low percentage of bitumen contributes to a lower cost and the coarse aggregate, if it makes any difference at all, makes a crust capable of carrying heavier traffic than the fine aggregate.

Due to the heavy base required in a country subject to deep frost action and moisture, it is doubtful whether new construction of this type will make a rapid advancement in such climates. If started from the ground to build up a base, the cost of this type would approach closely that of one of the standard pavements now (1932) being constructed. This is due to the extremely heavy base required on clay soils where the frost action and moisture are pronounced. However, in such climates, there are usually many miles of old stone and gravel roads which have been used for years and which frequently have a well compacted and solid base. These roads (especially where heavy trucking is not likely to develop), are very suitable foundations on which to build this low-cost bituminous surface. Frequently, they will serve the public as well as a higher type of surface.

Standardization of Types.—While a great variety of bituminous mixture is used as a top course (consisting of various sizes of aggregates and numerous kinds and grades of asphaltic oils, cut-back asphalts, and tars), it appears to the writer that the tendency is toward standardization into certain specific types which may be classified under the following five general classes, the first three of which are described by Mr. Frickstad:

1.—Surface treatments on traffic-bound gravel and stone roads wherein a light grade of bituminous material is used as a first application on the clean, compacted surface consisting largely of a fine aggregate; and, then, by successive treatments with medium grades of bituminous materials and the addition of aggregate covering, a bituminous crust is built up sufficiently strong to carry the traffic.

2.—The bituminous "mulch" or "oil mix" method wherein the light grade of bituminous material is mixed with fine aggregate on the surface to a depth of from 1 in. to 4 in.

3.—Coating the road with a plant mix 1 in. to 3 in. deep, wherein the mixture consists of an aggregate containing a large percentage of fines, which is spread on the road from a truck and leveled with a grader and other road machinery and maintained by blading and scraping until it hardens and traffic compacts it. (This mixture is virtually that described under Class 2, except that it is a plant mix instead of mixed in place.)

4.—A bituminous retread top made by mixing on the road an aggregate ranging in size from 2½ in. to 1 in. by successive applications of a cut-back asphalt, emulsified asphalt, or medium grade of tar, the first stages of this method resembling Class 2, and the final stages resembling the penetration macadam type.

5.—A plant mix of the same size of aggregate (unheated) as that used in Class 4, and an emulsified asphalt, a cut-back asphalt, or medium grade of tar made either by mixing the material by ordinary mixing-plant methods or by immersing it in such bituminous materials, the coated material being hauled to the road and spread in the same manner as in Class 3, and which, after thoroughly rolling and curing, is coated with ¾-in., coated aggregated applied and spread in the same manner, using a comparatively lean mix and sealing the surface with an ordinary seal or surface treatment coat if necessary.

In all the foregoing methods the low cost of the finished surface is brought about by the fact that the aggregate is handled, spread, and finished mostly by mechanical means, thus reducing the hand labor and expensive costs to a minimum; also, from the fact that cheaper processes are used in the mixing methods made possible by not heating the aggregate and in using a bitumen with a low viscosity and because frequently a less costly aggregate can be used in some of the work. Inasmuch as the aggregate is unheated in all these cheaper methods, it goes without saying that they are most suitable for use in a dry, warm climate, or during the dry, warm season in other climates.

Base Required Varies with Climatic and Soil Conditions.—Where deep frost action and excess moisture are prevalent, it is necessary to use greater precaution in having a suitable base than is required in the more arid districts and warmer climates. Many of the roads in California may be treated in the manner described by Mr. Frickstad, without developing the base to greater strength; but if that same base were used in other areas, it would prove a complete failure. It is evident that highway engineers are learning much about the construction of these cheaper types of surface and there is no doubt concerning their great value in developing at least a secondary road system. It is likely they will, as he states, encroach in many places upon the higher types of surface, yet it is extremely necessary that a thorough study of the local problems involved be made in order to avoid building such types where they are likely to prove failures. This would tend to discredit them in their legitimate and economical use in other places.

Perhaps there has been no phase of highway development that is more of a "missing link," than the need of a low-cost secondary road which will carry a limited amount of heavy traffic and an unlimited amount of light traffic. It is evident that the bill for the high-priced pavements on all highways will retard the proper development of any highway system unnecessarily.

Claude P. Owens,[13] **M. Am. Soc. C. E.** (by letter).—Few highway officials will question the need for a low-cost secondary road that will accommodate a limited heavy traffic and a fairly large volume of light traffic. The problem of keeping up with the fast-growing demand for increased road mileage and improved service with the limited funds available is one that faces every highway official. Traffic is not only increasing in volume, but also in speed. Certain types of surfaces which, a few years ago, were considered ideal and adequate, are now objectionable and unsafe due to the increase in speed and volume of traffic. Furthermore, maintenance engineers are finding their costs mounting to alarming totals such that road surfaces of the loose gravel and stone types cease to be economical. However, construction investments made only a few years ago cannot be discarded until their value has depreciated. Accordingly, any information as to the best methods of salvaging or treating such surfaces to reclaim the invested values, at the same time rendering improved service to the traveling public, is eagerly studied by highway engineers.

At highway conventions the problems and discussions on low-cost roads always occupy a prominent place on the programs. However, in the exchange of papers and discussions proper progress in solving the problems is seriously hampered by the lack of a common vocabulary, understandable by all. The terms introduced in such technical discussions are not clearly defined or are carelessly used. Even when specifications are quoted the discussion is often difficult to interpret. Different chemists have their own pet methods, and engineers their own taught or adopted practices. Viscosities run at 50° cent. are difficult to compare with those run at 60° or 40° cent. However, the U. S. Bureau of Public Roads has inaugurated a movement to bring the many groups together with a view of simplifying and standardizing terms, specifications, and testing methods. When this work is accomplished, the engineer will find it much easier and safer to compare notes, papers, and discussions.

There seems to be a general opinion that the present specifications and tests are not sufficiently comprehensive to be followed clearly or intelligently. Bituminous materials are derived from several sources and fields, each with varying and peculiar characteristics. An oil may contain 60 to 70% of 100-penetration asphalt, but what is the nature of this residue and what were the characteristics of the solvent or volatile portion? A cut-back asphalt may contain 25% solvent, but most specifications do not show, nor do common tests reveal, the nature of the solvent. Consequently, when reading or discussing technical papers on bituminous materials used in low-cost road construction, the engineer should do so with "his tongue in his cheek" and with a full understanding of the problem, if he desires to avoid costly errors. It is much better that he approach his problem hopefully, but carefully "feeling his way" with the materials and bitumens at hand.

The development of low-cost bituminous road surfaces in the Western States has been watched with considerable interest. The surface-treatment method is probably the oldest and best known. It requires a thoroughly compacted gravel or stone base. Usually, uncompacted or loose maintenance gravel that is swept from the surface, must be wasted on the shoulders. Most gravel and stone roads are none too thick at best to support surface treatments, and material should be added rather than removed. Furthermore, in compacting and cleaning the surface it is difficult to obtain the thoroughly smooth riding surface now demanded by high-speed traffic. Consequently, it would seem that the surface-treatment method has a rather limited field.

---

[13] Engr. of Maintenance, State Highway Dept., Jefferson City, Mo.

Road Surface Mixes.—The road surface mixes (or plant mixes) seem more nearly to fill all requirements for low-cost bituminous road surfaces. There are several types of mixed-in-place construction, and each type allows the utilization of existing uncompacted road surface metal, or added metal, to build extra thickness and strength to the gravel or stone base. At the same time, these methods permit the leveling and truing up of irregularities of the original gravel or stone surface.

Oil Mix and Fine Aggregate.—In 1928, the Missouri State Highway Department selected a section on U. S. Highway No. 71, in McDonald County, to try out a mixture of road oil and fine aggregate. Methods outlined by C. L. McKesson, M. Am. Soc. C. E., in his "Report of the Co-Operative Work Conducted by the California Highway Department and the U. S. Bureau of Public Roads," were adopted as a guide. The fine aggregate used is known locally as flint, or mine-run chats from the waste piles of the Joplin, Mo., lead fields. Selection was made to obtain as nearly as possible the following specifications:

Screen.	Percentage passing.
¾-in.	95 to 100
No. 4	50 to 80
No. 10	35 to 60
No. 200	5 to 15

The oil used in part met the following specifications:

Specific viscosity (Engler), 50 cu. cm. at 122° Fahr	50 to 65
Percentage of residue, 100 penetration	65 to 75
Percentage of volatilization, in 5 hours, at 160° cent., 20 grammes	15 to 25

Stain tests served as a guide in obtaining the proper mixtures; the mixing was done by blade graders and farm disks; the product was compacted under traffic; and blade graders were used to wipe out traffic marks until the mixture became thoroughly compacted.

The resulting surface texture closely approached sheet asphalt in appearance. Due to the inadequate base some failures occurred during the winter months. The following spring the job was re-worked and more thickness added, the original thickness being about 1½ in. The experimental work was also extended on U. S. Highway No. 71 through Newton and McDonald Counties, using several grades of oil. Oils of lower loss and heavier viscosity were used with fair success.

During construction it was found that to obtain good results, oil should be added in small quantities as the desired total quantity is approached, at the same time avoiding very carefully any excess. The experience with this type of construction has been variable. Aside from weak bases the main difficulty has been due to excess subgrade moisture. Ground-water causes failure apparently because it lifts the oil to the surface of the mix. The bottom portion of the aggregate may be found free of oil, whereas aggregate in the upper portion contains an excess, which results in the familiar corrugated effect. Mixtures of this type are not as adaptable to wet climates as to dry climates.

Road Mix: Retread Type.—The first low-cost bituminous road construction in Missouri was built by the State Highway Department in 1927, on U. S. Highway No. 60, in Greene County. Crushed and screened stone was mixed with several grades of tars and cut-back asphalt to produce a surface thickness of approximately 2 in. Crusher-run stones, 2½ in., 2 in., and 1½ in., in size, with fines out, have all been used. The preference seems to be for the 2-in. size. Stone chips of ¾-in. size are used to fill surface voids. Refined tar of 8–20 viscosity at 40° cent., has been used almost exclusively to prime the old gravel or stone base. Both refined tars and cut-back asphalts are used successfully in the stone mixture.

The equipment in such work consists of a distributor, a 30-h.p., crawler tractor, a multiple-blade maintainer for mixing, a 5-ton roller, a 10-ton roller, and trucks for hauling.

The advantages of this type of construction lie mainly in the fact that it can be built exactly to formula. Aggregate of known quantity and gradation is used. Care is exercised to spread the stone uniformly in a fixed amount per square yard. This is followed by definite alternate applications of bitumen and chips. Excessive mixing is avoided to prevent segregation of stone. An excess of bitumen must be avoided if shoving and corrugations are to be avoided later. In building roads of this type it is easy to add more bitumen if necessary, but very difficult to correct for any excess of bitumen applied. The mixing and leveling process enables the construction of exceptionally smooth-riding surfaces even over fairly rough bases. Large irregularities can be patched before the retread course is laid.

Sufficient time between applications must be allowed for solvents to come off, or for proper curing. The retread type of construction is open in texture due to the large aggregates used. This is an advantage in that proper aeration and curing are readily accomplished, which is necessary when cutbacks and tars are used. A seal may be applied later if necessary or desirable, but must not be applied until the bitumens are thoroughly cured.

During the five years since 1927 there have been no failures in this type of construction, except for lack of support, and these have been limited. Such failures are readily repaired by draining the subsoil and adding thickness to the base, and then patching. If failures are extensive the entire surface may be re-worked by leveling and adding more material. If necessary, another course may be built over the original one to obtain the necessary thickness.

Retread: Crushed-Gravel Type.—Where stone is not available at low cost, crushed, screened, and washed gravel may be used with equal success. If the gravel available is fine, crushed, and screened to pass a 1½-in., circular screen, tar has been found to be preferable. However, when the finer aggregates are used, it is necessary, of course, to increase the percentage of bitumen used.

Road Oil Mats.—During the two years, 1930–31, limited experiments have been conducted in compacting gravel and stone surfaces by the use of road oil. In modern gravel road construction, the road metal is windrowed along the shoulder and fed on to the surface blades as it is compacted by traffic. Maintenance replacement gravel is also placed in windrows and gradually bladed on to the surface. During dry weather, traffic loosens the gravel, and blades are used to return the surplus loose gravel to windrow, where it remains until wet weather will allow its return to the surface for compaction.

During experiments with road oil as a dust palliative, it was found that an excess of oil formed a mat. Under favorable conditions these oil mats gave good service. Consequently, road oil meeting the following specifications is being used experimentally for building oil gravel mats:

	Oil No. 2.	Oil No. 3.
Specific gravity, 60° Fahr./60° Fahr., not less than.........	0.930	0.960
Furol viscosity, at 122° Fahr..	125 to 225	225 to 380
Flash point, not less than......	190° Fahr.	194° Fahr.
Bitumen soluble in CS_2, not less than	99.5	99.5
Volatilization, 5 hours at 325° Fahr., 20 grammes	0 to 18%	0 to 18%
Percentage of residue, 100 penetration	55 to 75	65 to 80
Ductility residue, not less than.	50 cm.	50 cm.

The No. 2 oil is best for first or prime application, whereas the No. 3 oil is used for mixing with the gravel. The mixture is compacted under traffic and kept smooth by motor or blade graders until thoroughly compacted.

This method calls for an excess of oil, which is objectionable to traffic during the process of curing. During the first 2-week period the mixture is "messy," and traffic has just cause for complaint. Recently, a trial was made of the use of powdered asphalt, and early indications are most promising. Powdered asphalt shipped in paper bags was distributed through a lime spreader at the rate of ½ lb. per sq. yd. on a freshly oiled gravel surface. The powdered asphalt has a tendency to hasten the setting period, and possibly adds strength and body to the oil.

Width, Thickness, and Cost.—It would appear that any road carrying sufficient traffic to warrant these surfaces would also justify minimum widths of 20 ft. In some cases greater widths may be justified on account of their water-proofing value to shoulders and edges alone. Experience in Missouri proves that a 2-in. thickness is entirely sufficient to resist shear and scaling where the sub-base support is at all adequate. Greater thickness represents unnecessary waste of funds and possibly invites some trouble due to the difficulty of handling greater quantities in road mixing, and of proper curing which is a most important feature not to be overlooked, especially when tars and cut-backs are used with finer aggregates.

It is difficult to predetermine the strength of an old gravel or stone base. Slight movements under loads during frost or wet seasons are likely to be unobserved on a well-maintained gravel road. These movements are quite likely to become readily noticeable after the bituminous surface is built. Consequently, the type of bituminous construction first used should be of low cost, easy to reconstruct, easy to repair, and easy to add to, if necessary. As a general rule, base failures are confined to small isolated places or to particular portions of the projects. Funds conserved in the building of minimum thickness may be used for special treatment of these places.

Furthermore, in Missouri there is a marked tendency for any road (pavements included) to lose its true cross-section and profile under the action of climatic changes and the pounding of traffic. Therefore, it seems logical to conserve funds by building the required minimum thickness and to use the money so conserved at a later date to add extra thickness where necessary to obtain greater strength or to improve the cross-section and profile, or both.

Costs, exclusive of stone and gravel aggregate which vary greatly, range from $750 to $2 500 per mile for 20-ft. widths, depending upon the bitumens used. Oil-graveled mats, 1½ to 2 in. thick, cost from $750 to $1 000 per mile for oil, oil application, and mixing. Stone retread costs from $1 800 to $2 200 per mile, which includes cut-back or tar applied, spreading stone, mixing, and rolling. Seal coats of $\frac{1}{5}$-gal. application and 15 lb. of sand or chips per sq. yd., cost from $600 to $900 per mile additional. Gravel retread requires more bitumen on account of the greater percentage of fine materials.

If the cost of stone or gravel aggregates is charged against maintenance gravel replacement funds, the foregoing costs are net. Since these treatments conserve road-surface material from loss due to action of traffic and water, further reductions might be deemed proper.

Plant Mixing.—The experience in Missouri with plant mixes on low-cost bituminous road construction has been limited. Advocates of plant mixes claim certain advantages of control over mixtures not obtainable in road mixes. Possibly this is true with certain plants, but the contrary is only too true with many plant mixers. Where better control is obtained in the use of a plant mix without any appreciable increase in cost of production, a plant is justified. To justify its place in the highway program, the low-cost bituminous surface must remain in the low-cost field in fact and not in name only. Elaborate methods and expensive procedures must be avoided, especially if no material benefits are added. This type of construction does not justify frills.

On the other hand, low-cost bituminous road construction should not be haphazard or careless. Care and skill may be used without involving expensive methods.

Where tars and cut-backs are used, the engineer should remember the nature of his materials. These materials contain certain solvents that must come off and allow the body material to stiffen after mixing. Therefore, certain aeration is necessary, which is accomplished in a large measure during the turning and mixing process in the road-mix method.

New Construction.—The highway engineer should not confuse low-cost bituminous surfaces with high type pavements; they are poor substitutes. However, the low-cost bituminous surface has its own field, which lies between the traffic-bound stone or gravel road and the high type pavement designed to carry the combined traffic of high-speed and heavy vehicles.

Carlton N. Conner,[14] M. Am. Soc. C. E. (by letter).—All road builders are indebted to Mr. Frickstad for his successful efforts in developing low-cost roads on the Pacific Coast. Research and practice developed by him and his associates have gone a long way toward solving the problem of building thousands of miles of all-weather roads in the eleven Western and Mountain States at a total cost for surfacing, including base and bituminous surface, of less than $10 000 per mile.

Low-cost construction in the United States has been made possible by the extensive use of tars and asphalts as binders, local materials as aggregates, and improved equipment for the actual work. Developments have been so rapid that the time is now ripe for simplification of methods and specifications, and the standardization of tests for materials, in fact, a consolidation of the rapid and successful advances already made. A concerted effort at this time is particularly important because unmistakable signs and trends show that construction and maintenance of low-cost roads will more completely occupy the attention of road builders for several years to come.

To assist in clarifying the field for standardization and to focus attention on the principal types of low-cost roads, the writer invites attention to the following discussion which is based on present conditions.

Low-cost surfaces, of which there are large mileages, or which are growing in favor, are commonly grouped as: (1) Untreated surfaces; (2) non-bituminous surface treatments; (3) bituminous surface treatments; (4) bituminous road mixes; and, (5) bituminous plant mixes.

In 1931, the State highway systems had 169 000 miles of these low-type surfaces and 95 000 miles of high-type surfacing. Table 3 shows the trends in construction and maintenance of untreated and treated roads.

Untreated Surfaces.—Untreated surfaces are those which consist of mineral aggregates held together by the binding, compacting, or interlocking qualities of the materials themselves, or by the addition of mineral binder, such as clay. These untreated types include sand-clays, gravels, stone, chert, shale, and others less commonly used.

For the purpose of this discussion and to be consistent with tabulations already prepared by the American Association of State Highway Officials and the U. S. Bureau of Public Roads, untreated surfaces are grouped as: (*a*) Sand-clay and top-soil; (*b*) gravel, chert, shale, etc.; (*c*) water-bound macadam; and (*d*) miscellaneous.

---

[14] Engr.-Executive, Am. Road Builders' Assoc., Washington, D. C.

Sand-Clay and Top-Soil.—These types of road surfaces usually consist of clay, silt, fine sand, and coarse sand, with a total sand content of from 65 to 85 per cent. They seldom contain particles larger than ¾ in. in size.

TABLE 3.—STATE HIGHWAY SYSTEMS: TRENDS IN LOW-COST SURFACES BY MILES

State	Built during 1930, untreated and treated	PROPOSED 1931 CONSTRUCTION		EXPECTED 1932 CONSTRUCTION		EXPECTED 1932 MAINTENANCE

* Treated and untreated.

The States having from 800 to 3 000 miles of these surfaces are Alabama, Florida, Georgia, Kansas, North Carolina, South Carolina, Texas, and Vermont. In 1930, Alabama, South Carolina, and Virginia laid between 100 and 200 miles each, while Kansas surfaced more than 1 500 miles with sand-clay.

Gravel, Chert, Shale, etc.—Available tabulated classifications do not list separately the miles of treated and untreated roads, but the total at the end of 1930 was 107 000 miles. Only fourteen States have less than 1 000 miles of the gravel, chert, etc., types, while twenty-two have from 2 000 to 6 000 miles of each.

Gravel is used for surfacing in all States, and there is a marked trend toward using gravel passing the 1-in. screen with crushed particles favored. Until recently, traffic-bound surfaces of gravel, stone, or slag were used principally in Ohio, Indiana, Tennessee, Nebraska, and Iowa. This type has proved particularly economical and serviceable, and is meeting with favor in Kentucky, North Carolina, and elsewhere.

Traffic-bound surfaces consist of a layer of clean crushed stone, slag, and crushed or screened gravel evenly spread on a prepared sub-grade. This layer is kept smooth by constant blading. Traffic gradually compacts it from the sub-grade upward. Periodically, new aggregates are added, under traffic, until a surface of suitable thickness is built up.

Macadam.—Macadams of crushed stone, slag, crushed gravel, and Florida lime rock are commonly laid in one course, and, less frequently, in two courses, to form a well compacted surfacing, suitable for improvement with bituminous materials.

Roads of the macadam type, and specifications for them show notable differences in requirements for quality and size of aggregates, thickness of section, and details of construction, but a study of the specifications shows they are written to secure good quality and a practical gradation of the available local materials and that softer stone is permitted in base courses which, later, will be surface treated. In 1930, the State highway departments built 1 300 miles of this type, as compared with a total of 13 000 miles of gravel, chert, and similar types.

The States which have more than 1 000 miles of macadam types in their highway systems are Florida, Kentucky, Maryland, New York, Ohio, Pennsylvania, Tennessee, and Virginia. Kentucky leads the list with about 4 000 miles. Kentucky also built 400 miles of macadam in 1930, which was more than twice that built by any other State; but Florida, Pennsylvania, West Virginia, and Wisconsin each built more than 100 miles.

Miscellaneous Untreated Surfaces.— These include surfaces of various kinds of aggregate which are laid in one or two courses as a type of water or roller-bound macadam, or they are placed in loose layers of 1-in. or 2-in. thicknesses to form a traffic-bound surface.

Materials for them include scoria, decomposed (or disintegrated) granite, stone screenings, mine "chats," iron ore, top-soil, granulated slag, pea gravel, stamp sand, shell, and volcanic cinders.

The use of hand-napped field stone as a base, covered by crushed stone, slag, or gravel, has met with success in Pennsylvania in the surfacing of 1 700 miles of the 20 000-mile program of low-cost roads.

Non-Bituminous Surface Treatments.—The purpose of these treatments with calcium chloride or lignin binder is to lay dust and reduce the loss of aggregates.

Calcium chloride is commonly applied to the road surface in flake or powder form. It has been used quite extensively in Michigan, New York, Vermont, Maine, and, to a lesser degree, in other States east of the Mississippi River. It has not been successful in States having relatively low humidity.

Lignin binder is a liquid concentrate which when mixed with equal parts of water is sprinkled on a road surface. Lignin binders have been used principally in New Jersey and New York.

Bituminous Surface Treatments.—Bituminous surface treatments as commonly designated are two or three applications of bitumen which are covered by sand, gravel, stone, or slag. These successive applications of bitumen and cover make a thin bituminous mat from ½ in. to 1 in. in thickness, which is well bonded to the base; when more than 1 in. thick these dragged or mixed surfaces should be designated as road-mix. The recent and successful innovation of dragging surface treatments which are less than 1 in. in thickness, during construction, makes them approach the road-mix type in texture, appearance, thickness, and smooth-riding qualities.

Bituminous surface treatments have been extensively used in the North Atlantic and South Atlantic States, Ohio, Indiana, Kentucky, and Florida on macadams and, in more recent years, on gravels, sand-clays, and traffic-bound surfaces.

Applications of light asphaltic oils on earth roads have met with little success as compared with heavier bitumens on macadams and other substantial bases. In certain instances on selected soils which were stabilized naturally or artificially by coarse granular particles, such as coarse sand or stone screenings, they have improved the road surface.

Bituminous Road Mixes.—The term, "road mix," is used to designate the surface obtained by mechanical mixing of aggregates and bitumen directly on the road itself. "Mixed-in-place" is another term widely used and equally descriptive. Road mixes are commonly from 1 in. to 3 in. in thickness and are not to be confused with plant mixes or with dragged-surface treatments.

Although there are other types of bituminous road mix, such as the fine aggregate types, which use sand-clay or blow sand for aggregate, most of them are in the experimental stage. There are two distinct types of road mix which are identified by the characteristics of their aggregates. These types are the "graded aggregate" and the "coarse aggregate."

The "graded aggregate" type is usually composed of gravel or stone and sand uniformly graded from a maximum size of about 1 in. to dust. These aggregates are as found in the road, as added to the road surface, or as added and mixed with aggregate already in the road surface. The type is used extensively in the Western States, the Southwest, and parts of the Mississippi and Ohio Valleys, where it is known by such names as "oil mix," "oil process," and other designations.

The "coarse aggregate" type, or "macadam aggregate" type, as the name implies, is composed of aggregates the characteristics of which are similar to those commonly used in macadams. They must be hard, durable, and preferably angular, such as crushed stone, slag, and crushed gravel. The aggregates are uniformly graded from those passing the 1½-in. screen to those retained on the ¼ or ⅜-in. screens. This type, also widely known as "re-tread," is built principally east of the Mississippi River and west of the Atlantic Coast States. Indiana, Pennsylvania, Kentucky, and Tennessee have each several hundred miles.

Still another type of road mix should be mentioned which for convenience may be termed "road-mix—fine aggregate" type. This type includes bitumen mixed on the road with sand-clays, sand-gravels, fine clay-gravel, or blow sands, the aggregates in which are much finer and commonly of poorer quality than those of the "graded" or "coarse aggregate" types.

Work on such roads has been confined to limited areas or has been of an experimental nature. Experimental work on them is still in progress (1932), and they offer a potential field for needed development. Attention is invited to experimental work in South Carolina, Florida, North Carolina, California, Nevada, and Minnesota, and to extensive usage in Long Island, New York.

Bituminous Plant Mixes.—"Plant mix" means the utilization of fixed or portable plants to prepare low-cost surfacing mixtures of bitumen and aggregates. The aggregates for plant mixes in low-cost roads are commonly those of the graded type already described, but they may be of the coarser sizes.

The object of plant mixing is to insure closer control of proportions and uniformity of mix than is possible by mixing in place on the road surface. As a result any plant mixing produces more fully coated aggregates than road mixing, but the requirements in specifications should not be so severe as to discourage contractors and manufacturers from developing plant mixes at low cost.

Whether or not the extra cost of plant mixing is justifiable has not been fully established, but experience and trends indicate its growing popularity where cost of aggregates and hauling is low, or where the road needs surfacing with aggregates which are of better quality than those found in the existing surface.

HAROLD L. TILTON,[15] ASSOC. M. AM. SOC. C. E. (by letter).—To any one outside the Western States this paper emphasizes the fact that while the general methods of construction are quite similar throughout the country, the engineer in each section must adapt these methods and principles to meet the climatic conditions to be encountered in his State and utilize to the best advantage the particular aggregates and bituminous binders that are available to him.

In New England, the use of a light fuel oil which would tend to emulsify in the presence of moisture, would be out of the question in the construction of a road that would be satisfactory at all times of the year. Rain occurs often and at any time. In the winter, the frost penetrates deeply. In the spring, it comes out of the sub-base while the atmospheric temperature is still so low that a bituminous surface lacks the plasticity that it attains later in the season. Aggregates containing fillers, such as silt and argillaceous materials, which possess a greater affinity for water than for bitumen, must be avoided. Surfaces built with such materials would be summer roads only.

---

[15] With Vermont Dept. of Highways, Montpelier, Vt.

Engineers in New England are forced to use the heavier oils, and it is interesting to note that the author states that the trend in the West is in the same direction.

For dust-laying purposes only the Vermont Department of Highways ordinarily uses calcium chloride. Low-cost bituminous roads in Vermont are an intermediate type of surface designed to meet traffic conditions where the chloride-treated surface cannot be maintained satisfactorily, and yet where the cost of a high type of pavement is not warranted. One problem is common throughout the country. There are many miles of secondary roads badly in need of an improved surface and there are comparatively few dollars available for the needed improvement. The low-cost bituminous road seems likely to be the solution of that problem.

The use of the drag, the retread mixer, and the blade grader, together with the development of emulsions, retread tars, and cut-back asphalts, has revolutionized the art of constructing and maintaining low-cost bituminous surfaces. In the past most of them were far from being smooth-riding roads. This was due to the fact that hand labor was used so largely in spreading the aggregates. To-day, it is possible to build low-cost bituminous roads by machinery with a minimum of hand labor, that are very smooth riding. Furthermore, by similar methods, they can be kept smooth riding, which is a highly essential factor to be considered.

Mr. Frickstad's statement that the principal failures continue to arise from faulty support, due to deficiency in thickness of metal or stability of subgrade, deserves careful consideration.

It is quite evident that a bituminous-treated surface of gravel or broken stone 2 or 3 in. thick, has little inherent resistance to deflection. Such a surface will retain its true cross-section and grade just as long as it is unyieldingly supported by the foundation on which it rests. An adequate and well-drained sub-base is absolutely essential to the success of such a road. It is a waste of money to construct a bituminous treated surface on a subgrade that will fail to support it.

The importance of a sufficient thickness of metal is the reason why the mixed-in-place method is used on gravel surfaces in Vermont, instead of surface treatment. By the former method an adequate and fairly uniform thickness of metal is obtained at once, which, by the latter method, is usually secured only after several successive years of treatment. The depth of surface obtained by the penetration method varies according to differences in the grading of the gravel, and most of the aggregate particles have a heavier coating of bitumen than is necessary to make them adhere to adjoining particles. A familiar comparable fact is that a thin film of glue will make two pieces of wood adhere more strongly than a thick film. In the mixed-in-place method, the particles are coated with only enough bitumen to bind them together properly and a fairly uniform depth is obtained.

Thus far, experience has led highway engineers in Vermont to prefer the use of tar in the construction of gravel surfaces and the use of cut-back asphalts and emulsions in the construction of broken-stone surfaces.

The author states that "the grading of aggregate has not tended to become standardized, which confirms the opinion that a wide range is acceptable for oil mixing." This bears out experience in tar mixing in Vermont, where aggregates have been used with a range in maximum size from ¾ in. to 2 in. and containing a variation in fineness modulus of the sand from 2.60 to 4.10. Good results have been obtained with the stone content of the aggregate ranging from 40 to 75 per cent. An aggregate containing about 70% of stone produces the most stable and best wearing gravel surface.

In oil mixing the author states that the proportion passing the 200-mesh sieve is an important element. In tar mixing its importance lies in the desirability of its elimination. An excessive quantity of material passing not only the 200-mesh, but also the 100-mesh, sieve, almost invariably is present in surfaces that have failed from lack of stability. Particularly is this true when the fine material is argillaceous, which type possesses a greater affinity for water than for bituminous binder.

A broken-stone mixed-in-place surface is unquestionably stable. Its stability is due to three factors, namely, the keying and interlocking of the angular pieces of stone, the grading of the stone, and the binding qualities of the bitumen. In such a surface there is a considerable percentage of voids both large and small.

A gravel surface containing a coarse sand may contain a small percentage of voids such as would be caused by the absence of material passing the 100-mesh sieve. It may possess high stability due to the fact that so many of the stone and sand particles are quite angular. When the gravel is crushed, this characteristic is even more pronounced. A washed, crushed gravel surface containing 70% of stone is not greatly inferior to a broken-stone road when the stones in each case are of an equal degree of hardness and the proper bitumen is used in each surface. The removal of the very fine material is a decided advantage. As in the broken-stone road, a limited excess of bitumen can be taken care of by the voids. On the other hand, an excess of bitumen with a gravel in which all the voids are already filled with fine material, will be quite likely to develop instability.

A sharp sand, with a fineness modulus of not less than 2.65 and preferably about 3.50, with a color rating of not more than 2, and containing not more than 5% passing the 100-mesh sieve, is most satisfactory for tar mixing. The more closely the characteristics of a gravel surface approach those of a broken-stone surface, the more stable it is likely to be, and the less maintenance it will require.

The author notes the presence of an excess of 200-mesh material, usually clay, whenever failures occur from moisture conditions. This appears to be almost invariably the case. On one project in Vermont the gravel was washed to remove the fine material of an argillaceous nature and the results were decidedly satisfactory. Clay, silt, and loam are no more desirable when mixed with bitumen than when mixed with cement.

The wear of the gravel preferably should be not more than 20%, although gravel with 24% wear may be used if no harder gravel is available. The best results have been obtained by crushing and screening the gravel, separating the sand, and re-combining them in definite proportions. For most gravels a tar of 20 viscosity is advisable for the mix and one of 40 viscosity for the seal, although the lighter tar has produced a good seal. On one project a retread tar of 65 viscosity was used for the seal. It was covered with a coarse hard gravel of 1¼-in. maximum size and dragged and rolled. This produced an excellent non-skid surface. Two additional requirements in tar specifications are now under consideration by the New England States. A requirement for specific gravity will eliminate an excess of water-gas tar in the blending. A lower limit for the softening-point requirement should eliminate a tar unsuitable for cold wet weather conditions. The author's estimate for bitumen, of ½ gal. per sq. yd. per in. of finished thickness (varying, of course, with the grading of the aggregate), seems to be the general experience.

For gravel mixing a 20-ft. drag has been designed, with blades in zigzag arrangement, which has proved the fastest and most efficient mixer. A grader with approximately the same wheel-base is a necessary supplementary piece of equipment for the final shaping.

It is advisable in the construction of both gravel and broken-stone surfaces to apply a prime coat of bitumen to the sub-grade about a week in advance of the surface construction. This serves the double purpose of eliminating the dust nuisance to the public during construction and prevents the inclusion in the mix of undesirable fine and unclean materials from the sub-base.

Broken-stone surfaces may be constructed successfully with an aggregate not larger than 2½ in., which materially increases plant production and decreases costs. It is desirable, as in hot-penetration macadam, to have the maximum size of stone nearly equal to the depth of surface. For the seal, a stone graded from ¼ to ¾ in. is used. In a New England climate the heavier cut-back asphalts are the most satisfactory. The best results have been obtained with the use of a so-called benzol cut-back having a viscosity (Engler, 50° cent.) of 150 to 175, distillate at 680° Fahr., of about 20%, and penetration of the residue of 90 to 100. The surface obtained with this asphalt compares favorably with that produced by the use of a hot-penetration asphalt in macadam construction. In building broken-stone mixed-in-place surfaces, a grader with a wheel-base of 18 ft., or more, is a satisfactory mixing and smoothing agent. The seal is smoothed by the use of the drag or the retread mixer.

Good results have been obtained with the use of a penetration emulsion, the stone being smoothed by a grader, and the emulsion applied in three applications, each properly keyed and rolled. The emulsion has one property very definitely in its favor in a New England climate; it may be used with a wet aggregate. The time lost in construction in Vermont during 1931, while waiting for aggregates to dry, represented no small sum of money.

The average cost of gravel mixed-in-place surfaces constructed in 1931, including the cost of the new gravel, was about $3 600 per mile. On most projects this gravel had to be hauled from 3 to 8 miles. The cost of mixing and rolling alone was about $200 per mile.

The average cost of broken-stone mixed-in-place surfaces constructed in 1931, including the cost of the stone, was about $5 600 per mile. All this work was done by State forces.

The construction of low-cost bituminous roads necessarily means that local aggregates should be used to as great an extent as possible. This requires study as to the best methods of combining them with the bitumens that are available in that particular section of the country.

L. I. HEWES,[16] M. AM. SOC. C. E. (by letter).—That low cost or intermediate types of bituminous road have made substantial contribution to the road developments of the West cannot be questioned. On December 31, 1930, practically 20% of the Federal Aid highway system of the Western States consisted of a surface-treated, plant-mix, or road-mix construction, described by Mr. Frickstad.

Materials.—Aggregate of surprisingly wide range of grading continues to be successful in road mix under varying conditions and with different available local materials. General Western practice in 1932 is to use aggregates of 1-in. maximum size to dust, and a 2½-in. minimum compacted thickness of road-mix or plant-mix surface courses. Oils of higher viscosity are meeting with increased favor, especially where moisture influence is expected. When light oils are used, some engineers are placing a seal coat of heavier oil, with sand or screenings, two weeks or more after completing the road mix. There has been a limited use of "armor coat" treatment approximately ½ in. to ¾ in. thick placed on previously constructed road mixes. All surface treatment requires great care in distribution of material and cannot wholly correct imperfections in the under surface. Cut-back plant mixes are being tried, especially in California. It should be borne in mind that the use of cut-back asphalts or asphaltic oil of higher viscosity increases the cost of scarifying or remixing whenever required during maintenance.

Construction.—No formula yet proposed for the control of the oil and aggregate has received general endorsement. Advance laboratory analyses and tests of the aggregates and bituminous materials will usually furnish valuable indications. It is well to know in advance whether the aggregate is highly absorptive, in order to avoid a lean mix which might ravel. Bituminous mixes that would give unsatisfactory service under unfavorable moisture conditions because of characteristics of the fine material, are often detected in the laboratory by a swell test.

A moist or loose uncompacted base is a frequent cause of distress. Many road-mix or plant-mix projects, with aggregate ranging from 1 in. to 200-mesh material, have shown failures traceable to excess moisture in the materials during the mixing or prior to the final spread and compaction. Most engineers think that an excess of 3% moisture will prevent satisfactory compaction on the road, or possibly cause failure. Accordingly, the practice of heating aggregates in plant mixing is increasing.

Adherents of plant mix claim better control and the possibility of using materials of higher viscosity. Its field is limited, necessarily, to projects on which the mineral aggregates to be treated have not been placed on the road. Plant-mixed material that becomes wet before spreading should be bladed until the condition is corrected. This operation is also frequently used to increase the evaporation of the solvent in cut-back mixes. Contractors do not resort to rolling ordinarily. However, it is advantageous under unfavorable traffic conditions, for compacting the edges, also when heavy rains are expected, or when relatively quick-hardening asphalt products are used in late season work.

---

[16] Deputy Chf. Engr., U. S. Bureau of Public Roads, San Francisco, Calif.

Equipment manufacturers are developing several types of self-propelled machines designed to mix the materials while moving along the road. There may be a field for further experimentation in this direction.

Oil road construction commends itself because of low first cost and cheap maintenance. Expensive refinements in plant mixing and road mixing should be avoided unless the results are certain to be commensurate with the increased cost. Unwarranted expenditures, especially when expensive importation of aggregates is involved, also must be watched.

Paper No. 1838

EFFECTS OF BENDING WIRE ROPE

BY FREDERICK C. CARSTARPHEN[1], M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. ROBERT C. STRACHAN, C. D. MEALS, O. P. ERICKSON, F. W. DECK, O. G. JULIAN AND J. C. DAMON, A. S. RAIRDEN, AND FREDERICK C. CARSTARPHEN

SYNOPSIS

An ever-present suspicion appears in the discussion of wire rope to the effect that the popular formulas for the estimation of the loss of strength due to bending may not be consistent with experiment. This can be settled only by holding the problem up to engineering and analytical scrutiny.

This paper is a start along this path. New and more comprehensive formulas are presented, which may serve a useful purpose in bringing to light data and analyses of the problem that have not been published by those who have given their attention to the subject. Wire rope is one of the most used, and most abused, commodities of industry. Therefore, all its properties should be known, to the end that the public and the wire rope manufacturer may agree upon the increase in its cost, if necessary to provide for more safeguards in the selection of materials and in the process of manufacture, so that its performance may be predicted for a properly supervised service.

Notation.—The symbols used in this paper are defined at the place in which they are first introduced in the text and, in addition, they are completely listed and defined in Appendix I.

HISTORICAL NOTES

The name of the inventor of wire rope is probably lost forever in the mist of antiquity. Samples of wire rope made of bronze have been excavated among the ruins of Pompeii; but, apparently, they consist of three strands twisted without the use of a center. Albert of Clausthal made ropes of both regular and lang lay in 1834, and for some years thereafter, and discussed

NOTE.—Published in December, 1931, *Proceedings*.

[1] Cons. Engr., Denver, Colo.

haulage technique.[2] In America, credit is given to the late John A. Roebling, M. Am. Soc. C. E., as the pioneer wire rope maker. He manufactured a piece of $\frac{3}{4}$-in., 6 × 7, iron rope, about 300 ft. long, at Saxonburg, Pa., in 1840. This rope, which was used on the canal plane near Portage, Pa., was made on a ropewalk such as was formerly used in the manufacture of fiber ropes. In 1848, the works were moved to Trenton, N. J., and wire ropes were made for use on suspension bridges, for towing canal-boats, and for such other service as required greater strength than could be secured from hemp ropes of reasonable size.

The excellent qualities possessed by wire rope soon won for it deserved popularity and, in 1886, the Trenton Iron Company undertook its manufacture, using machines designed in accordance with the best English practice. As in the case of many other innovations, the market was soon "saturated," and in order to stimulate sales each manufacturer began to offer different types, styles, and grades of rope. This was the period when iron was being abandoned for steel, and it was the proper thing to claim that certain ropes were made of the highest grade crucible cast steel, plow steel, and super-plow steel. It was not sufficient alone to vary the grades of steel, but the construction of wire rope was varied so as to appeal to the whim of the most exacting customer, and each change was always heralded as being a superior product and claims were made that it could not be excelled for the use intended. Although many bizarre constructions of rope have been abandoned, many wire rope catalogs contain more than eighty tables giving the properties of the different styles of wire rope that are manufactured. To quote Mr. Thomas Woodhouse, of Dundee, Scotland:[3]

> "The introduction of aerial ropeways as a means of transportation some 50 or 60 years ago, created a demand for steel wire ropes previously non-existent. * * * Aerial ropeways now provide a big outlet for steel wire ropes of almost all constructions."

TERMINOLOGY

It is reasonable to assume that with so many different kinds of wire rope, confusion sometimes arises concerning its properties and its ability to render service. As a matter of fact, wire rope is nothing more than an assemblage of wires arranged so as to permit it to meet, in the best manner, several general conditions which bound the limit of its use. It may be ideally adapted to discharge a certain duty, but as the limits of its usefulness are extended the border line is reached at which failure is encountered, not through any inherent defect in the wire rope, but because it is not capable of service in an infinite number of fields. There is no other material used for engineering purposes which will stand greater abuse and still function satisfactorily than wire rope; yet it has its limitations and should be used accordingly. It is proposed, therefore, to consider several properties of wire rope which follow from the nature of its construction.

In the remarks that follow, the lines that are of such size and construction that they can be put in motion, will be considered as "ropes," and those that remain at rest, as "cables." The term, "cable," is also applied to ropes of large size, as is also the word, "hawser," when the cable is used for towing purposes. In the electrical field, the words, "cables" and "guys," are in general use.

---

[2] *Mining Journal*, London, England, 1837.

[3] Encyclopedia Britannica, Edition XIV, Vol. 23, p. 675.

Wire rope is an assemblage of wires, and the strength of each wire depends upon the composition of the material from which it is drawn, the number of drafts given, the diameter, and the heat treatment which it receives. Hence, it follows that those wires which have been subjected to the greatest number of drafts, and are properly heat-treated, have a higher tensile strength than those of larger size. Unfortunately, wires of small diameter will not stand abrasion and abuse without breaking. It is concluded, therefore, that strong ropes should be built of a number of small wires. Those which are subject to surface wear should be built of larger wires. When both strength and resistance to wear are desired these two properties must be combined, and it is here that the skill of the rope maker is best shown.

Obviously, as long as ropes remain stationary and sustain loads which do nothing more than cause a variation in tension, it is quite sufficient to gather the wires together in a bundle and serve them with wire or tape so as to preserve their grouping and protect them from the weather. Cables of this so-called "selvagee" construction are used on suspension bridges, particularly because this type of cable may be erected in position by stringing the individual wires in place between the bridge towers. To speed the completion of suspension bridge cables, wires are assembled in groups of 200 or more, or as wire cables, and are set into place to make the bridge cable, thus doing in days what formerly required months by "spinning."

CHARACTERISTICS

In addition to strength, wire rope must acquire two other qualities, namely, flexibility and resistance to wear. Since fiber ropes have been made from the earliest times, it is natural to wonder why the development of wire rope did not advance accordingly; but like all great innovations, apparently simple, it was impossible until several associated problems were solved. Just as it is impossible to build an arch without a center, so it was impossible to undertake the construction of wire rope on a commercial scale until sufficient progress had been made in the wire and steel industries, that would insure the production of rods of such quality and quantity that they could be drawn into long wires possessing adequate strength. Prior to about 1850 the iron and steel industry had not made sufficient progress to permit the development of wire rope as it is now known.

Some time in the early part of the Nineteenth Century the important discovery was made, by either Albert of Clausthal, or J. Wilson of Derby, or by both independently, that flexibility could be secured by using fine wires twisted into strands and that the strands could be laid about a fiber center to form ropes. As this process can be done in a great variety of ways, different manufacturers adopted different designs for the symmetrical arrangement of the wires in the strands, the direction of the twist, and its pitch, which is called the lay. Reference to any company's rope list will show the arrangements which are considered to be standard. As experience was gathered in the use of wire rope there has been a gradual shortening of the lay of the wires and strand. In 1890 it was not uncommon to find 6 × 7 wire rope having a lay of wires forming the strand equal to thirty times the diameter of the wire, and a lay of rope equal to nine times the diameter of the strand. In modern practice the corresponding ratios would be nearly 22.5 and 6.5. In other words, with increased tensile strength of wires, it is possible to increase flexibility without a serious sacrifice of strength, although the tables adopted by the Wire Users Association in 1910 and in 1929 each assigned lower values to the breaking strengths of plow and super-steel ropes than formerly.

As an aid in estimating the theoretical number of wires in the diameter of a rope, the lay of the strand, and the lay of the rope, in terms of the diameter of the wires, Table 1 is presented.

TABLE 1.—STANDARD CHARACTERISTICS OF WIRE ROPE

Kind of rope	Lay of strand*	Lay of rope*	Number of wires in the diameter of rope
7-wire, ordinary	$22.4d'$	$58.3d'$	9
7-wire, lang lay	$22.4d'$	$62.8d'$	9
Seale, ordinary	$29.4d'$	$76.6d'$	12
Seale, lang lay	$31.4d'$	$82.6d'$	12
19-wire, ordinary	$35.7d'$	$93.0d'$	15
19-wire, lang lay	$38.1d'$	$100.0d'$	15

* d' = diameter of wire.

The strengths of the various steels used in the manufacture of wire rope (in kips[4] per square inch), are generally accepted, as follows:

Iron wire	85 to 105
Mild cast steel	160 to 180
Cast steel	180 to 200
Extra cast steel	200 to 220
Plow	220 to 240
Super-plow	240 to 280

All the foregoing varieties of steel are used in the manufacture of wire rope. However, it is not sufficient to examine the wires for tensile strength alone; they must also be examined for torsion, bending, and elongation. The tensile strength and elongation are determined in the usual manner in a standard testing machine. When elongations are required an extensometer is used to ascertain the increments in loading. When the yield point is reached the instrument is removed. From the data secured, plus a knowledge of the area and the length of the specimen tested, it is possible to calculate the modulus of elasticity of the steel. This factor varies, of course, depending upon the composition of the steel, but will usually be found to be between the limits of 25 000 to 30 000 kips per sq. in. In other words, the modulus of elasticity is the load required (theoretically) to extend the specimen a distance equal to its own length, and is of considerable importance in solving problems connected with the stresses caused by changes in length of the specimen, whether it be by temperature, or by exterior or interior loading.

---

[4] 1 kip = 1 000 lb.

The torsion test is made to determine the number of twists about a longitudinal axis which a wire will stand and, in a way, it is a measure of its ductility. Wires possessing a diameter greater than 0.04 in. are mounted in a machine constructed so that it has two opposed heads fitted with chucks or clamps for holding the wire. These heads are usually spaced 8 in. apart and run 33 rev. per min. in opposite directions, giving an equivalent twisting speed of 66 rev. per min. Means are provided for placing the wire under a known tension, thus standardizing the test. The torsion test quickly reveals brittle wires and is confirmed by the results of the kink and jig tests. Wires which are sufficiently small to be bent by hand into loops such that the diameter is approximately that of the wire, are tested accordingly. This is the kink test and is usually confined to wires less than 0.04 in. in diameter. Larger wires are bent 120° in four directions about dies of a given radius, depending upon their size, by means of a special device called a jig. As an illustration of the variation of the torsion and bending resistance in different grades, Table 2 is presented for a 0.111-in. wire such as would be used in a 1-in., 6 × 7 rope. The torsion specimens are under a tension of 23 lb.

TABLE 2.—TORSION TEST OF WIRES, 0.111 INCH IN DIAMETER

Grade	Breaking strength, in kips	Twists in 8 in.	Jig test (in standard jig)	Percentage elongation
Mild steel	1.57	26	Four 120° bends	2.3 to 3
Cast steel	1.70	26	Four 120° bends	2.3 to 3
Extra strong cast steel	1.96	25	Four 120° bends	1.8 to 2.8
Plow	2.16	24	Four 120° bends	1.8 to 2.6
Super-plow	2.36	22	Four 120° bends	1.6 to 2.6

It is possible to make wire for ropes from both basic and acid steels up to the plow grade, but open-hearth acid steels are preferred. It is understood that steel wire possessing the requisite properties for making suitable wire rope can be secured only by a careful control of the composition of the steel in the furnace, by a proper cropping of blooms, and by the discreet rolling of billets into rods. These steps must be followed by the elaborate and painstaking processes of cleaning, baking, wire-drawing, annealing, and heat treating, or "patenting," all of which combine to make possible the production of the high tensile strengths which characterize wires used for this purpose.

Table 3 illustrates the progressive increase in strength acquired by an acid open-hearth steel rod, $\frac{5}{16}$ in. in diameter, due to wire-drawing. The specimen had the following composition: Carbon, 0.8%; manganese, 0.6%; silica, 0.14%; sulfur, 0.009%; phosphorus, . . . ; and copper, 0.03 per cent. The fact that the elongation in 10 in. had dropped from 4% to less than 1.1% emphasizes the interdependence between the elasticity and strength. In other words, flexibility is not a property of wires possessing high resistance to rupture. Accordingly, wires possessing a strength of 300 kips per sq. in., or more, are usually so brittle as to be considered worthless for wire rope manufacture. This statement is qualified for steels of music-wire grade, and a few alloyed steels, the cost of which precludes them from use in wire ropes.

TABLE 3.—INCREASE IN STRENGTH ACQUIRED BY WIRE DRAWING

Observation	Diameter, in inches	Breaking Strength		Percentage elongation, in 10 in.
		In kips	In kips per square inch	
0	0.3125	4.60	60	(Unstressed)
1	0.191	5.160	180	4.0
2	0.159	3.975	200	3.5
3	0.132	3.145	230	2.4
4	0.093	2.095	308	1.1

MECHANICAL DEVELOPMENT OF MANUFACTURE

When the testing room passes the wire as satisfactory, it is delivered to the rope shop and wound upon bobbins for use in the strand-making machines. The development of wire-rope stranding machines is an interesting one. When Mr. Roebling undertook the manufacture of his first wire rope it was done in a rope walk, similar to the method used in the manufacture of fiber ropes. Albert of Clausthal, the accredited inventor of wire rope, followed a similar method of manufacture. It happens that, in 1838, Mr. R. S. Newall, of Dundee, Scotland, received a letter from a friend commenting upon the method in vogue in Saxony for making wire rope, consisting of four strands of four wires, $\frac{3}{32}$ in. in diameter, twisted together. The friend stated that the process was exceedingly crude and urged Mr. Newall to design a machine for this purpose. Within a month he had prepared the plans of the machine, and, in August, 1840, secured the British patents for the production of wire rope formed by closing strands about a core.

For many years after the introduction of this machine it was felt that means must be used to prevent twisting the individual wires when incorporated into the strand. This resulted in keeping the velocity of the machine at a minimum, 40 to 50 rev. per min. being considered a maximum. An American, Mr. J. B. Stone, of Worcester, Mass., invented a stranding machine which eliminated the gears and other equipment used to prevent torsion in the wires, and, as a result, higher operating speeds were secured.

WIRE-STRANDING MACHINES

The type of machine most favored in America consists of a suitable bedplate, supporting rollers; these, in turn, carry the flyers which are connected by rods. The flyers are placed so as to accommodate a floating cradle which, in turn, carries a bobbin. On the 19-wire stranding machine provision is made for supporting nineteen bobbins. The cradle is constructed with a counterweight and is mounted in the machine so that it does not revolve when the machine is in motion. By giving over to gravity the control of the position of the bobbins, the machine may be operated at high speed. The wires are conducted to the front end of the machine and are led from the ports of the flyers through the slots of the twisting head which wraps them about the wire center.

There must also be longitudinal motion to form the strand. The machine is equipped, therefore, with a draw-out mechanism, which consists of multiple grooved sheaves arranged so as to revolve at a speed which bears a fixed ratio to the number of revolutions of the machine proper. As an illustration, for a certain size of strand the draw-out mechanism handles 1 in. of strand per revolution of the machine. If the draw-out mechanism should cease to function, the strand would soon be twisted in two. In order to vary the velocity of the draw-out mechanism a speed-changing device is used. For instance, two spur gears may be carried in a frame equipped with a handle and mounted upon a spline shaft. When the operator wishes to change the speed ratio it is only necessary to raise the frame, slide it along the shaft until the proper driving gear is encountered, and then drop it into position. Since right or left-lay strands may be required, it is necessary for the draw-out mechanism always to run in the same direction irrespective of the rotation of the machine. This is accomplished by using opposed bevel gears and a pinion.

These machines are rated according to the weight of the wire held by the bobbins, such as 50, 100, or 250-lb. machines. The greater the weight of the bobbin the larger the machine and the slower it must run because of the rotative forces developed. This machine is not rigid, and each flyer is supported on rollers. Both ends of the machine are driven from a countershaft which extends its full length. In practice, it is found difficult to keep a constant pressure on the several rollers. The machine is also equipped with multiple solenoid brakes that act simultaneously and tend to reduce unbalanced stresses in the frame when being brought to rest.

Machines have been built so that strands composed of more than nineteen wires could be laid up in a sequence of continuous operation. Such a machine would be called a tandem compound wire-stranding machine. The first unit would be arranged so as to lay the six wires on the center, the next would place twelve wires, then eighteen, and finally, twenty-four, making a strand of sixty-one wires. Unfortunately, the speed of the assembly depends upon the rate of laying the initial six wires. Since these tandem machines were of considerable length, it was necessary to group each multiple of six flyers in the same transverse plane, giving the planetary arrangement. This arrangement entailed flyers of large dimensions, so that the centrifugal stresses were considerable. The result secured was not satisfactory because of the lack of speed of the assembly. It has been found preferable to prepare the strands as a series of single operations and thereby increase the speed of each one to the limit of economical and satisfactory manufacture. Compound rope machines were also perfected based on the idea of arranging six stranding machines so as to manufacture the strand and close the rope in one continuous operation. These machines have also been superseded because of their inability to give a satisfactory output in competition with superior high-speed stranding machines and a closing machine which run independently at efficient speeds.

The method of assembling the strands into wire rope is very similar to that used in making strand, except that the rope is formed by closing the strands about the fiber or wire rope center. The speed of a closing machine is much less than that of a stranding machine, because of the great increase in weight of the revolving parts. A fair speed is 45 rev. per min.

TYPES OF WIRE ROPE

There are several other classes of cable which are worthy of attention. Locked-coil cables consist of a center of seven or nineteen round wires. When of sufficient diameter the core is covered with several layers of trapezoidal or key wires. The exterior surface consists of a layer of interlocking wires which are placed so snugly as to give a smooth and cylindrical appearance to the cable. Unfortunately, these wires are of large relative cross-section, and as made in America, do not exceed 150 kips per sq. in. in tensile strength (secured by special heat treatment called "patenting").

Half-lock cables are wire strands covered with round and shaped wires to give a smooth exterior. Wires of relatively large diameter are used. In order to improve the tensile properties of the cable, the expedient has been adopted of using many layers of small cross-sectional key wires and covering the assemblage with lock wires. This type of cable is known as locked-wire cable, the word, "wire," conveying the idea of the small key wires in its construction.

Cables formed of nineteen, thirty-seven, and sixty-one round wires as a single strand are known as track strand or smooth-coil cables. All the types aforementioned find their primary use as track cables for aerial tramways and cableways.

Experience in the use of wire rope has demonstrated that one of the most vital factors for long life is interior lubrication. Therefore, the most modern practice of rope construction demands that a center be used which is thoroughly impregnated with a lubricant. Various methods have been tried, such as running the rope, when closed, through a bath of melted petrolatum or a solution of vaseline in fuel oil. The drawback to this system comes from the fact that commercial African or Javanese hemp contains considerable air and moisture which prevents the saturation of the center with the heated oil. To overcome this it is considered good practice to saturate the rope center with hot lubricant in a vacuum chamber. This process impregnates the center with sufficient oil to meet any demand which may reasonably come upon the rope, if properly cared for, during its life.

Practically all ropes of the twisted-strand construction, if more than 200 ft. in length, are wound on wooden reels, which are all built to dimensions that have been standardized by the wire companies.

ANALYSIS OF STRENGTH

Since wire rope, from the inherent nature of its construction, is based upon the twisting of wires, it is proper to investigate the strength of the strand as compared with the sum of the strengths of the individual wires.

Example 1.—Curved Wire About a Straight Center Wire.—Fig. 1 represents a piece of straight wire, l', loaded axially by the tension, T'.

If a piece of the same kind of wire is wrapped about it so as to form a helix (Fig. 2(a)), the stress in the curved wire as compared to that in the straight one may be investigated. It is not so easy to visualize a force acting in curved wires as in straight ones, so the bent wire may be straightened after cutting both the wires by parallel planes a distance of one unit apart, which is assumed to be the lay or pitch, l', of the helix. In twisting the wire its center moves in a curve the horizontal projection of which is a circle whose diameter is equal to $2\,d'$; but the horizontal distance is equal to the circumference of this generating circle, or $2\pi d'$. The vertical distance is l'. Fig. 2(c) shows the right-angle triangle the base of which is $2\pi d'$, and the height, l'; the length of the hypotenuse, l_1, is required.

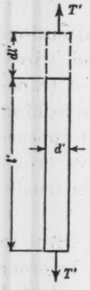

FIG. 1.

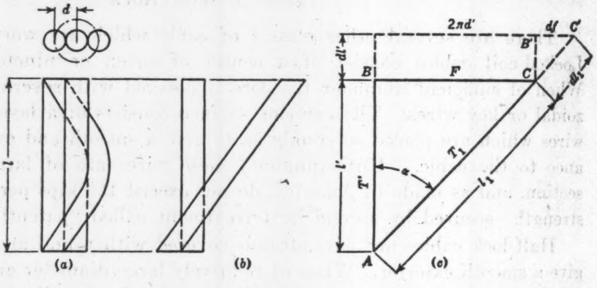

FIG. 2.

Since $l' = 22.5d'$, the hypotenuse equals,

$$\sqrt{506.25(d')^2 + 4\pi^2(d')^2} = d'\sqrt{506.25 + 39.48} = 23.36d'$$

Therefore, the length of l_1 is, $\dfrac{23.36d'}{22.5d'} \times l' = 1.03822\ l'$. Incidentally, 1.03822 is the secant of the angle of lay, which is 15° 35′.

If the two wires are considered to carry a load so that the stress in the straight wire is equal to T' (Fig. 1), and no slipping occurs between them, then the bent wire will be elongated in a direction parallel with the axis of the straight wire an equal amount, or dl'.

The triangles, ABC and $CB'C'$ (Fig. 2(c)), are similar because their sides are parallel; that is, $\dfrac{dl_1}{dl'} = \dfrac{l_1}{l'} = 1.038 = \dfrac{T_1}{T'}$. (The ratio, $\dfrac{T'}{T_1} = \dfrac{1}{1.04} = 0.96$.) The load, T_1, on the twisted wire, is $1.038T'$ If $S' =$ the ultimate strength of the wires and is assumed to be the same for all of them, and S'_s = the effective strength of the strand, then, $S'_s = 0.96 \times 7 \times S' = 6.72S'$, and the strand has a strength equal to 96% of the sum of the individual wires.

If this strand is to be used in a rope the lay of which is $58.3d'$, the diameter of the helix formed by the strand is equal to $6d'$, and the length of the developed strand is equal to,

$$\sqrt{6^2\pi^2(d')^2} = d'\sqrt{355.32 + 3398.89} = 61.2d'$$

Hence, in Fig. 2(*c*), $\sec \alpha = \sec \beta = \frac{61.2}{58.3} = 1.049$, or $\beta = 17° 35'$.

Example 2.—Curved Wire About a Curved Center Wire.—If a curved wire, twisted about a curved center wire, is untwisted, the two will appear as in Fig. 3. The center wire of the strand has a strength equal to $\frac{S'}{1.049}$, and, of the six remaining wires, $\cos(\beta + \alpha)\,S' = \cos 33° 10'\,S' = 0.837S'$. The effective strength of the strand is, therefore, $7 \times 0.837S' = 5.86S'$, since it is evident that the center wire will never be stressed more than the breaking point of the outside wires.

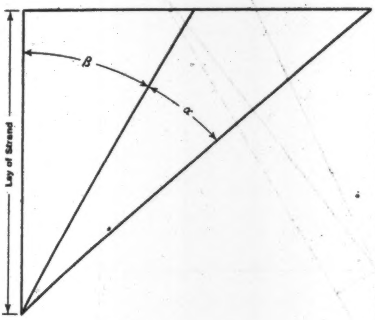

FIG. 3.

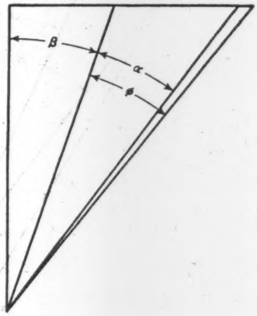

FIG. 4.

The rope will have a strength of $6 \times 5.86S' = 35.16S'$. Since there are 42 wires in the rope, the strength efficiency is $\frac{35.16}{42} = 83.7$ per cent. This value has been established by many tests and may be compared with the rope list for 1-in., 6 × 7, crucible rope which is composed of 42 wires, 0.111 in. in diameter. The area of such a wire is 0.0097 sq. in., and the area of the rope is $42 \times 0.0097 = 0.4074$ sq. in.

If cast steel has an ultimate strength of 180 kips per sq. in., then the strength of the rope will be $83.7 \times 0.4074 \times 180 = 61.370$ kips, or 30.7 tons. The 1910 catalog value is 31 tons, which is a sufficient check. The value in the 1930 American Manufacturers' list is 29 tons, showing the onward decline in the standard wire strengths. Foreign rope lists carry higher breaking strengths, and should be a challenge to American rope manufacturers.

Strength of a 6 × 19 Rope.—The diameter of the wires in a 6 × 19 rope is $\frac{d}{15}$; and these are laid in a strand of 1–6–12 wires, respectively, having lays of $22.5d'$ and $35.7d'$. Let the angle of lay of the outside wires of the strand be ϕ, which is computed to be 19° 22′; the lay of the rope may be $93d'$ for modern practice, as against $112d'$ used so long in the past. To find the angle of the center of the strand, the diameter of the helix is $10d'$, and the circumference is $10\pi d'$. Then, from Fig. 5, $\sec \beta = \frac{d'}{93} \sqrt{93^2 + (10\,\pi)^2} = \frac{98.16}{93} = 1.0554$, and $\beta = 18^\circ\ 39'$. Then, $\cos\,(\beta + \phi) = \cos 37^\circ\ 01' = 0.7986$. The strength of the 6 × 19 cast-steel cable may be $0.7986 \times 114 \times 0.003525 \times 180$, or 57.78 kips.

If slipping occurs between the straight and curved wires the method of computing the strength of the rope is as follows: Assume that a 6 × 19 strand is arranged so that a plane projection is as shown by the solid lines in Fig. 5. The lengths of the wires are $y = X \sec \alpha$ and $z = X \sec \beta$. Then,

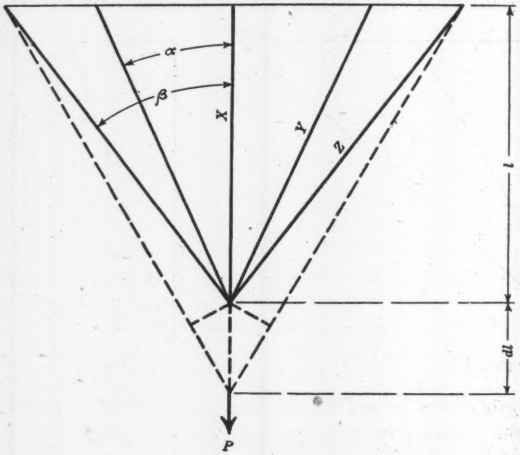

FIG. 5.

$$X + 6Y \cos \alpha + 12\, z \cos \beta = P \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

The load on the rope is determined as follows: If $\delta X = \delta l$, then $\delta Y = \delta X \cos \alpha$, and $\delta Z = \delta X \cos \beta$, from which the following elongations may be written:

$$e_X = \frac{\delta l}{l}\,;\ \sigma_X = \frac{E\,\delta X}{l}\,;$$

$$e_Y = \frac{\delta X \cos^2 \alpha}{l}\,;\ \sigma_Y = \frac{E\,\delta X \cos^2 \alpha}{l}\,;$$

$$e_Z = \frac{\delta X \cos^2 \beta}{l}\,;\ \text{and}\ \sigma_Z = \frac{E\,\delta X \cos^2 \beta}{l}.$$

Assuming that all wires have equal areas:

$$X = \sigma_X;\ Y = \sigma_X \cos^2 \alpha;\ \text{and}\ Z = \sigma_X \cos^2 \beta.$$

Substituting these values in Equation (1):

$$X = \frac{P}{1 + 6 \cos^3 \alpha + 12 \cos^3 \beta} \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

For the rope in Fig. 6 let $\alpha = 17° \ 39'$ and $\beta = 33° \ 10'$. Substituting in Equation (2),

$$X = \frac{1}{13.2} P = 0.076\ P;\ 6\,Y = 6\,X \cos^2 \alpha = 6 \times 0.076\ P_X \cos^2 \alpha = 0.410\,P$$

and,

$$12\ Z = 12 \times 0.076\ P_X \cos \beta = 0.640\,P$$

The strength equals the sum of 0.076 P, 0.410 P, and 0.640 P, or 1.126 P. The strength of the total wires is $19 \times 0.076 = 1.44\ P$ and the ratio of strengths equals $\frac{1.126}{1.44} = 78.5\%$, as compared with 79.9% obtained in the previous calculation.

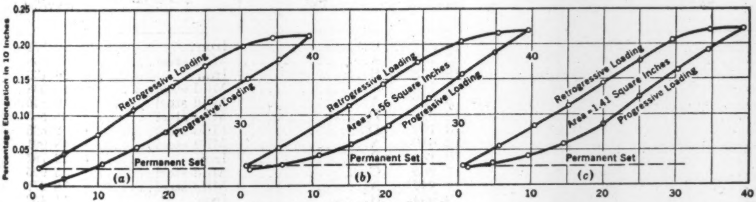

FIG. 6.

Effect of Varying Diameter of Helix.—In making these calculations it is assumed that the diameter of the helix is maintained by the core. It is quite remarkable what profound changes take place in the value of the modulus of elasticity of a rope if the helix diameter varies. Assume the value of E for the steel of the 6 × 19 rope as 27 000 kips per sq. in. The modulus for the rope might be 0.7986 × 27 000, or 21 500 kips per sq. in. By test it may be found to be 10 750 kips per sq. in., the elongations in the latter case being twice the former. If a load of 10 kips is applied to the rope, it is easy to show that a reduction in diameter of the core of 0.007 in. is sufficient to account for the difference in the theoretical and actual moduli of elasticity. Thus, if the lay of the rope is $93d'$, and $d' = 0.067$ in., the lay is 6.231 in.; for 10 kips, the actual elongation (permanent stretch eliminated) equals $\frac{10 \times 6.231}{10\,750 \times 0.4019} = 0.0144$ in. For 21 500 kips, the amount is 0.0072 in. Theoretically, it should elongate to $6.231 + 0.0072 = 6.2382$ in., but actually it elongates to $6.231 + 0.0144 = 6.2454$ in. Because of the modulus of the steel the length of the strand is $6.2382 \times 1.0554 = 6.5838$ in., but it is a question as to how much too short this length is to accommodate the change in length of rope from 6.231 to 6.2454 in. The answer is found thus: $(6.5838)^2 = (6.2454)^2 + C^2$; $C = 2.083$ in.

In this computation, C is the circumference of the helix circle; its radius is 0.3315 in. compared with $5 \times 0.067 = 0.3350$ in. at the beginning. The difference in the diameters of the core to meet the conditions imposed is $2 \times 0.3350 - 0.3315 = 0.007$ in. Of course, this calculation also illustrates the profound easing of the tension in a strand of a bent rope if the core yields ever so little. From experience it is known that the rope centers vary in diameter, and have varying resistances to crushing, through such wide limits that the behavior of rope in service is not a matter of exact prophecy. As an illustration of this fact scan the records of the ropes in Table 4.

TABLE 4.—Service Record of Wire Ropes $\frac{5}{8}$ Inch in Diameter.

(Tension, 1.25 kips; velocity, 550 feet per minute; diameter of sheaves, 34 inches; 6 × 19 construction; regular lay.)

Properties of Wire Rope

Under tension, wire rope behaves very differently from a homogeneous bar. For instance, a sample of rope may be placed in a testing machine and subjected to stress. If an extensometer is used the strain corresponding to any stress may be noted. If the loading is progressive to a value within the yield point and is then reversed, the stress-strain diagram will fail to close by an amount equal to the permanent stretch. However, if these reversals of stress are repeated a sufficient number of times the stress-strain diagram will become a closed figure, showing that the specimen has reached a condition in which it has completely recovered from the effects of loading. The stress-strain graphs of the progressive and retrogressive loadings do not coincide, but they bound an area which represents work in a manner similar to the well-known indicator diagram. These stress-strain graphs are shown in Fig. 6.

By a proper determination of the average tension and elongation, as shown by the diagram, the amount of work lost in stretching the rope may be estimated. This result indicates the value of the internal friction developed in the interior of the rope and such a stress-strain curve is called a frictional hysteresis diagram. It will be noted that when the loading is relatively light the elongations for a constant increment of loading are not equal and the graph is curved. When the loading becomes relatively high, the stress-strain graph approaches a straight line. The explanation is simple. The modulus of elasticity of wire rope is variable under moderate tensions, but it follows Hooke's law when the loads applied develop internal friction sufficient to compare with the cohesive forces that exist in a solid homogeneous bar. It is evident from the nature of the construction of wire rope that it is not adapted to resist longitudinal compression. Therefore, the modulus of elasticity in compression lengthwise is too small to consider. The neutral axis of a bent rope seldom coincides with the gravity axis of its section.

BENDING STRESS IN WIRE ROPE

The question of bending stresses in wire rope is a mooted subject. It is the usual procedure to rely upon the theory of flexure as developed for homogeneous prisms as an aid in determining these bending stresses. It is admitted by those who have a proper knowledge of the theory of flexure that it is only approximate and its use is permitted in engineering calculations because a great number of physical tests have demonstrated its limitations. It is founded on nine assumptions, three of the most important of which are:

1.—The bending must be slight;
2.—Plane surfaces before, must remain plane surfaces after, bending; and
3.—The modulus of elasticity in tension must be equal to the modulus of elasticity in compression.

In bending wire rope around the usual sheaves these criteria are violated and the use of the accredited formulas yields delusive results. Those who have studied the elastic curve of loaded beams will recall that the theory of flexure gives an approximate formula which may be written, $EI\frac{d^2y}{dx^2} = M$; that is, the modulus of elasticity times the moment of inertia times the rate of curvature of the deflected beam is equal to the external moment. However, the rate of curvature is equal to the reciprocal of the radius, and the external moment (by the theory of flexure) is,

$$E \times \frac{\text{unit stress in the outermost fiber}}{\text{distance from the internal axis to outermost fiber}}$$

Hence, the unit bending stress, b, in a homogeneous circular bar that has been slightly bent, would be given by the formula,

$$b = E\,\frac{r'}{R} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

in which, r' is the radius of the rod, and R, the radius of bend. When Equation (3) is used to determine the stresses arising from sharp bends, the stresses indicated are of such magnitude that no one of experience would place reliance in the results obtained.

However, a wire rope is not a homogeneous rod, but an assemblage of wires, and, for that purpose, Equation (3) has been arbitrarily modified by substituting the diameter of the wire used in the construction of the rope for the rod, giving the Reuleux formula,

$$b = E\,\frac{d'}{D} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

in which, D = diameter of sheave.

Since the diameter of a wire in a 6 × 19 rope is one-fifteenth the diameter of the rope, and if the modulus of elasticity of steel is taken at 28 400 kips per sq. in., then,

$$b = 1\,894\,\frac{d}{D} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

which is the well-known Rankine formula. It will be noted that the d' in the Reuleux formula indicates diameter of wire; the d in the Rankine formula is the diameter of the rope.

A large part of the literature on wire rope is devoted to the presentation of tables and diagrams of stresses due to bending, which are based directly, or with slight modification, upon these formulas. In the opinion of many this information is most deceptive and has played a prominent part in blocking the advance of the Engineering Profession to a true knowledge of the behavior of a wire rope in service.

When an engineer purchases his first piece of wire rope he is filled with fear that it will be severely injured if subjected to bends of short radius. When the "rough and ready" rigger immediately forms a bight in the end of the rope by bending it around the usual sized thimble, he is quite sure that the rigger is taking liberties with the rope that are not justified by the tables presented by wire-rope manufacturers. When the rigger proceeds to reeve a set of wire-rope blocks which have sheaves 8 or 10 in. in diameter, with a $\frac{5}{8}$-in. or $\frac{3}{4}$-in. rope, and forthwith uses the blocks to lift weights of many tons without having the rope fall in pieces, the buyer obtains a true insight into the value of the tables of bending stress and minimum sizes of sheaves as published.

Mr. James F. Howe has stated[5] that "bending stress has been confused with the effect of bending or the loss of strength due to bending, two entirely different factors." If the stress under discussion is produced by bending and a designer is trying to determine a suitable allowance to make in his calculations for its effect, the sentence quoted becomes unintelligible; but if it is meant that the tabulated stresses are fictitious, then everything becomes clear.

To put the matter to a test, a $\frac{3}{4}$-in., 6 × 19 rope was cut into six pieces approximately 6 ft. in length. All were fitted with sockets carefully zinced into position. Of the six pieces the even numbered ones were tested in direct tension and failed, respectively, at 35.00, 35.05, and 35.10 kips. The odd numbered samples were bent around a sheave 6 in. in diameter and attached to an equalizing arm, as shown in Fig. 7. The three samples broke within the limits of 63.90, 64.00, and 64.05 kips. Since the rope in this position carries double the load, it broke at 32 kips, or 3 kips less than the 35 kips when tested in direct tension. There can be no other conclusion but that the strength of the rope was reduced 3 kips when bent 180° around a 6-in. sheave.

---

[5] *Transactions*, Am. Soc. M. E., December, 1918, p. 17.

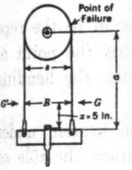

FIG. 7.

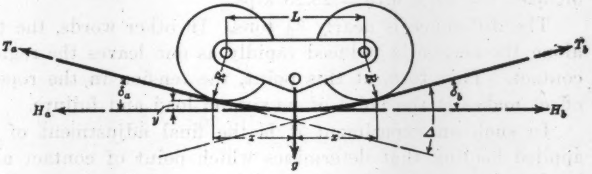

FIG. 8.

The area of the rope was 0.241 sq. in. and the bending stress, therefore, on the usual assumptions, was equal to 12.45 kips per sq. in. If these data are used for determining the constant for the Reuleux formula (Equation (4)), $\frac{E}{15}$ becomes $1\,285\,\frac{d'}{D}$, instead of 1 894 with $E = 28\,400$, as used in the original Equation (5), or the 12 000 as advocated by other authorities. (The answers resulting from these small constants are in kips (1 kip = 1 000 lb.).

This discrepancy between theory and practice is due to the fact that a wire rope, in passing around a sheave, has but one point of distortion, namely, the point of tangency of the rope and the sheave. This is a point of instantaneous bending, provided the rope is in motion. If the bending is performed slowly, the stress developed in the top position of a strand is distributed through its helical winding to the bottom.

The tightening of the top strands of the rope as it passes the point of contact with the sheave, causes a slight twisting of the free portion of the rope, and the resistance to this moment of torsion develops a slight curvature near the sheave. These reactions tend to reduce the magnitude of the bending stress aside from any distortion of the core. This slight rotation of the rope on guide sheaves is clearly shown by the grooving of the tread to the lay of the rope. In most cases the rotation is of the order of 0.05 in., measured on the circumference of the rope.

In testing ropes at rest on sheaves, by breaking them in tension, it has been noted that the failure often occurs in the bent portion near the point of contact of the rope and sheave. If it is admitted that bending increases the strand tension, then the point shown in Fig. 7 is the position of the greatest tension in the rope. Due to the friction of the strand contacts with the sheave in such an experiment, the tension in the rope at the crest of the sheave is a minimum. This may be shown by a simple computation in which the tension, T, in the rope will be taken as 32 kips, the coefficient of friction, f, as 0.15, the angle of contact as $\frac{\pi}{2}$, and T_c as the crown tension,

$$T_c = T e^{-f\gamma} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

or, $32 e^{-0.24} = 32 \times 0.79 = 25.28$ kips.

The difference is nearly 3½ tons. In other words, the tension in the rope along the sheave is reduced rapidly as one leaves the region of the point of contact. Therefore, at this point, the tension in the rope plus the bending effect makes it the point of maximum load and failure.

In such an experiment it is the final adjustment of the system under applied loading that determines which point of contact assumes the rôle of bending or straightening the rope. A revolving sheave determines the question at once. Just as a set of rolls bend a plate on the element of a cylinder, so does a sheave bend a rope at the point of curvature; but unlike the rolls, the sheave supports the rope in the curve developed, and then straightens it at the point of tangency. Accordingly, a sheave is a wonderful device for bending and straightening every portion of a running rope.

The reduction in the distance between the two arms of the rope loop of the test pieces, with increasing tension is noteworthy. A tension of 22.7 kips reduced the distance from $7\frac{1}{8}$ in. to $6\frac{7}{16}$ in., or $\frac{11}{16}$ in. The amount contributed by each rope is not known, but for the sake of making a calculation, assume a span of 1.83 ft., the distance from sheave to equalizing bar, a deflection of 0.029 ft. at a point 0.25 ft. from the sheave, and compute the lateral thrust required to produce the deflection by the formula,[6] $G = \frac{yst}{x\,(s - x)}$. In the present case,

$$G = \frac{0.029 \times 1.83 \times 22.7}{0.25 \times 1.58} = \frac{1.205}{0.395} = 3.05 \text{ kips}$$

It may be significant that this result, derived from the maximum deflection of the system, is in almost perfect agreement with the measured reduction in strength of the rope.

LOSS OF STRENGTH IN A WIRE ROPE DUE TO BENDING

For the purposes of easy reference some of the well-known formulas for bending stress may be summarized. Rankine's formula (Equation (5)) is, $b = 1\,894 \frac{d}{D}$. Since other formulas give total rather than unit stresses, Equation (5) is modified by introducing the area of the rope, say, $0.43\,d^2$. Then,

$$T = 1\,894 \times 0.43\,d^2 \times \frac{d}{D} = 814\,\frac{d^3}{D} \quad \ldots\ldots\ldots\ldots\ldots (7)$$

---

[6] *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 916. Equation (30).

For a $\frac{3}{4}$-in., 6 × 19 rope bent around a sheave 6 in. in diameter, Equation (7) becomes, $T = 814 \times \frac{0.75^3}{6} = 56.98$ kips, which is to be reconciled with an ultimate strength of 35 kips.

Hewitt's formula is,

$$T = \frac{E\,A}{2.06\,\frac{R}{d'} + K} \qquad \text{(8)}$$

in which, A is the cross-sectional area of a wire rope, and K, the ratio $\left(\frac{d}{d'}\right)$ of rope diameter to the diameter of the wire.

Reducing Equation (8) by inserting numerical values and substituting $2.06\,R = D$ and $d' = \frac{d}{13}$,

$$T = 910\,\frac{d^3}{D} \qquad \text{(9)}$$

Equation (9) is about the same as the Rankine formula (Equation (7)) corrected for the angle of lay of the rope.

The modified Reuleux formula (see Equation (4)) is,

$$b = E'\,\frac{d'}{D} \qquad \text{(10)}$$

in which, E' is the modulus of elasticity of the rope in tension, say, 12 000 kips per sq. in. Reducing this form to the value of:

$$T = \frac{12\,000 \times 0.43\,(d')^2 \times d'}{13 \times D} = 397\,\frac{(d')^3}{D} \qquad \text{(11)}$$

According to Equation (11), the $\frac{3}{4}$-in., 6 × 19 rope on a 6-in. sheave has a bending stress of 27.9 kips. In other words, the specimen will not fall to pieces before entering the testing machine.

Chapman's formula is,

$$b = \frac{E d' \cos^2\beta \cos^2(\alpha + \beta)}{D} \qquad \text{(12)}$$

in which, β is the angle of helix of a single wire, with the axis of the rope, and $(\alpha + \beta)$ is the angle of helix of a strand, with the axis of the rope (see Fig. 3). Bending stresses computed by Equation (12) fall between the Hewitt formula (Equation (8)), and the modified Reuleux formula (Equation (10)), and may be dismissed without further argument.

A New Formula for Wire Rope

It has been the aim of this paper to show that wire rope is a systematic grouping of wires into helices bent about a core that may be regarded as having the properties of a yielding foundation.

Years ago it was recognized that the curving of a rod into a helix resulted in the setting up of stresses due to bending and twisting.[7] In subjecting a helical spring to axial tension the free end rotates, unless restrained. Accordingly, one must conclude that the wires and strands of a wire rope have been subjected to bending and twisting, and that when they are passed over a sheave, under tension, the rim of the sheave will be cut intaglio, by the rotation of the rope due to torsion. That this is so is a matter of observation, and is well known to users of wire rope. It is the manufacturer's aim to balance these effects, so that, in general, the twist of the rope may be kept at a minimum, but the torsion stresses are always present in the wires. These rim cuts raise the inquiry, "If a wire rope, under tension, passes around a sheave, is it in a state of pure bending? If not, where is the neutral surface?"

---

[7] "Natural Philosophy", by Kelvin and Tait, Paragraph 120.

By definition pure bending is the effect produced in a bar by two equal and opposite couples acting upon its ends. In pure bending there is a gravity surface passing through the centroid of the section between the fibers in tension and compression—that is, in the region of neutrality between fibers that are elongated and those that are shortened. In general, it may be said, that as a wire rope under tension approaches the point of contact (curvature) with the sheave, all wires are under tension. When these wires pass on to the sheave surface, those in contact with it remain in tension, because the rim friction prevents the compressive accommodation. Since all wires are in tension, they are on one side of the neutral surface, which, therefore, must be at or near the rim surface of the sheave. The rim is subjected to circumferential and radial compression.

It seems that calculations for loss of strength due to bending wire rope, that are made upon the assumption of pure bending, must lead to results that are not satisfactory. For this reason there has been much speculation as to the wide discrepancy between the theoretical and the actual performance of ropes in service.

Fig. 9 shows a wire rope as an assemblage of open-coiled helical springs, made of high-class steel. It is proposed to investigate the possibility of computing rational values for the loss of strength due to bending a wire rope on this hypothesis. It is granted that the derivation of the several formulas leads to approximate answers, because it is assumed that the radius of rope, of the strands, and the angle of pitch of the several wire springs remain constant, while it is evident that the former becomes less, and the latter larger, when the rope is in service. It is not believed that serious errors arise from this expedient for simplicity. It must be admitted, however, that the bending effect is a function of the tension, if precision of statement is demanded.

The mathematical theory of open-coiled helical springs is well known, and has been tested by numerous investigators, with satisfactory results. The treatment covers axial load, extension, twist, and bending. The axial bending is of importance in this problem, because all the "springs" in the rope have their axes curved about the center of rotation of the sheave.

In Fig. 9, let the heavy line represent the position of the core wire of a strand, in both a straight and a bent section of the rope. Let O be a point for investigation that may be at any point, in projection, upon the circumference of the circle of the helix. Therefore, O is defined by the radius of

the generating circle and the angle, ϕ, between this radius and the principal axial plane. The resistance offered by the open spring to axial bending results in a moment, M, which is to be used to estimate the loss in strength of the wire due to bending it. The axis of the moment, M, will be parallel to the shaft of the sheave. Let O-P be a vector representing the moment, M. This vector may be resolved into two components, O-B producing bending of the wire in the plane of the tangent to the surface of cylinder enclosing the helix, and the moment, O-C, acting in this plane. Therefore, O-B is equal to $M \cos \phi$. The vector, O-C, in turn, may be resolved into two components giving the torque moment, M_t, and bending moment, M_b, in the plane of the coil. If the complement of the angle of lay of the strand, say, is α (equals the angle of the helix), that is, the angle measured from the perpendicular to the axis counter-clockwise to the tangent to the center line of the wire, then these two components may be written in terms of the moment, M: $M_t = -M \sin \phi \cos \alpha$; and, $M_b = M \sin \phi \sin \alpha$.

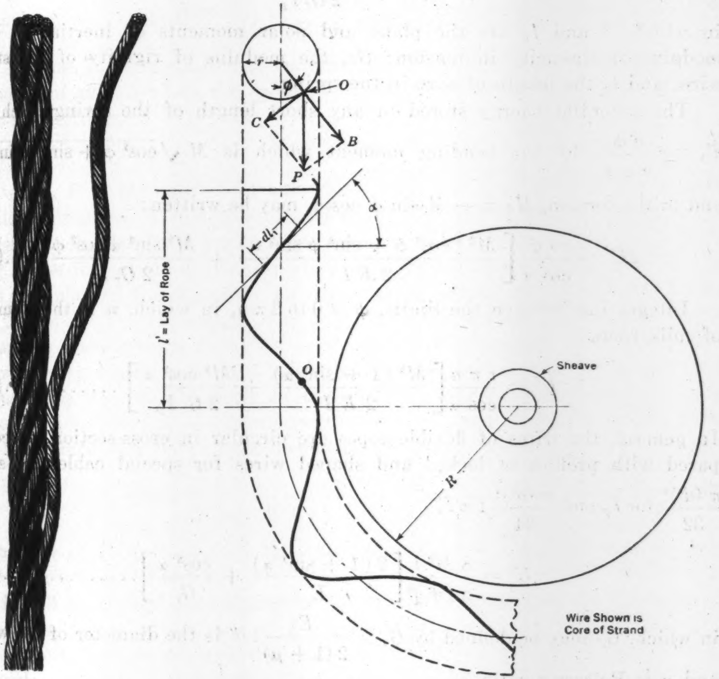

FIG. 9.

The bending due to O-B and M_b must be combined in the usual manner for obtaining maximum and minimum stresses. The bending moment thus considered is measured by $M \sqrt{\cos^2 \phi + \sin^2 \phi \sin^2 \alpha}$.

At this point it is well to recall that the potential energy of bending is given by the expression:

$$U'_b = \frac{M_b^2 l}{2\,E I}$$

Likewise, the potential energy of twist is given by:

$$U'_t = \frac{M_t^2\, l_1}{2\,G_r\, I_p}$$

in which, I and I_p are the plane and polar moments of inertia; E, the modulus of elasticity in tension; Gr, the modulus of rigidity of the steel wire; and l_1, the length of wire in the spring.

The potential energy stored in any short length of the spring, such as $dl_1 = r\,\dfrac{d\,\phi}{\cos\alpha}$, by the bending moment which is $M\sqrt{\cos^2\phi + \sin^2\phi\sin^2\alpha}$, and to the torsion, $M_t = -M\sin\phi\cos\alpha$, may be written:

$$dU' = \frac{rd\,\phi}{\cos\alpha}\left[\frac{M^2\,(\cos^2\phi + \sin^2\phi\sin^2\alpha)}{2\,E\,I} + \frac{M^2\sin^2\alpha\cos^2\phi}{2\,G_r\,I_p}\right]\ldots(13)$$

Integrating between the limits, $\phi = 0$ to $2\,\pi\,n$, in which, n is the number of coils, then,

$$U' = \frac{r\,\pi\,n}{\cos\alpha}\left[\frac{M^2\,(1 + \sin^2\alpha)}{2\,E\,I} + \frac{M^2\cos^2\alpha}{2\,G_r\,I_p}\right]\ldots\ldots\ldots\ldots(14)$$

In general, the wires of flexible ropes are circular in cross-section, as compared with profiles of locked and shaped wires for special cables. Using $\dfrac{\pi\,(d')^4}{32}$ for I_p and $\dfrac{\pi\,(d')^4}{64}$ for I,

$$U' = \frac{8\,M^2\,l_1}{\pi\,(d')^4}\left[\frac{2\,(1 + \sin^2\alpha)}{E} + \frac{\cos^2\alpha}{G_r}\right]\ldots\ldots\ldots\ldots\ldots(15)$$

in which, G_r may be defined by $G_r = \dfrac{E}{2\,(1+\mu)}$, d' is the diameter of the wire, and μ is Poisson's ratio.

Assume that the rope is fixed at, and beyond, the point of curvature (contact) with the sheave; also, that the work done by the moment in bending the axis of the spring to the radius, ρ, will be equal to the energy stored in the spring; that is, if l, the lay of the rope, is equal to $l_1\sin\alpha$,

$$\frac{1}{\rho} = \frac{16\,M}{\pi\,(d')^4\sin\alpha}\left[\frac{2\,(1+\sin^2\alpha)}{E} + \frac{\cos^2\alpha}{G_r}\right]\ldots\ldots\ldots(16)$$

and the moment due to bending a wire shaped as an open helical spring about the center of curvature of the sheave is,

$$M = \frac{\pi\,(d')^4\sin\alpha\,E\,G_r}{16\,\rho\,[2\,G_r\,(1+\sin^2\alpha) + E\cos^2\alpha]}\ldots\ldots\ldots\ldots\ldots(17)$$

which seems to be correct in form, at least, for it meets the well known test that when the elastic curve is an arc of a circle the bending moment is constant. To obtain a value for the stress in the outermost fiber of the wire, in the simplest possible way, for comparison purposes only, $M = \dfrac{S\,I}{\dfrac{d'}{2}}$, or,

$$S = \frac{2\,d' \sin \alpha\, E\, G_r}{[2\,G_r\,(1 + \sin^2 \alpha) + E \cos^2 \alpha]} \text{ .... (18)}$$

The loss in strength due to bending may be evaluated by ascertaining the amount of axial load on the spring that will give an equal moment. This is done by writing,

$$M = P\, r_1 \sin \alpha \text{ .... (19)}$$

in which, P is the equivalent axial load, and r_1 is the radius of the strand. This assumption is somewhat justified by the observation of the effect of tension upon wire ropes having fiber centers. The core is compressed, resulting in the formation of grooves, which thus furnishes a partial restriction to the free play of the strand as an open spring having an axis at the center of the rope. Nevertheless, it does not hinder the action of the wires in the strand as open springs about its own center. Furthermore, it is convenient to work with a dimension that is easily attained; for instance, it is a general assumption that the diameter of the strand is one-third the diameter of a 6 × 19 rope; hence, r_1 equals one-sixth of the diameter of the rope. The axial load sustained by a wire of the strand is determined by,

$$P = \frac{\pi\,(d')^4\, E\, G}{16\,\rho\, r_1\,[2\,G_r\,(1 + \sin^2 \alpha) + E \cos^2 \alpha]} \text{ .... (20)}$$

The value of P multiplied by the number of wires in the rope gives the loss of strength due to bending.

It will be noticed that Equation (20) takes into account the diameter of the wires, the rope, the radius of curvature, the angle of lay, the modulus of elasticity in tension, and the modulus of rigidity, thereby differing from formulas heretofore proposed. In a broad sense, it may be necessary to determine coefficients by actual tests for different kinds of ropes, just as in the practical application of hydraulic and many other formulas, but as a test of its worth, the loss of strength of the ¾-in. rope which was bent around the 6-in. sheave and described in the paper, will next be computed by this formula. It will be recalled that the loss of strength was 3 kips, due to bending.

The actual diameter of the rope as made of cast steel and standard lay, 6 × 19 construction and with hemp center, was 0.79 in. There were 114 wires of 0.054 in. each. (The lay of the rope is 4.94 in., and of the strand, 1.81 in.). The angle of lay of the strand is 18° 40′, and of the wires in the straight strand, 7° 33′; and, hence, of the wires in the rope, 26° 13′; hence, $\alpha = 63° 47'$. The radius of curvature, ρ, is assumed equal to 3.37 in., in the belief that the mean diameter of the rope, when under tension, is 0.74 in. Furthermore,

$$G_r = \frac{E}{1.3 \times 2} = 11\ 000 \text{ kips per sq. in., when } E = 28\ 500 \text{ kips per sq. in.}$$

Therefore, by Equation (20), in pounds per wire,

$$P = \frac{3.14 \times 0.054^4 \times 28.5 \times 10^6 \times 11 \times 10^6}{16 \times 3.37 \times 0.125 [2 \times 11 \times 10^6 (1 + 0.81) + 28.5 \times 10^6 \times 0.19]} = 27.4$$

Multiply by the number of wires, 114 × 27.4 lb. = 3 125 lb., which is in satisfactory agreement with results secured from the test. The writer has experienced considerable satisfaction in estimating the loss of strength due to bending ropes about sheaves and to find the results secured in service were in sufficient agreement so that the riggers and other practical rope users did not smile and turn away when the conversation turned to the strength of ropes, when reeved, say, in the usual wire-rope blocks, an achievement that many sympathetic readers will endorse as being well worth while. It is hoped that the wire rope companies will make the necessary tests to ascertain the general usefulness of this formula, or a comparable one, to the end that the engineer having to do with wire rope may have an accurate estimate of the reduction in strength of the rope due to bending.

The discussion should close at this point because all the foregoing remarks lie in the "battle zone" of wire rope considerations. In order to hold aloft a new target "to shoot at," the following "service factor" formula is offered for discussion. It aims to consider tension and velocity as well as rope-sheave ratios. Since E, the modulus of elasticity of the steel or the rope, is a function of the tension, it is omitted, and the formula is as follows:

$$T_s = k \frac{d^3}{D} (1 + V)^{0.67} \ (10 + T)^{0.50} \ \ldots\ldots\ldots\ldots\ldots (21)$$

in which,

T_s = the total service stress, in kips;
T = the tension on the rope, in kips;
V = velocity, in feet per second; and,
k = a constant for any one type of rope.

Three values may be listed, as follows: For 6 × 7 rope, $k = 300$; for 6 × 19 rope, $k = 250$; and, for 6 × 19 Seale type of rope, $k = 275$.

If V is zero and T is 32 kips, a $\frac{3}{4}$-in. rope on a 6-in. sheave loses 3.6 kips in strength. On a $\frac{3}{4}$-in. sheave, with no velocity, a tension, T, of 12 kips gives a service stress, T_s, of 22 kips; that is, the rope will hold 5 tons when bent on its own diameter without clipping. On the other hand, if a $\frac{3}{4}$-in. rope on a 10-in. sheave has a tension of 5 kips and a velocity of 6 100 ft. per min., the service factor plus the tension will approach the ultimate strength of the rope. In its final form, Equation (21) will probably have a selective coefficient for various conditions of lubrication and exposure. In its present form it is based on the assumption of adequate lubrication and favorable use. If such a service formula is to prevail, the selection of a wire rope for a given duty must be more rational than the guesses of former years.

EQUATION FOR AN ELASTIC CURVE OF A LOCKED-COIL CABLE SUPPORTING A CARRIER

The running of sheaves on standing ropes, or the support of moving ropes on guide-sheaves, presents a variation of the bending stress problem, because the radius of curvature of the rope is, in general, greater than the radius of the carriage wheels, or rollers, as the case may be. The following analysis is based on the theory of flexure, because it contemplates lock-coil track cables operating under sufficient tensions to keep the curvature within the limits demanded by classical theory. Pressures from the helical winding of the several layers of wire give properties to the cable, that are similar but of less magnitude than those of a homogeneous bar.

If a portion of such a cable is supposedly taken from a loaded span, it will present the aspect of a beam with fixed ends, in so far as the direction of the axis is concerned, and an analysis to discover the relation of the tension, moment of inertia, modulus of elasticity, load, and other factors may be made as follows: Assume that the cable has sufficient resistance to flexure to form an elastic curve between the points of tangency of the cable to the right and left carriage wheels. Referring to Fig. 8, the summation of the vertical components equals zero and the summation of the horizontal components equals zero; hence,

$$g = T_a \sin \delta_a + T_b \sin \delta_b \quad \ldots\ldots\ldots\ldots\ldots\ldots (22)$$

and,

$$H = T_a \cos \delta_a + T_b \cos \delta_b \quad \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

If $\delta_a = \delta_b$ in Equations (22) and (23),

$$g = 2\,T \sin \delta = 2\,H \tan \delta$$

and,

$$\tan \delta = \frac{g}{2H} = \frac{g}{2} \times \frac{1}{H}$$

That is, the section represented by Fig. 8 may be replaced by a free body similar to Fig. 10. It will be noted that either side of the curve assumes a position of equilibrium under the conditions of a vertical load and a horizontal load acting simultaneously. It will be assumed that the conditions controlling the theory of flexure in homogeneous bodies can be applied to locked-coil cable, provided the bending modulus is regarded as variable between the limits of $E = 1\,500$ for no tension and $23\,000$ for a tension of 25 kips.

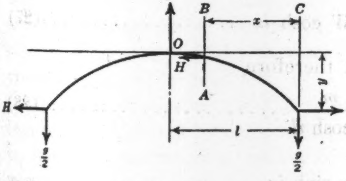

FIG. 10.

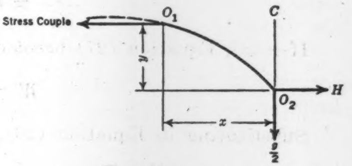

FIG. 11.

Since the curvature is slight under ordinary conditions of tension and loading, the approximate formula, $EI\,\frac{d^2y}{dx^2} = M$, may be used. To apply this equation of the elastic curve consider a free body to the right of Section A-B in Fig 10. Taking the summation of moments about O_1 (Fig. 11),

$$M = -\tfrac{1}{2}\,gx + yH = EI\,\frac{d^2y}{dx^2}$$

and,

$$\frac{d^2y}{dx^2} = \left(y - \frac{gx}{2H}\right)\frac{H}{EI} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(24)$$

For convenience, let $\frac{H}{EI} = i^2$, and $y - \frac{gx}{2H} = u$; then Equation (24) becomes,

$$\frac{d^2y}{dx^2} = i^2\,u = \frac{d^2u}{dx^2}$$

This expression is immediately recognized as a cyclic function because the second differential is a multiple of the function. By integration,

$$\int_0^u \frac{d^2u}{dx^2} = \int_0^u i^2u = Ue^{ix} + We^{-ix}$$

A solution, expressed in hyperbolic functions, is,

$$u = U\cosh ix + W\sinh ix$$

and,

$$y = \frac{gx}{2H} + U\cosh ix + W\sinh ix \quad\ldots\ldots\ldots\ldots\ldots(25)$$

If O_2 is taken as the origin, $x = 0$, $y = 0$, and $U = 0$; let $\frac{g}{2H} = m$; then Equation (25) becomes,

$$y = mx + W\sinh ix \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(26)$$

and,

$$\frac{dy}{dx} = m + i\,W\cosh ix \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(27)$$

If $x = l$, Equation (27) becomes zero; therefore,

$$W = -\frac{m}{i\cosh il} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(28)$$

Substituting in Equation (26),

$$y = mx - \frac{m\sinh ix}{i\cosh il} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(29)$$

or, for $x = l$,

$$y = \frac{g}{2H}\left[\,l - \frac{\tanh\sqrt{\frac{H}{EI}}\,l}{\sqrt{\frac{H}{EI}}}\,\right] \quad\ldots\ldots\ldots\ldots(30)$$

The general equation may be written,

$$y = \frac{g}{2H}\left[x - \frac{\sinh ix}{i \cosh il}\right] \ldots\ldots\ldots\ldots\ldots\ldots (31)$$

in which, $i = \sqrt{\frac{H}{EI}}$ to simplify typography.

The slope of the tangent at the point, xy (Fig. 8), is,

$$\frac{dy}{dx} = \frac{g}{2H}\left[1 - \frac{\cosh ix}{\cosh il}\right] \ldots\ldots\ldots\ldots\ldots\ldots (32)$$

If the curve (Fig. 8) is assumed to be a circular arc, the radius of curvature can be found for the arc, $O_1\ O_2$, (Fig. 11), for any value of Δ and any slope of cable, provided $\tan \Delta = \frac{g}{H}$.[8]

CONCLUSION

There are many phases of wire rope—its attributes and its manufacture—that may well remind one of the philosopher's "category" and the "unknowable." Modern wire rope represents the best in mining and selecting iron ore and limestone, in the making of coke, in blast-furnace operations, in the selection of scrap, in the control of the "heat" of the open hearth, in the human equation of the melter, in the boss roller, in the soaking shift foreman, in the cleaning house boss, the wire drawer, the tester, the manila rope manufacturer, the annealer, the spooler, the men on the stranding and laying machines, the warehouse, salesmen, and numerous chemists, physicists, executives, and in the use of the power of wealth; all co-ordinated to produce the best product that can be made within the price the purchaser will pay. Every one of these items and more have uncertain factors that may not have been safeguarded against or eliminated, but will be when the art of steel and wire-rope making ceases to be extremely competitive and is directed toward the creation of quality products.

In any symposium for the improvement of the service life of wire the issue must be joined by considering this question: Can the processes involved in the manufacture, the rolling of rods, the drawing of wire, the laying of wire rope, and its uses, be brought under critical technical control to the end that a behavior of wire rope in service may be predicted with assurance? Of course, some ropes fail to render service. The wonder is that so many prove satisfactory in spite of abuse and neglect. It is probable that the improvement of wire rope will be the result of a gradual advance in the control of the basic operations of its manufacture and use.

APPENDIX I

NOTATION

The following will serve as a general guide for the definition of all symbols used in the paper:

b = unit bending stress.
d = diameter of a wire rope; d' = diameter of a single wire.
e = base of natural logarithms.
f = coefficient of friction.
g = total weight applied by a tramway carriage.
i = substitution factor $= \sqrt{\frac{H}{EI}}$ (Equation (25)).
k = a constant varying with the type of rope (Equation (21)).
l = length along a rope; l' = length of lay, or the pitch of a single wire; l_1 = length of a twisted wire in the straight distance, l' (Fig. 2).
m = a substitution factor $= \frac{g}{2t}$ (Equation (26)).
n = number of coils.
r = radius of a rope; r' = radius of a circular bar, or a single wire. (Distance between the two arms of a wire rope loop.) r_1 = radius of a strand.
s = a sheave.
u = a substitution factor $= y - \frac{gx}{2H}$.
w = suspended weight; w' = unit dead load weight of rope. Distance from the origin of ordinates to a point, $x\,y$ (see Fig. 8).
x = horizontal distance from origin to point, $x\,y$.
y = deflection of a wire rope.
A = cross-sectional area of a rope; A' = section area of a single wire.
B = reduced distance between arms of a wire rope around a sheave, supporting a load (Fig. 7).
C = circumference of a helix circle.
D = diameter of a sheave.
E = modulus of elasticity; E', in tension; E_b in bending.
F = length of circumference of helix circle (see Fig. 2).
G = a force normal to a cable at any point; G_r = modulus of rigidity.
H = horizontal components of tension; H_a and H_b = components of T_a and T_b, respectively.
I = planar moment of inertia; I_p = polar moment of inertia.
K = ratio of rope diameter to wire diameter, $= \frac{d}{d'}$.
L = length of wheel-base of a tramway carriage.
M = bending moment.
P = an axial load on a wire.
R = radius of curvature of bends in rope, or semi-diameter of a sheave; R_w = radius of carriage wheels; R_t = radius of tread of a carriage wheel; R_c = radius of curvature of a bent rope.
S = strength of wire rope; S' = strength of a single wire; S_s = strength of a strand.

$T =$ tension in a wire rope; $T_c =$ tension at the crest of a sheave; $T_s =$ total service strength; $T' =$ load on a single straight wire (Fig. 1); $T_1 =$ load on a single twisted wire (Fig. 2); $T_a =$ rope tension toward the left; $T_b =$ rope tension toward the right.
$U =$ a substitution factor in Equation (25).
$U' =$ potential energy; U'_b, of bending; and U'_t, of twisting.
$V =$ velocity of a wire rope.
$W =$ a substitution factor in Equation (25).
$\alpha =$ angle between a curved center wire and a wire twisted about it (Fig. 3), or the angle of pitch of an open spring.
$\beta =$ angle between the axis of a rope and a curved center wire (Fig. 3).
$\gamma =$ angle of contact between rope and sheave
$\delta =$ angle between forces, T and H.
$\theta =$ angle between principal axial plane and radius to Point O (Fig. 9), on open helical spring.
$\Delta =$ angle of intersection of the tangents of a bent wire rope $= \delta_a + \delta_b$ (Fig. 8).
$\phi =$ angle of lay of the outside wires of a strand of rope.
$\mu =$ Poisson's ratio.
$\rho =$ radius of curvature.

DISCUSSION

Robert C. Strachan,[9] M. Am. Soc. C. E. (by letter).—In many respects, a wire rope is similar to a solid bar. It stretches under tension and recovers when released, in a manner well known through many tests. Short pieces show regularity in measured deflections under lateral forces. Naturally, much attention has been given to the effect of passing a rope around a sheave, since one of the main purposes of a rope is to enable one to change the line of application of a force. As previously noted by the writer,[10] rope action is complicated by the presence of fiber cores, by the twisted state of the wires, and by other factors.

Analogy with a homogeneous bar is entirely lacking when a sheave is present; hence, the diversity in results based on the assumption of such an analogy is not surprising. The fact of extremely large deformations, to which this diversity must be largely attributed, will be easily perceived if values of 35 kips and 30 000 kips for b and E, respectively, are inserted in the author's Equation (3), and R is deduced. It is found thus that at the elastic limit, beyond which the formula is inapplicable, the radius of curvature of a steel specimen is approximately 430 times its depth. This would seem to show conclusively that the result of applying the common theory of flexure to a $\frac{3}{4}$-in. rope, bent around a 6-in. sheave, must be fallacious.

That there are many reasons for conflict between theory and practice is recognized by the author, who grants, in preparing to derive a rational expression for bending stress, that "the derivation * * * leads to approximate answers." One of the reasons not mentioned in the paper is the important fact that many ropes are composed of wires of different sizes. It is evident that any formula such as Equation (20), which assumes uniformity of wires, must be considerably in error for the large class of ropes in which such uniformity does not exist.

The probability of error in numerical application is enhanced by the smallness of the dimensions of the elemental parts. The effect is to make minute absolute differences become large proportional differences. This may be seen in the author's application of Equation (20), where the wire diameter is taken as 0.054 in. So small a difference as 0.001 in this dimension leads to a difference of 6% in the calculated value of P.

The presence of error due to the exclusion of the effect of direct tension in deriving Equation (20) is recognized by the author, but it is altogether probable that this error is of greater importance than his somewhat casual reference to it would indicate.

Taking into consideration the complex mechanics of combined tension and torsion in a compound wire helix, the large deformations, the small dimensions of parts, the internal conditions not discernible by visual inspection, but in fact affecting core resistance, and the variety of materials, as well as the different wire sizes in one rope, it appears to the writer impracticable to derive a satisfactory rational formula for bending stress. In the last analysis, reliance must be placed on the "life-saver" coefficient derived by experiment.

---

[9] Cons. Engr., New York, N. Y. Mr. Strachan died on April 16, 1933.

[10] *Civil Engineering*, November, 1930, p. 111.

The comparatively simple Equation (21) would seem preferable in form to Equation (20); but a better line of approach to the problem is that taken by the National Bureau of Standards, in making and recording tests which show how much loss in strength is caused by passing a rope around a sheave. It is to be regretted that the published results do not cover a more extended range of both rope types and sheave sizes. In the writer's opinion, an exhaustive series of tests such as these, would be of far greater benefit than any rational formula for bending stress, however plausible its bases and beautiful its derivation.

C. D. MEALS,[11] ASSOC. M. AM. SOC. C. E. (by letter).—The wire of the ancients was produced solely by hammering and not by the process of "drawing" as practised to-day. The "drawing" of wire was mentioned in an old Latin manuscript by Theophilus, written during the Eighth or Ninth Centuries. Undoubtedly, the art was known and practised before that date. Authentic records are available to show that wire drawing, on a commercial scale, was practised in France, in 1270, in Germany, in 1350, in England, in 1465, and in America, in 1775.

It was a simple beginning of a business of great importance; there are sixteen wire-rope manufacturers in America to-day (1932), capable of producing more than 150 000 tons of wire rope annually, excluding ordinary strand as used by the public utility companies. Of this number, only three make their wire from the open-hearth furnaces to the finished product; most of the others draw the wire from rods purchased from the steel manufacturers.

It is doubtful whether Albert of Clausthal made lang lay ropes, since John Lang, of England, patented this lay in 1879; although in Germany it is called Albert Lay. It is easy to visualize the possibility that hemp rope manufacturing practice influenced the early wire-rope making, and hemp ropes have always been made "regular" lay.

The development of the various constructions and lays of ropes started in 1875. The non-spinning and flattened strand ropes and locked-coil cables were first made and patented in England, and the British manufacturers have developed these ropes to a high degree of efficiency, while American manufacturers have lagged decidedly. American manufacturers, however, have developed the round strand ropes to a much higher degree of efficiency than those made in other countries.

Prior to 1854, all wire rope was made of iron wire, a grade that is relatively soft and easy to handle. The first of the higher grades of steel wire, as used so extensively to-day, was produced in England in 1854; it was a tempered or "patented" wire and represented a great advance in the trade or art.

Mechanical Development of Machines.—The Stone stranding machine is different in construction than is implied from the description given of it, following its mention in the paper. It was found unsuited for high-class wire-rope making and is not used to-day. Instead the "rod and disk" strander, as described by Mr. Carstarphen, and the tubular strander, are the high-speed horizontal stranding machines now in use. The tubular strander is the more rugged and costs less to maintain than the "rod and disk" type machine, but it has the disadvantage of being more difficult to load with bobbins, which slows up production.

---

[11] Wire Rope Engr., The B. Greening Wire Co., Ltd., Hamilton, Ont., Canada.

The stranders described herein may have from seven to thirty-seven bobbins arranged in one machine; the latter makes an extremely long unit, and one in which a tubular machine is practically a necessity; or the machine may be split in two units and geared to drive together at the same speed, or at varying speeds.

The tandem horizontal stranders as described by Mr. Carstarphen are of the old English type, which are being supplanted to-day by the high-speed stranders described in the foregoing paragraphs. It is merely a question of production; the high-speed stranders will produce two to three times as much strand per day as the tandem horizontal stranders, at no sacrifice in quality.

Some of the larger companies have vertical stranders in operation, particularly for making the more flexible rope strands. All these machines have a planetary motion imparted to the bobbins, and many are geared to give a back or forward turning motion to the bobbins for making strands for lang lay ropes. It is possible to provide the bobbins in the tubular high-speed stranders with a back-turning motion by a set of ring and internal gearing.

At least six of the American firms have stranding equipment capable of laying 37 wires together in one operation and several have stranders that will lay 41, 43, and 46 wires. Some of these large vertical stranders will make up 20 tons of strand at one setting of the machine.

The "closing" or "laying" machines, in which six or eight strands are laid around the hemp center to form the finished rope, are either horizontal or vertical, with a planetary motion imparted to the spools. They are often geared to give a back turn to the spools for making lang lay ropes and, in addition, may be equipped with a straightening device to neutralize the liveliness of a lang lay rope still further.

Several of the American firms have large vertical closers, capable of making 60 tons of rope at one setting of the machine—a machine that will make 20 000 ft. of 2-in., or 8 000 ft. of 3-in., steel wire rope. It is possible, however, to make 30 tons of rope in one continuous length on a closer of 15-ton capacity.

The compound strander and closer mentioned by Mr. Carstarphen is known as the "Canadian" machine, as it was first built in Canada. It is interesting as an exhibition model; but it was not practical for several reasons, such as, (1) reduced production, and (2) an inferior and cranky rope.

Characteristics of Wire Ropes.—Strands made up "as a series of single operations," as described by Mr. Carstarphen—as, for example, a 37-wire strand made up by laying 18 wires over 12 over 6 over 1 wire—are not offered to the trade by the better rope makers, as it is a well known and established fact that a rope strand of the "one-operation" class is far superior to a rope strand of the "multiple-operation" class. The former has each wire in the strand interlocked with each adjacent wire; the latter has wire crossing wire within the strand, resulting in internal friction and a decidedly inferior rope.

Impregnated hemp centers were an improvement over the old method of running a center through a bath of hot lubricant which did not penetrate, because a hemp center is, next to lariat and yacht rope, the hardest hemp rope made. Impregnation of the centers has some detrimental points; one is that in drying out the centers in a vacuum tank, the fibers lose their resilience to a certain extent and the original diameter of the center is not maintained. Consequently, the progressive makers are now using pre-lubricated centers in which every fiber is given a spraying of hot lubricant before being spun into the yarns. Hemp centers for wire ropes should be uniform in both diameter and hardness. The quality of fiber may well be submerged, within reasonable limits, to these two properties.

Consideration of a wire rope as a machine, having many moving parts and wearing surfaces, should force the realization that it must be lubricated if satisfactory rope service is to result. Proper lubrication retards corrosion and rotting of the hemp center; it decreases external wear of rope and equipment and reduces friction between the component parts of the rope. Varying rope service requires different kinds of lubrication and, primarily, the lubricant should be "built" into the rope during its manufacture, both at the stranding and closing machines, with exterior applications, as required, when the rope is in service.

Admittedly, sheave and drum equipment are generally too small for satisfactory rope service; power and space requirements set a limit to their sizes, but it must be appreciated that tight grooves in sheaves, that wedge or pinch the rope, prevent the unrestricted wire and strand movement that is so necessary to least resistance to bending. Consequently, such grooves subject the rope to greatly increased bending stresses—causing premature breaking of the wires and preventing a new rope from rotating freely—and increase the wear on the wires of the rope.

A new wire rope, operating under varying stresses, will elongate, and this lengthening of the lay is equalized by an untwisting or rotating action of the rope. In a regular lay rope, the wires in the strands are laid in the opposite direction to that of the strands in the rope. Consequently, any untwisting will tighten the wires in the strand and aid in the resistance of the rope to untwisting.

In a lang lay rope, the wires and strands are laid up in the same direction and, consequently, an untwisting action will cause an opening out or "bird-caging" of the individual wires of the strand, because every two and one-half rotations of the rope result in a full rotation of the individual strands. This causes the wires of the strands to "bird-cage," and the strands in the rope will also "bird-cage" or arch away from the hemp center.

An important fact is inferred in the foregoing—never use a lang lay rope where the untwisting action cannot be controlled or limited. Consequently, a lang lay rope should not be used where its ends are not permanently fastened; where a swivel is used; nor where grooves in the sheaves are tight.

There is some limitation to this in the sense that a coarse and stiff rope, as a 6 × 7 or a 6 × 8 flattened-strand lang lay rope, will not "bird-cage" as easily as the more flexible 6 × 19 ropes, because the large wires of the stiff ropes offer considerable resistance to "bird-caging."

Strand and rope lays are not usually given in terms of the wire diameters, as indicated in Table 1, but in terms of the rope diameter, and the outer wires of the strands are fixed by allowance for the angle of twist of the strand and a proper clearance between adjoining wires in the same layer. Accordingly, Table 1 may well be changed to read as shown in Table 5 for a 1-in., or base-size, rope.

TABLE 5.—STANDARD CHARACTERISTICS OF WIRE ROPE

Rope	Outer Wires in Strands		Regular Lay Ropes		Lang Lay Ropes	
	Number	Diameter, in inches	Strand lay	Rope lay	Strand lay	Rope lay
6 × 7	6	0.106	2½ *d*	6¾ *d*	2¾ *d*	7½ *d*
6 × 19 Seale	9	0.080	2½ *d*	6¼ *d*	2¾ *d*	7 *d*
6 × 19 filler wire Seale	12	0.064	2⅝ *d*	6¼ *d*	3 *d*	7 *d*
6 × 19 Warrington	12	0.054 0.072	2⅝ *d*	6¼ *d*	....	....
6 × 37	18	0.046	2⅞ *d*	6¼ *d*	3⅛ *d*	7 *d*
8 × 19	12	0.052	2 *d*	6¼ *d*	....	....
6 × 8 flattened strand	7	0.108	....	....	2¾ *d*	7½ *d*
6 × 25 flattened strand	12	0.073	....	....	2¾ *d*	7 *d*

These values in Table 5 correspond quite closely with those in Table 1, but it must be understood that each manufacturer has his own ideas regarding strand and rope lays. Table 5, however, represents average American practice for high-class operating ropes. For galvanized guy ropes and other stationary ropes as used in suspension bridges, etc., the rope lays may average 8 *d* to 9 *d* lays.

The unit tensile strengths of wire for any grade vary with the wire diameter, as indicated for plow-steel quality in Table 6 (Item Nos. 1 to 4), Mild cast-steel wire is now termed "traction steel" since it is used for elevator rope service, and the super-plow steel ropes are known as "improved plow steel," with the makers' trade designations for this quality of wire.

Torsion requirements for wires are usually given in terms of twists per length of 100 *d′*, even if the tests are made in a gauge length of 6 in. or 8 in. They vary as indicated in Table 6 (Items Nos. 5 to 19). Small wires will show higher torsions than large ones of the same quality, although this fact is not considered in most commercial specifications.

American mills are very reluctant to furnish galvanized wire to a torsion requirement. In fact, some will not accept orders on this basis; but the British and German mills will do so, and the British and Canadian Engineering Standards Associations give torsion values as shown in Table 6 (Items Nos. 11 to 15). Some recent vertical lift-bridge specifications for galvanized improved plow-steel wire are as listed in Table 6 (Items Nos. 16 to 19).

Elongations of rope wire will vary with the diameter of the wire, the process of "patenting" (as "air-patented" or "lead-patented"), and the

* Tests of wires from finished ropes.

† Tests of wires from coils before being stranded for ropes.

quality of the wire. Values in Table 6 (Items Nos. 20 to 24) are typical of minimum elongations at breaking loads.

There is still another physical property of rope wire that may be of interest, namely, the hardness. Item No. 25 of Table 6 indicates the relative abrasive and wearing resistance of the various grades of wire in terms of the Brinell hardness number (B H N). It will be found that a fairly close relation exists between the tensile strength and the B H N from the formula given by Abbott,[13] in units of 1 000 lb., as follows,

$$S = 0.73\,[\mathrm{B\;H\;N}] - 28 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (33)$$

The chemical properties of the various grades of rope wire may be of interest; while each manufacturer has his own ideas, the values in Table 6 (Items Nos. 26 to 33) are typical specifications.

Acid or Basic Open-Hearth Steel?—A few years ago the writer conducted a series of bending tests on wire ropes of the various grades and constructions, and it was shown that a good basic steel was as satisfactory as a good acid steel, but the writer favors the acid steel because it is more likely to be consistently good than the basic steel.

The question is occasionally raised, "Why do not the wire-rope manufacturers use alloy steel for wire ropes?" Some research work has been done on nickel, vanadium, molybdenum, and stainless (chromium and nickel) steel wire ropes and some of them have shown considerable merit; but the price of these alloy steels is relatively so prohibitive that they are not commercially practical for wire ropes.

Wire-rope strengths were revised and generally lowered in 1929; on some grades, sizes, and constructions of ropes it was a necessity. In a general sense, it was a move in the right direction since recent research has indicated that wires of lower strength will withstand bending over sheaves better than wires of excessively high strength. Therefore, while ropes can be furnished, in most cases, to the old lists, the new strengths permit of the usage of a better steel for operating ropes.

Foreign ropes are listed at higher strengths than American ropes; but practices abroad differ in that longer lays of ropes prevail. It should be kept in mind that sheaves and drums on equipment abroad are of more liberal proportions than those in the United States. Consequently, each country has developed rope practices to suit its own particular requirements, and the higher strengths of foreign ropes need not be considered as a "challenge" to American manufacturers.

Admittedly, wire ropes made to foreign standards are unsuited for American equipment, but if made to American standards (and the writer has had this done) there is very little, if any, choice between the merits of American and of Canadian, English, and German wire ropes.

Properties of Wire Rope; Analysis of Strength.—For the usual wire-rope problems, detailed calculation of strength is scarcely required, as the approximate breaking strengths as given in the manufacturers' lists will serve most purposes just as the properties of structural shapes given in the steel handbooks serve the structural engineer. However, it may be desirable to make calculations for strengths for special ropes, such as suspender ropes for suspension bridges, vertical lift-bridge ropes, etc.

---

[13] **"Strength and Hardness of Steels", *Proceedings*, Am. Soc. for Testing Materials, 1915, p. 42.**

A more accurate method of calculating the strengths of wire ropes than that given by the author (see "Strength of a 6 × 19 Rope"), is, as follows:

$$S = N \cos \beta \left(\sum_{1}^{n} S' \cos^3 \alpha\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (34)$$

which for a 6 × 19 rope becomes:

$$S = 6 \cos \beta \left(S'_1 + 6\,S'_2 \cos^3 \alpha_2 + 12\,S'_3 \cos^3 \alpha_3\right) \ldots\ldots\ldots (35)$$

Table 7 contains efficiencies of wire ropes listed in Table 5.

TABLE 7.—EFFICIENCIES OF WIRE ROPES

Rope	Equation (34)		Metallic area in 1-in. rope (base size), in square inches	Test Results		British Engineering Standard Association long lay rope
	Regular lay	Lang lay		Regular lay	Lang lay	
6 × 7	86.5%	88.8%	0.3893	87%	90%	92.5%
6 × 19 Seale	84.8%	87.6%	0.4000	85%	88%	87.5%
6 × 19 filler wire Seale	85.5%	88.5%	0.4063	85%	88%	87.5%
6 × 19 Warrington	85.8%	......	0.4034	85%	....	87.5%
6 × 37	84%	86.9%	0.3803	82%	85%	82.5%
8 × 19	83.5%	......	0.3658	82%	....	......
6 × 8 flat; strand	......	88%	0.4766	....	....	92.5%
6 × 25 flat; strand	......	85.4%	0.4782	....	....	87.5%

For the two examples given by Mr. Carstarphen, the efficiencies as given by Equation (34), are as follows:

	Equation (34)	Carstarphen
1-in. 6 × 7 cast-steel rope	86.6%	83.7%
1-in. 6 × 19 cast-steel rope	83.4%	78.5 and 79.9%

For improved plow-steel and for iron ropes, the efficiencies as given by Equation (34) should be reduced by 5 per cent. This value is in conformance with test results and may be explained by the extremely high pressures and wire nicking in the improved plow-steel ropes and the wire nicking in the relatively soft iron ropes. Therefore, for 6 × 19 rope, 85.5% × 95% = 81.2%, etc. A check of Equation (34) is offered by the strengths of ropes used on some well-known bridges, as noted in Table 8.

TABLE 8.—STRENGTHS OF SPECIAL ROPES

Rope	Use	Area, in square inches	By Equation (34)		Average of Tests	
			Strength, in kips	Efficiency	Strength, in kips	Efficiency
$1\frac{3}{4}$-in., 6 × 19	Counterweight ropes, Newark Bay vertical lift bridge Central Railroad of New Jersey.	1.223	255	88.5%	263	91%
$2\frac{1}{8}$-in., 6 × 19		1.729	363	89.7%	367	90.6%
$1\frac{7}{8}$-in., 6 × 19, with 7 × 7 IWRC	Suspender ropes, Ambassador Bridge, Detroit, Mich.	1.668	308	86%	303	84.5%
$2\frac{1}{4}$-in., 6 × 37, with 7 × 7 IWRC	Suspender ropes, Philadelphia–Camden Bridge.	2.226	428	87.3%	436	89.2%

In calculating strengths of ropes with independent wire rope centers (IWRC) the strength of the IWRC is only 80% effective in the rope on account of the heavy pressures on it by the enveloping 6-rope strands. Consequently, a 7 × 7 IWRC will be only 0.865 × 0.80, or 69% efficient

Equation (34) is also of value in calculating the strength of ropes with broken or worn outer wires. In the case of broken wires, it is of value when the breaks are distributed over the various strands and not concentrated in one strand; the latter case leads to an unbalanced distribution of stress which cannot be calculated accurately.

A check of the foregoing is the tests[13] reported by the U. S. Bureau of Mines. In one test, three large and three small outer wires of a 6 × 19 Warrington rope were cut in each of the six strands. Considering metallic area, 68.8% of the rope strength remained, and by test the efficiency was 74.5% and by Equation (34), 72.6 per cent.

Incidentally, it is of interest to note that American manufacturers do not include the strength of the solid triangular wires in the cores of the strands of their flattened strand ropes; the English, Canadian, and German firms do. This fact was disclosed by Equation (34), and it should be kept in mind if a comparison of strengths is made. It is known that these solid triangular wires break up in quite short lengths when such ropes are operated over small sheaves and drums; consequently, it is advisable to neglect the strength of these shaped wires in the strength of flattened strand ropes.

Bending Stress in Wire Rope.—The determination of the bending stresses is in the "battle zone" of wire-rope engineering and no two writers agree on the subject. The writer has stated his views in two previous discussions[14] and still considers that such stresses are not susceptible to mathematical deductions with any reasonable degree of accuracy.

Consider the results of bending tests made of $\frac{5}{8}$-in. ropes on a fatigue bending test machine, in which the ropes were reeved on three sheaves placed closely together. The rope was subjected to a reverse bending operation over and under the three 12-in. tread sheaves, under constant tensions of 1 500 and 2 000 lb. Five different series of tests will be given; after which the reader may decide that bending stresses are an uncertain quantity after all.

Example 1.—In two comparable specimens of 6 × 37 plow-steel rope, $\frac{5}{8}$ in. in diameter, the diameters (in inches), were as follows:

	Rope A	Rope B
One core wire	0.036	0.033
Six inner wires	0.033	0.030
Fifteen inner wires	0.025	0.023
Fifteen outer wires	0.033	0.033

It will be noted that the strand and rope lays were identical as well as the diameter of the hemp center. The outer wires were also identical, and yet the result of the bending tests (in number of bends) was as follows:

---

[13] "Rules and Regulations for Metal Mines", *Bulletin No. 75,* U. S. Bureau of Mines, 1915.

[14] "Aerial Tramways", by F. C. Carstarphen, M. Am. Soc. C. E., *Transactions,* Am. Soc. C. E., Vol. 92 (1928), p. 966; and "Heavy Duty Wire Ropes and Sheaves", by B. R. Leffler, M. Am. Soc. C. E., *Civil Engineering,* Vol. 1, No. 2, November, 1930, p. 110.

Broken Wires	Rope A	Rope B
First outer wire	87 000	30 000
Forty outer wires per foot	150 000	67 500
Rope pulled apart	425 000	210 000

This was purely a case of proper and improper strand design, most certainly not susceptible to mathematical analysis.

Example 2.—Two samples of two types of $\frac{5}{8}$-in., traction steel elevator ropes, under a tension of 1 500 lb., were tested with the following results (in number of bends):

	First Piece:		Second Piece:	
	First wire	Rope failure	First wire	Rope failure
$\frac{5}{8}$-in., 6 × 27 Seale.......	40 300	244 300	48 000	341 800
$\frac{5}{8}$-in., 6 × 19 Warrington.	40 800	121 600	51 000	170 000

In each case the first and second pieces were cut from the same reel and the tests show a difference of approximately 40% at rope failure.

Example 3.—Samples of $\frac{5}{8}$-in., 6 × 19 Seale traction steel elevator ropes, under a tension of 1 500 lb., were subjected to both reverse bending (three sheaves) and continuous bending (over one sheave in one plane only), with the following results (in number of bends):

	Forty outer wires broken per foot
Reverse bending	102 000
Continuous bending	270 000

The effect is scarcely susceptible to mathematical analysis.

Example 4.—The effect of strand construction for $\frac{5}{8}$-in., 6 × 19 and 6 × 37 plow-steel ropes, under 2 000 lb. tension, is shown in Table 9. The outer wires were identical in each type of wire and the difference in strand construction is seen to be scarcely susceptible to mathematical analysis in comparison to test results.

The writer saw a striking demonstration of Example 4 on a standard type of steam shovel, equipped with $2\frac{1}{8}$-in., 6 × 37 lang lay (IWRC) hoist lines; two ropes made of "three-operation" strand gave only 12 and 13 days' service, respectively; while the 6 × 37 filler wire ropes were giving an average of 33 days' service.

TABLE 9.—RELATIVE BENDING LIFE OF ROPES OF DIFFERENT STRAND CONSTRUCTIONS

Rope	Strand Details		Bends of Rope	
	Construction	Type strand (operations)	Forty wires broken per foot	Rope failure
6 × 19 regular..................................	12/6/1	Two	34 000	59 000
6 × 19 filler wire Seale.........................	12/6/6/1	One	105 600	158 400
6 × 37 ordinary................................	18/12/6/1	Three	82 500	156 700
6 × 37 regular.................................	18/19	Two	104 000	212 000
6 × 37 filler wire..............................	18/9/9/1	One	121 000	312 000

Example 5.—Lubrication, or lack of it, greatly influences the bending life of wire ropes, as Biggart's tests made in 1890 for the Forth Bridge on $\frac{9}{16}$-in., 6 × 19, plow-steel ropes show in the following (number of bends):

	10-in. sheave	24-in. sheave
Dry rope	16 000	74 000
Lubricated rope	38 700	386 000

The foregoing tests (covering strand construction, Examples 1 and 4; reverse bending, Example 3; lubrication, Example 5; and manufacturing variation, Example 2) clearly indicate that bending stresses are not susceptible to mathematical analysis. Nevertheless, such stresses must be considered, even if empirically, and the writer prefers the formula:

$$b = \frac{E_r d'}{D} \qquad \text{......................} (36)$$

in which, values of E_r, the modulus of elasticity of the rope for various rope constructions, are given in the writer's discussions[14] of the two papers, previously mentioned. Equation (36) allows for an increase in Er values for ropes that have been in service some time, which is an important consideration not fully allowed for in other bending stress formulas.

As to the factor of safety on load, acceleration, and bending stresses, experience is the only safe guide, and the late R. C. Strachan, M. Am. Soc. C. E., covered[15] this point in his discussion of the paper by B. R. Leffler, M. Am. Soc. C. E., in which he stated that "the choice of a value for k [a modifier of E] should be governed by the conditions of the particular job and the known results in work of a similar character."

Incidentally, the variables of wire ropes as indicated by tests noted in Examples 1 to 5, will explain the difference in service of the $\frac{5}{8}$-in. elevator ropes in a Cincinnati, Ohio, building, as given in Table 4. Similar variations in elevator rope service were noted[16] by Mr. C. T. Coley and such variations are typical of many wire-rope installations, particularly in elevator service, because it is doubtful whether equal tensions are maintained in a set of six hoisting ropes on an elevator in its travel up and down the shaft, unless some type of equalizer is used on the ropes.

It was thought that Equation (20) would be applicable to wire ropes under static loading, such as suspender ropes on suspension bridges. As the limitations noted by Examples 1, 2, and 4, would not be applicable to such ropes, a check was made with Skillman's tests[17] of ropes over sheaves and of tests[18] of the $2\frac{1}{4}$-in., 6 × 37, suspender ropes of the Philadelphia-Camden Suspension Bridge, and these results, together with tests of the $\frac{3}{4}$-in. ropes noted by Mr. Carstarphen, are arranged in Table 10.

[16] Third Conference on Wire Rope Research, under the Auspices of American Engineering Council and American Society of Mechanical Engineeers, September 13, 1929.

[17] "Some Tests of Steel Wire Ropes on Sheaves", by E. Skillman, *Paper No.* 229, U. S. Bureau of Standards, 1923.

[18] Final Report of the Board of Engineers to the Delaware River Joint Commission of Pennsylvania and New Jersey, 1927, p. 118.

TABLE 10.—Tests of Ropes Over Sheaves

Rope	Diameter of sheave, in inches	$\frac{D}{d}$	Breaking Strengths, in Kips		Efficiency	
			Straight rope	Over sheave	Tests	Equation (20)
Skillman:						
¾-in, 6 × 19 plow steel,	10	13.3	49.7	39.8	80.3%	97.3%
1¼-in, 6 × 19, plow steel	10	8	130.7	99.1	75.8%	95.4%
1¼-in., 6 × 19, plow steel	18	14.4	130.7	110.6	84.7%	97.3%
Carstarphen:						
¾-in., 6 × 19, cast steel	6	8	35.0	32.0	91.5%	91%
2¼-in., 6 × 37, with IWRC	32	14.2	436.5	388.4	89%	98.5%

Skillman's tests covered a series of 6 × 19, plow-steel ropes, ⅝ in., ¾ in., ⅞ in., 1 in., and 1¼ in. in diameter, over sheaves, 10 in., 14 in., and 18 in. in diameter, and the results obtained for the various ratios of $\frac{D}{d}$ were quite consistent. They check quite closely with the efficiency given by the 2¼-in., suspender ropes when the difference in construction and flexibility of the latter are taken into consideration, and it is rather difficult to reconcile the great difference in efficiencies between these tests and those reported by Mr. Carstarphen for ¾-in. ropes.

It is obvious from Table 10 that Equation (20) is not satisfactory to use for suspender ropes, slung over cable bands on the main cables of suspension bridges, and for similar reeving of ropes over sheaves. There is a need for a solution of this problem, and the writer has been using the formula given by Mr. Leffler,[19] which is modified by the efficiency factor, ϵ, as follows:

$$S = A\left(t - \frac{E_r d'}{D + d}\right)\epsilon \qquad (37)$$

in which, t is the ultimate tensile strength of the wire, in pounds per square inch, and ϵ is the efficiency of rope in Equation (34).

In the discussion of Mr. Leffler's paper, the writer criticized the use of Equation (37) for bending stresses in operating ropes; but for a non-operating or stationary rope, it gives an approximation that is on the safe side, which results in a lower efficiency than that observed by tests. As examples, for the 2¼-in. rope in Table 10, the value of S becomes 388.6 kips, as compared to test results of 388.4; for the 1¼-in. rope on the 18-in. sheave, it is 104.8 kips, compared to 110.6 by test; and for the 1¼-in. rope on the 10-in. sheave, it is 91.5 kips, compared to 99.1 by test. For the lower ratios of $\frac{D}{d}$, the error is a maximum.

The New Target, A Service Factor Formula, Equation (21).—Much that has been noted in the foregoing discussion of bending stresses, will indicate that so little, really definite, is known about the mechanics of wire rope, that engineers are not ready yet for the advance suggested by Mr. Carstarphen.

---

[19] "Heavy Duty Wire Ropes and Sheaves", by B. F. Leffler, M. Am. Soc. C. E., *Civil Engineering,* Vol. 1, No. 2, November, 1930, Equation (4).

At best, all that could hope to be done with such a formula, would be to set up different constants, factors, and exponents in Equation (21) for varying services, as elevators, mines, shovels, tramways, etc., as well as for the many different constructions, lays, and grades of ropes. Then, the "yardstick" would be difficult of application because no two manufacturers make their ropes alike, even for, presumably, the same rope.

Compared to many other engineering materials and products, the knowledge of wire rope is quite limited and, unfortunately, the manufacturers are very reluctant to join in any outside research work to improve the art, such as that sponsored by the Wire Rope Research Board of Engineering Foundation and the American Society of Mechanical Engineers, the last report of which appeared in 1929. The British and German engineering societies have done considerably more research work on wire rope and are being more actively supported by the manufacturers. They have published some excellent reports of their results as accomplished to date (1932), but most of the work is still ahead of them before anything definite on the subject is known.

It must not be considered that the American manufacturers have lagged in research work, such a monumental work as the George Washington Bridge attests to this fact and at least five of the leading manufacturers have research and adequate testing facilities, not only for finished ropes but also for individual wires. The results are kept confidential, however, and until either the National Bureau of Standards or Engineering Foundation equips a laboratory with suitable machines and competent research workers to carry on investigations on wire and wire rope, independent of any aid or encouragement from the wire-rope manufacturers, will anything of definite value be known about the subject.

Had the works of predecessors and contemporaries in the various engineering sciences, such as those of Galileo, Newton, Kelvin, Rankine, St. Venant, Winkler, Whipple, Einstein, etc., been withheld from publication, engineering sciences would have been greatly retarded. Their works have served a twofold purpose: To create an acquaintance with their thoughts and, equally important, to encourage others to think, because the real value of a book is in what it "pulls" out of one rather than what one gets out of it.

Wire-rope engineering owes a debt of gratitude to the writings of Roebling, Hrabak, Vaughan, Epton, Hewitt, Bucknall Smith, Chapman, Adamson, Howe, Sunderland, Carstarphen, and many others. It is to be hoped that in the near future much more will be added to the present meager knowledge of the subject by competent men who are engaged in the industry.

O. P. ERICKSON,[20] M. AM. SOC. C. E. (by letter).—This is a timely paper on a product of wide use in engineering construction and operation activities. That considerable difference of opinion exists regarding the stresses in wire rope is indicated by the many formulas encountered in wire rope literature. As shown by the author,[21] by the late R. C. Strachan,[10] M. Am. Soc. C. E., and others, none of these formulas agrees even approximately with each other.

---

[20] St. Augustine, Fla.

[21] See p. 579.

The reason for this is the many variables involved, the most important being lubrication, size arrangement and condition of sheaves and drums, type and size of rope center, length of strand, strand construction, and rope lays. Mr. J. F. Howe[22] states that the modulus of elasticity for high-grade rope wire varies between 25 500 000 and 29 000 000. For stressed ropes, he gives modulus values ranging from 7 000 000 to 13 000 000, depending on the construction of the rope as an average of test results, and states that for new unstressed ropes these values will be somewhat reduced. The foregoing makes the selection of a piece of wire rope seem a formidable task.

Actually, however, rope users can obtain considerable practical information from manufacturers' catalogues. The wire rope user and his consulting engineer can also avail themselves of the rope maker's wide experience regarding sheave and drum diameters, rope leads, and type of rope to use. This information, which may be both theoretical and practical, is freely given, and the rope maker because he is consulted on the problem will make a special effort to furnish the best possible type of rope and service. On the other hand, if the rope user and his consultant specifies all the physical properties of the rope and its application, the rope maker may feel, and perhaps rightly so, that his responsibility ends on delivery of the rope. Therefore, in order to insure better service co-operation between the rope user and the rope maker, the specifications should be made sufficiently flexible to cover the operating life of the rope, and the rope should be paid for according to its hours of service.

As pointed out by rope makers, and confirmed by the experience of most rope users, the importance of proper lubrication cannot be over-emphasized. The proper working load of a well lubricated rope running over a sheave may become a dangerous over-load for the same rope when devoid of lubrication. Ropes subjected to temporary over-loads or under-water usage require much more than the average lubrication due to the lubricant being squeezed out or washed away. In order to penetrate between the wires to the rope core most lubricants must be applied hot. Unless they penetrate between the wires they are of little value in prolonging the rope life.

Other causes for exceedingly short rope life are too small sheaves and reverse bends. The U. S. Government Master Specifications for Wire Rope,[23] gives the following sheave diameters: For 6 × 19 rope construction good practice requires the sheave to be 50 rope diameters, and under no circumstances less than 20 rope diameters. For 6 × 37 or 8 × 19 rope construction good practice requires the sheave to be 30 rope diameters, and under no circumstances less than 15 rope diameters. If reverse bending cannot be avoided the sheave about which it occurs, if possible, should be larger than the other sheaves. This applies to bends of even small angularity.

F. W. Deck,[24] Assoc. M. Am. Soc. C. E. (by letter).—The author's method of attacking the problem of the effects of bending should serve to clear up many of the difficulties that attend the study of wire rope, and all kinds of stranded cables that act under bending similarly to wire rope. A complete understanding of what takes place when a stranded cable is bent is necessary not only in considering the more violent and acute bendings that take place, such as those in wire ropes used for hoisting, cableways, elevators, etc., but also in the study of the high frequency vibration that occurs in ropes and cables. This latter action causes a repetitive bending, usually of low amplitude and high frequency, which, if it occurs at a point of restriction to the free movement of the strands, may soon cause failure through fatigue in the metal of which the strands are composed.

---

[22] *Transactions*, Am. Soc. Mech. Engrs., 1918, p. 1061.

[23] No. 297, May, 1925, p. 32.

[24] Structural Engr., Mech. Div., Philadelphia Elec. Co., Philadelphia, Pa.

Failures of this kind are experienced in many cases of cables used in the transmission of electric energy, or under similar conditions of usage, where they may be subjected to the constant action of wind or other forces tending to set up a condition of resonance. Under the condition of free vibration, the cable does not usually sustain serious injury, but where the cable is restrained, as at its terminal or clamp, the free slippage of strands and the stress equalization due to stranding are not allowed to take place, and, consequently, the bending becomes excessive.

In any study of this action, an analysis of the effects of bending, such as is described by the author, is of material service. While the bending in vibration is slight as compared with bending around a sheave, the incipent action of the strands is similar. In the vibrational bending, it is consistent to use the beam elastic curve analysis; while in bending about a sheave, as the author points out, this principle may lead to serious error in calculations.

The experience which some public utilities have had in the use of wire rope bears out many of Mr. Carstarphen's statements. One of the primary uses to which wire rope is subjected in the public utility service is the handling of coal at steam-generating stations. This involves heavy loads, high accelerations, and severe abrasive action. Among the factors that are most important in contributing to rope failures, is friction. Abrasion nearly always precedes the breaking of wires, and practically none of the reduction in size is due to corrosion, which is almost unknown in coal-handling service. The bending, tensile, and shearing stresses are severely augmented by small sheaves, small drums, and reverse bends, together with rapid acceleration and deceleration of the loads and improper reeving of the rope.

Proper size and maintenance of sheaves have naturally been found to be one solution in increasing wire-rope life. Proper lubrication and care in handling are probably the most improtant factors, after care has been taken of the mechanical features of the equipment. The most important of these (care in handling) can be obtained only by careful attention to the operating personnel that handles the rope. It has been found possible to increase the life of rope several times by introducing a spirit of responsibility and competition among the men whose duty it is to use it. Consciousness on the part of the personnel that rope made by reliable manufacturers will give long life, and that early faults can not always be ascribed to poor manufacture, but are usually due to improper usage, will serve to increase such life to a rather remarkable degree.

Specifically commenting on the mathematics used by the author, the writer suggests revision of the substantiating statements in Example 1 as follows: If the two wires are stressed, and if no slipping occurs between them, the bent wire will be elongated and will rotate about A so that its end, C, will take the new position, B'; but if no slipping occurs, there is no increase in length, F (Fig. 12), which remains $2\pi d'$, and hence dl_1 becomes equal to the distance, AB', minus AC, while the angle decreases. The increment, dl_1, will always be less than dl', because it is one of the legs of an approximate right triangle, while dl' is the hypotenuse. Hence, the true ratio of stresses,

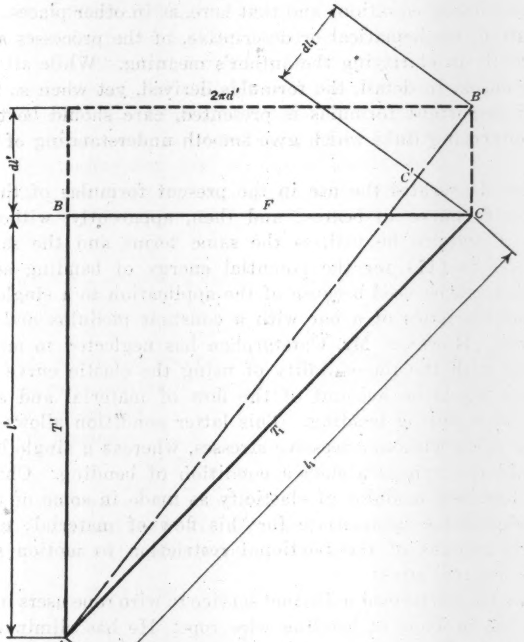

FIG. 12.

$$\frac{T_1}{T'} = \frac{\dfrac{dl_1}{l_1}}{\dfrac{dl'}{l'}} = \frac{l'\,dl_1}{l_1\,d\,l'}$$

; therefore, T_1 is less than T', or the reverse of the condition specified by the author. It is not the inner wire that fails to take its full share of stress to prevent overstressing the outer wires; it is the outer wires, which are not stressed fully to avoid overstressing in the inner wire.

Furthermore with the symbols used by the author, if $\frac{dl_1}{dl'} = \frac{l_1}{l'}$ then $\frac{dl_1}{l_1} = \frac{dl'}{l'}$ and $T_1 = T'$ and, hence, $\frac{T_1}{T'}$ cannot equal 1.038. The results are similar, in giving a strand of lesser strength than the sum of the individual strengths of its wires.

The writer feels that there is some confusion of symbols in Equation (1) and the substantiating equation; and that here, as in other places, a more complete explanation, mathematical or descriptive, of the processes accomplished would aid greatly in clarifying the author's meaning. While all readers may not desire to check, in detail, the formulas derived, yet when so much of the derivation of important formulas is presented, care should be taken not to omit those connecting links which give smooth understanding of the author's meaning.

The author deprecates the use in the present formulas of the expression for the elasticity curve in beams; and then, apparently, without sufficient explanation or reasons, he utilizes the same terms and the same basis in Equations (13) to (17) for the potential energy of bending and twisting. These formulas can be used because of the application to a single wire which takes the characteristics of a bar with a constant modulus and a relatively small diameter. However, Mr. Carstarphen has neglected to make this fact clear, together with the impossibility of using the elastic curve formula for the cable as a whole on account of the flow of material and stress in the wires and strands during bending. This latter condition allows the bending of a stranded cable without excessive stresses, whereas a single bar of larger diameter could not approach such a condition of bending. Changes in the value of the assumed modulus of elasticity as made in some of the formulas in current use cannot compensate for this flow of material; nor can such formulas take account of the frictional restriction to motion and bending which causes the real stress.

The author has performed a distinct service to wire rope users in his method of attacking the problem of bending wire rope. He has eliminated from his mathematical solution of the problem, those features which would tend to lead the analyst astray, and has given a reasonable formula for ascertaining the loss in strength of the wire when bent around a sheave.

The formulas given in this paper for the bending of ordinary stranded cables and the study of the elasticity curve for locked-coil cables, should be of great assistance when combined with tabulated results of experiments along these same lines.

O. G. JULIAN,[25] M. AM. SOC. C. E., and J. C. DAMON[26] ESQ. (by letter).—An interesting account of the development and use of ropes and an analysis of certain problems are contained in this paper. The writers appreciate Mr. Carstarphen's initiative in taking up a subject on which little has been written, and regarding which exact knowledge is scarce.

---

[25] Engr., Jackson & Moreland, Boston, Mass.

[26] Engr., Jackson & Moreland, Boston, Mass.

Regarding the modulus of elasticity of steel the author states (in commenting on Table 1) that, "this factor varies, of course, depending upon the composition of the steel, but will usually be found to be between the limits of 25 000 and 30 000 kips per sq. in." This is contrary to the writers' understanding. The late George F. Swain, Past-President and Hon. M. Am. Soc. C. E., has stated[27] that, "notwithstanding the great variation in strength, it is remarkable that the modulus of elasticity of all grades of steel remains nearly constant at about 30 000 000 lb. per sq. in."

The section of the paper entitled 'Analysis of Strength" is interesting and the numerical value obtained for the ratio of the strength of a strand to the sum of the strengths of the individual wires making up the strand (which ratio may be termed the "efficiency" of the strand), agrees well with known values obtained from tests; however, the writers have some qualms regarding the method Mr. Carstarphen uses to obtain these values.

In Example 1, commenting on Fig. 2(*c*), the author states parenthetically that, "the ratio, $\frac{T'}{T_1} = \frac{1}{1.04} = 0.96$." For the case given, $0.96 = \cos\alpha$ (the angle of lay); hence, according to the author, the ratio of the stresses in the center wire, and the curved wire equals $\cos\alpha$. As α approaches $\frac{\pi}{2}$, however, $\cos\alpha$ approaches zero, and the ratio of the stresses in the center and curved wires must also approach zero, according to the foregoing hypothesis. This does not appear reasonable.

According to statics,

$$a'\,T' + a_1\,T_1\cos\alpha = P \qquad (38)$$

in which, a' is the area of the straight wire; a_1, the area of the curved wire; and P, the total applied load. If α is zero, the wires share the load equally (provided $a' = a_1$ and the elastic properties of the wires are identical); but as α approaches $\frac{\pi}{2}$, the curved wire supports a lesser, and the center wire a greater, proportion of the total load, P.

According to Fig. 2 and Hooke's law, provided the proportional limit is not exceeded:

$$T' = \frac{E'\,(dl')}{l'} \qquad (39)$$

while,

$$T_1 = \frac{E_1\,(dl')\sec\alpha}{l'\sec\alpha} \qquad (40)$$

in which, E' and E_1 equal the moduli of elasticity of the center and curved wires, respectively. According to Equations (39) and (40),

$$\frac{T_1}{T'} = \frac{E_1}{E'} \qquad (41)$$

that is, the stresses in the wires are equal if $E_1 = E'$.

---

[27] "Structural Engineering, Fundamental Properties of Materials," p. 97.

Combining Equations (38) and (41),

$$T' = \frac{P}{a' + a_1 \frac{E_1}{E'} \cos \alpha} \ldots\ldots\ldots\ldots\ldots (42)$$

and,

$$T_1 = \frac{P}{a' \frac{E'}{E_1} + a_1 \cos \alpha} \ldots\ldots\ldots\ldots\ldots (43)$$

are obtained.

If instead of being surrounded by only a single wire as indicated by Fig. 2, the center wire is surrounded by several wires, Equation (38) becomes,

$$a'\,T' + \Sigma\,(a_1\,T_1 \cos \alpha) = P \ldots\ldots\ldots\ldots\ldots (44)$$

and Equations (42) and (43) become, respectively,

$$T' = \frac{P}{a' + \Sigma\,(a_1 \frac{E_1}{E'} \cos \alpha)} \ldots\ldots\ldots\ldots\ldots (45)$$

and,

$$a'\,T_1 \frac{E'}{E_1} + \Sigma\,(a_1\,T_1 \cos \alpha) = P \ldots\ldots\ldots\ldots\ldots (46)$$

If n_1 equals the number of wires to which T_1, a_1, and α, apply, n_2 equals the number of wires to which T_2, a_2, and β apply, and n_3 equals the number of wires to which T_3, a_3, and λ apply, etc., Equations (44), (45), and (46) may be written in the more general form:

$$a'\,T' + n_1 a_1\,T_1 \cos \alpha + n_2 a_2\,T_2 \cos \beta + \ldots\ldots = P \ldots\ldots\ldots (47)$$

and,

$$T' = \frac{P}{a' + n_1 a_1 \frac{E_1}{E'} \cos \alpha + n_2 a_2 \frac{E_2}{E'} \cos \beta + \ldots\ldots} \ldots\ldots\ldots (48)$$

$$T_1 = \frac{P}{a' \frac{E'}{E_1} + n_1 a_1 \cos \alpha + n_2 a_2 \frac{E_2}{E_1} \cos \beta + \ldots\ldots} \ldots\ldots\ldots (49)$$

$$T_2 = \frac{P}{a' \frac{E'}{E_2} + n_1 a_1 \frac{E_1}{E_2} \cos \alpha + n_2 a_2 \cos \beta + \ldots\ldots} \ldots\ldots\ldots (50)$$

and so on.

If P is the limiting load for the strand and Σp the limiting load for all the individual wires which make up the strand (when the wires are straight), the efficiency is,

$$\frac{P}{\Sigma\,p} = \frac{a'\,T' + n_1 a_1\,T_1 \cos \alpha + n_2 a_2\,T_2 \cos \beta + \ldots\ldots}{a'\,T' + n_1 a_1\,T_1 + n_2 a_2\,T_2 + \ldots\ldots} \ldots\ldots\ldots (51)$$

Then, for the example cited by the author (that is, a center wire surrounded by several others having the same areas as the center wire, and $\alpha = 15° 35'$), $\cos \alpha = 0.96$. Equation (51) becomes,

$$\text{Efficiency} = \frac{1 + n_1 \cos \alpha}{1 + n_1} \ldots\ldots\ldots\ldots\ldots\ldots (52)$$

If $n_1 = 6$, as is usual under these conditions, the efficiency of the strand according to Equation (52) is 96.6%, which differs by only approximately 0.5% from the value given by the author. However, in the extreme case, in which $n_1 = 1$ and $\alpha = \frac{\pi}{2}$, by Equation (52), efficiency $= \frac{1 + 1(0)}{1 + 1} = \frac{1}{2}$, or 50%; whereas by the author's method (as understood by the writers), efficiency $= \frac{(\cos \alpha)\, 2\, S'}{2\, S'} = 0$. The results of the two methods are seen to diverge as α increases. The writers believe that the author is unwarranted in stating that $\frac{dl_1}{dl'} = \frac{T_1}{T'}$.

Regarding "Strength of a 6 × 19 Rope," Equation (1) may be written in the more general form,

$$X + n_Y Y \cos \alpha + n_Z Z \cos \beta + \ldots = P \ldots\ldots\ldots\ldots (53)$$

in which, n_Y and n_z equal the number of wires making angles of α and β, respectively, with the axis of the rope. It will be noted that, except for notation, Equations (53) and (47) are identical.

It is not clear what the author means by the phrase "if slipping occurs," nor is it clear how "slipping" is taken into account in his calculations for strength efficiency. The effect of any individual wire slipping with respect to the others would appear to be a function of: (*a*) The manner in which the ends of the strand of rope are secured; (*b*) the length of the member; (*c*) the coefficient of friction between the component parts; and (*d*) the applied load.

If the ends of the member are secured by wire-rope sockets properly installed so that each wire can assume its due share of the applied load, and if the member is of considerable length, the writers believe that fair approximations of stresses and efficiency may be obtained from Equations (47) to (51). However, it is obvious that if the ends of the member are secured so that certain individual wires may be taut while others are slack, the problem is not susceptible of calculation. It is also evident that the effect of inevitable errors in socketing will have more influence on short members, such as those ordinarily used in tests, than on members of considerable length, such as those actually used in construction.

The analysis given neglects the effect of:

(1) The wires and strands drawing together as the load is increased.
(2) The end sockets or other fastenings and attachments causing compression at right angles to the axis of the member.
(3) Compression resulting from each wire or strand pushing against its neighbors.

(4) Friction between the individual wires or strands.
(5) The change in angle of lay as the load is increased.

On account of the effect of the foregoing, especially Item (1), the writers believe that the moduli of elasticity of strands and ropes are not susceptible of even approximate determination by calculations. They should be determined from tests and, if practicable, the tests should be made on members of lengths comparable to those used in construction. However, Mr. James F. Howe has given[28] formulas for the determination of the modulus of elasticity of strands and ropes, and it is remarkable to note that the results obtained from his formulas agree well with values determined by tests on pre-stressed members.

As pointed out by the author the modulus of elasticity of strands and ropes is not constant for low stresses. It has been found that both the elastic limit and the modulus of elasticity of such members can be raised materially by subjecting them to a cycle or two of comparatively high stress, and that the primitive elastic properties are apt to be quite misleading. It is believed that, when erected, all such members should be pre-stressed to at least the highest point to which they are likely to be subjected while in service, and that by this simple procedure their modulus of elasticity can be made practically constant throughout the range of working stresses.

The author gives Equations (3), (4), and (5), as if they were derived from the approximate formula for beams, $EI \frac{d^2y}{dx^2} = M$. The writers believe that this is an erroneous view. Consider an element of a straight bar of length, ds, and having a radius of cross-section, r'. Let this bar be bent until the radius of the arc is R. Let $d\theta$ equal the angle between two radii subtended by ds. Then, $ds = Rd\theta$, but the unit elongation of an extreme fiber equals $\frac{r'd\theta}{ds} = \frac{b}{E}$; hence, $b = E\frac{r'}{R}$, which is the author's Equation (3). The only assumptions made in deriving this formula are that "plane sections remain plane," and that E is constant and the same for tension as for compression (the stress as well as the strain has plane distribution), which assumptions are substantially true within the proportional limit. The approximate formula, $EI\frac{d^2y}{dx^2} = M$, referred to by the author, is based on the further assumption that the curvature, $\frac{1}{R}$, is small and, therefore, its exact value, $\frac{d^2y}{dx^2}\left(\frac{1}{1+\frac{dy^2}{dx^2}}\right)^{\frac{3}{2}}$, may be taken as equal to $\frac{d^2y}{dx^2}$. This assumption is not involved in the derivation of Equation (3). This equation is not applicable beyond the elastic limit, because then E is not constant. Since the working stress should not exceed the elastic limit the more involved stress conditions prevailing beyond that point are only of academic interest and ordinarily need not be investigated.

---

[28] *Transactions*, Am. Soc. Mech. Engrs., Vol. 40, 1918, p. 1058 *et seq.*

The well-known Reuleux formula (Equation (4)) is obtained from Equation (3) by multiplying both numerator and denominator of the right-hand side by 2. The writers fail to see where there is anything "arbitrary" in the argument leading to Equations (3) and (4), and believe them to be rational. From Equation (3) it follows that,

$$b = Er' \, \Delta \frac{1}{R} \quad \text{.........................} (54)$$

in which, $\Delta \frac{1}{R}$ is the change in curvature due to flexure.

It has been shown[29] that for a rope,

$$\Delta \frac{1}{R} = \frac{2 \cos^2\alpha \cos^2\sigma}{D} \quad \text{.........................} (55)$$

in which, α is the angle of lay of a single wire with the axis of a strand, and σ is the angle of lay of a strand with the axis of the rope. Substituting this value of the change of curvature in Equation (54) and substituting d' for $2r'$, Equation (54) becomes[29],

$$b = \frac{Ed' \cos^2\alpha \cos^2\sigma}{D} \quad \text{.........................} (56)$$

It will be noted that Equation (56) differs from Chapman's formula (Equation (12)), as given by the author.

Taking cos α and cos σ as each equal to 0.95 and E as 28 500 kips per sq. in., for a $\frac{3}{4}$-in., 6 × 19 rope bent around a 6-in sheave, Equation (56) gives,

$$b = \frac{28\,500\,(0.95)^4 \left(\dfrac{0.75}{15}\right)}{6} = 193.5 \text{ kips per sq. in.}$$

for the extreme fiber stress due to flexure, in the wires bent on the sharpest curvature. Equation (56) does not state that the total tensile stress on the rope due to bending is the product of b and the area of cross-section of the rope; that is, 193.5 × 0.241 = 46.6 kips, as intimated by the author. Since the extreme fiber stress obtained is above the proportional limit, and since Equation (56) is based on the hypothesis that this limit be not exceeded, the only true conclusion that can be made from the result — $b = 193.5$ kips per sq. in. — is that the proportional limit has been exceeded. However, assuming that the proportional limit of the wires is greater than 193.5 kips per sq. in. and that the radii of bend of all the wires are equal to the radius of the sheave, then,

$$T = 2 \times 6 \times 19 \, \frac{b}{r'} \int_0^{r'} \left[(r')^2 - y^2 \right]^{\frac{1}{2}} y \, dy = 76 \, b \, (r')^2$$

$$= 76 \;\; (193.5) \; (0.000625) = 9.2 \text{ kips}$$

Chapman made a number of experiments to determine the forces required to bend wire ropes and "found a close agreement between the observed and calculated deflections".[30] His calculations were based on Equation (56). In the concluding paragraph of the paper, in which he reports the results of these experiments, Chapman states that, in applying the formulas to any particular ropes, it must be borne in mind that they were established on the assumption that the wires of the rope are not strained beyond the elastic limit. Furthermore, he points out that it is easy to get ridiculous results from the formulas by applying them to ropes bent over too small pulleys. His calculations were applied only to cases in which the wires are not strained to such an extent that they do not completely recover.

---

[29] *The Engineering Review* (Lond.), October, 1908, paper by R. W. Chapman.

Since friction between the various individual wires is not taken into account in the derivation of Equation (56), it would appear that the extreme fiber stress, b, obtained from this equation would be low rather than high. If the static friction between the individual wires is sufficient to develop the longitudinal shear required to make the rope act as a beam having a solid cross-section, the following equation,

$$b = E_r \frac{d}{D} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (57)$$

(in which, E_r is the modulus of elasticity of the rope and d, the diameter of the rope) rather than Chapman's formula, should be applicable. As the ratio of the static friction to this longitudinal shear between the wires approaches zero, the extreme fiber stress due to flexure should approach the values given by Chapman's formula. All cases (for stresses within the proportional limit) lie between these two extremes. Chapman[31] found that the area of the hysteresis loop of the deflection force diagram was materially decreased by lubricating the rope. It would appear, therefore, that b is a function of the degree of lubrication, and since friction can not be entirely eliminated, the value of b is somewhat higher than that given by Equation (56). For a given coefficient of friction, the total friction between the individual wires and strands will be a function of the axial tension, P, on the member and hence, as stated by the author, "the bending effect is a function of the tension" (see "A New Formula for Wire Rope"). It is clear, also, that the friction between the individual wires and strands is a function of the degree of tightness to which the individual wires are laid up in the strands, and the strands in the rope.

It has been shown that for parallel wire cables the force required to produce a given deflection is materially effected by the tightness of the wrapping wire.[32] With a tension of 96 lb. in the wrapping wire, it required an applied central load of only slightly more than 4 000 lb. to cause 1.0-in. deflection in a 9-ft. cable containing 1 904 individual No. 6 wires, while with a tension of 200 lb. in the wrapping wire, it required a load of 23 000 lb. to cause the same deflection. In these tests, the cable was mounted so as to act as a pin-ended beam subjected to a concentrated load at mid-span. It would appear that in ropes and strands the outer layers of wires have an effect on the remainder comparable to the effect the wrapping wire of a parallel-wire cable has on the longitudinal wires.

[31] *Loc. cit.*, Fig. 3, and adjacent text, p. 265.

[32] "Construction of Parallel Wire Cables for Suspension Bridges," pub. by John A. Roebling's Sons Co., Chart I and p. 10 *et seq.*

The writers do not find the arguments leading up to Equations (13) to (20) clear. It is believed that the value of the paper would be considerably enhanced, if the author would clarify and amplify these arguments. It should be noted that the well-known equations given for the potential energy of bending and twisting, $U'_b = \frac{M^2_b l}{2\,EI}$ and $U'_t = \frac{M^2_t l_1}{2\,G_r I_p}$, are based on the proportional limit not being exceeded and, therefore, calculations depending on them are only applicable for stresses below that limit.

Formulas have been proposed elsewhere[33] for the limiting load on ropes subjected to static and moving loads. These are based on Chapman's findings, the law of conservation of energy, and the obvious fact that if the rope is to last, the limiting stress should be not more than the endurance limit. Of course, ropes used for temporary rigging may be stressed well past this point without serious consequences. However, this does not imply that it is good practice so to stress rope used in permanent engineering structures of any importance.

A. S. RAIRDEN,[34] ESQ. (by letter).—The author has contributed some valuable information on a subject that has been under controversy for considerable time. As pointed out, bending stress formulas on wire rope developed, respectively, by Reuleux, Rankine, and Chapman give bending stress values out of proportion to the breaking strength of the rope. The problem is solved most easily and accurately by the development of empirical formulas by extending breaking-strength tests of wire rope bent to varying radii of curvature.

A series of tests were conducted to determine the breaking strength of $\frac{5}{8}$-in. rope (improved plow steel), of varying constructions bent over sheaves, as given in Table 11. The sheaves contained **U**-grooves conforming to the contour of the $\frac{5}{8}$-in. ropes.

TABLE 11

Diameter, in inches	3	6	8	10	16
Ratio of sheave diameter to rope diameter..................	4.8	9.6	12.8	16.0	25.6

For each test a length of wire rope was carefully socketed on both ends. The wire-rope sample was bent around the sheave (which was free to revolve around its axis), and anchored to the stationary head of a 250 000-lb. vertical testing machine (see Fig. 13). The two ends of rope, leading vertically downward and parallel to each other, were securely attached by sockets to a horizontal bar which, in turn, was attached to the movable head of the testing machine. Gradually the load was applied to the specimen bent around the sheaves until complete rupture occurred.

---

[33] *Civil Engineering,* March, 1931, p. 547.

[34] Chf. Engr., Am. Cable Co., Inc., New York, N. Y.

Corresponding to each series of bending tests, a regular straight breaking-strength test of the rope was also conducted. In this test the straight sample of rope was subjected to loads of gradually increasing intensity until it broke.

The load applied to the bent specimen at rupture was divided by two, in order to obtain the load on one end. The value thus obtained was subtracted from the breaking strength of the wire rope obtained by a straight pull, in order to determine the loss in breaking strength of the rope due to being bent around the sheave. In each case this loss is expressed in terms of percentage loss of the breaking-strength value of the rope when pulled to destruction straight. The breaking-strength losses corresponding to each sheave diameter factor are interpreted graphically in Fig. 14, which also shows the cross-sections of the corresponding ropes. The details of construction of these ropes are listed in Table 12.

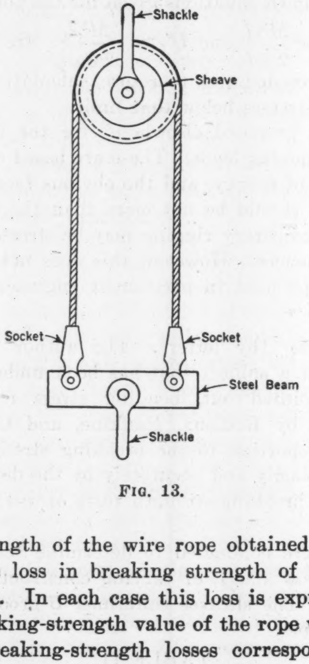

FIG. 13.

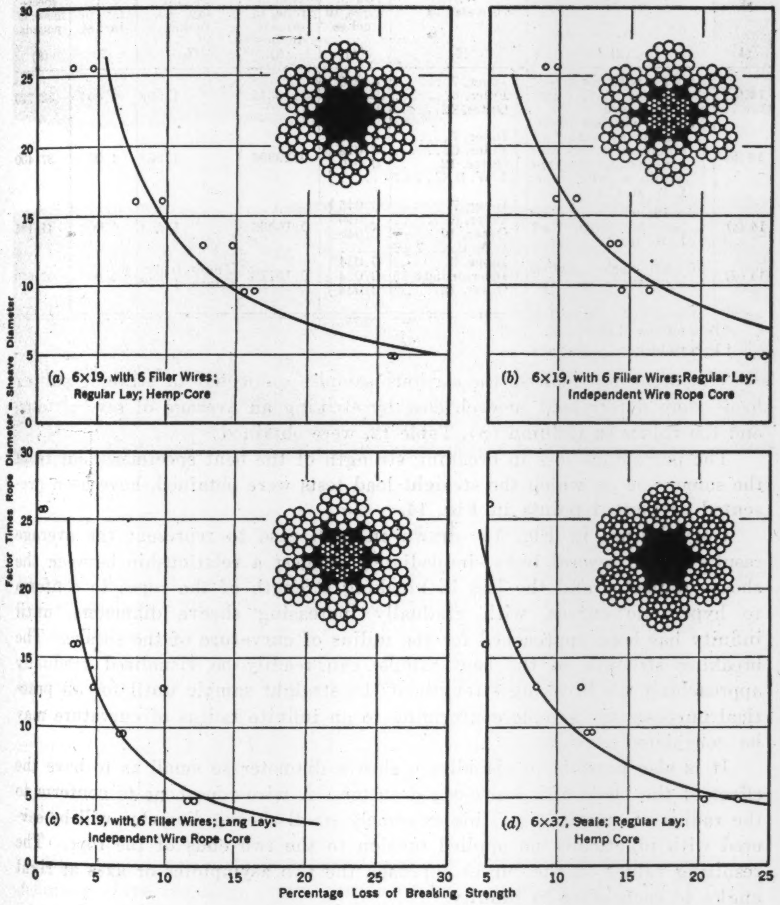
The important difference between the sample in Fig. 14(*b*) (regular lay rope) and that in Fig. 14(*c*) (lang lay rope) may be studied in Fig. 15. The details of construction are absolutely identical in all respects except that the direction of twist in the case of the lang lay rope (Fig. 15(*b*)) is the same for the wires in the strands and the strands in the rope. In the case of the regular lay rope the direction of twist of the wires in the strands is opposite to that of the strands in the rope.

The length of lay or pitch of the wires in the strands and the strands in the rope are, in all cases, of such a proportion that the imaginary angles formed by a wire with respect to the strand axis or by a strand with respect to the rope axis are equal and equivalent to 18.5° in magnitude.

In the case of a regular lay rope the angle of lay of the wires is equal and opposite in value to that of the lay of the strands. The resultant angle, therefore, is zero, and the wires on the crowns of the strands run parallel to the rope axis.



(*a*) 6×19, with 6 Filler Wires; Regular Lay; Hemp Core

(*b*) 6×19, with 6 Filler Wires; Regular Lay; Independent Wire Rope Core

(*c*) 6×19, with 6 Filler Wires; Lang Lay; Independent Wire Rope Core

(*d*) 6×37, Seale; Regular Lay; Hemp Core

FIG. 14.—LOSS OF STRENGTH IN WIRE ROPE, DUE TO BENDING AROUND SHEAVES.

In the case of a lang lay rope the angle of lay of the wires is equal in magnitude and direction to that of the strands. The resultant angle is, therefore, 18.5 + 18.5 = 37°, and the axes of the wires on the crowns of the strands form imaginary angles of 37° with respect to the rope axis.

* In a left-hand direction.

† In a right-hand direction.

The breaking load of the various samples subjected to straight pulling loads were determined in each case by striking an average of several tests, and the values in Column (8), Table 12, were obtained.

The percentage loss in breaking strength of the bent specimens, cut from the same rope on which the straight load tests were obtained, have been presented as plotted points in Fig. 14.

Curved lines in Fig. 14—drawn in each case to represent the average results of the several tests—immediately suggest a relationship between the sheave diameter and the loss in breaking strength of the ropes to conform to hyperbolic curves, with gradually increasing sheave diameters, until infinity has been approached for the radius of curvature of the sheave. The breaking strength of the bent sample can readily be visualized gradually approaching the breaking strength of the straight sample until for all practical purposes the sample conforming to an infinite radius of curvature may be considered straight.

It is also possible to visualize a sheave diameter so small as to have the effect of the blade of a knife-edged cutter. A wire rope bent to conform to the radius of curvature of this extremely small sheave diameter will be severed with practically no applied tension to the two ends of the rope. The resulting values on the curves approach the two asymptotes or axes at right angles to each other in infinity.

The proper definition of a hyperbola is "the locus of a point such that the difference in distances between it and two fixed points is constant." The equation for the rectangular equilateral hyperbola, when the asymptotes conform to the abscissa and ordinate, is,

$$x\,y = \pm \frac{a^2}{2} \quad \text{..........................} \quad (58)$$

(*a*) REGULAR LAY ROPE.

(*b*) LANG LAY ROPE.

FIG. 15.—COMPARISON, SHOWING DIFFERENCE BETWEEN REGULAR LAY AND LANG LAY WIRE ROPE.

in which, a is the distance from the origin or common meeting point of the abscissa and ordinate to the point of inflection of the curve.

For the various types of wire rope in Fig. 14 the following formulas apply:

In Fig. 14(a), $xy = \frac{(\sqrt{12^2 + 12^2})^2}{2} = 144$; in Fig. 14($b$), $xy = \frac{(\sqrt{13^2 + 13^2})^2}{2} = 169$; in Fig. 14($c$), $xy = \frac{(\sqrt{8^2 + 8^2})^2}{2} = 64$; and, in Fig. 14($d$), $xy = \frac{(\sqrt{10.5^2 + 10.5^2})^2}{2} = 110.25$.

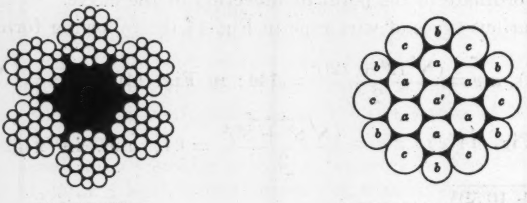
Mr. Carstarphen's static formula and the foregoing empirical formulas definitely prove the large error introduced by the use of the ordinary theory of flexure of solid beams for the development of bending-stress formulas for wire rope. The development of the problem from an angle of considering a wire rope equivalent to a spring is a closer approach to accuracy. However a definite error is introduced by the use of this theory due to the discrepancy between helix characteristics of the outer and inner wires in the strands making up a wire rope.

Frederick C. Carstarphen,[35] **M. Am. Soc. C. E.** (by letter).—It may be in order to remark that this paper was written as a defense of wire rope in the part it plays in industry, and, therefore, must refer to many topics in the use of wire rope that are controversial. It struck at the importance that is attached to the ratio of sheave-rope diameters as a criterion of the service life of wire rope, and called attention to the importance of velocity in such considerations.

It was hoped that the discussion would be extensive, and would cover all phases of the problems considered. Although this hope was not fully realized (more being said about subjects already familiar, than about those that are obscure), the writer is greatly pleased with the data that have been submitted, and feels indebted to those who have taken part in the discussion. The paper and its discussion is a start toward a symposium of the subject and may inspire research on some of the points raised. It is noted that the several discussers have covered and enlightened most of the obscure points in the original paper, so that but little need be said in closing the discussion.

Since the writer does not wish to assume to be true that which is to be proved, it is particularly fitting that the discussion of this paper be closed without serious comment, because the record should stand as it is written, a register of many views on an important subject. Several minor questions may be answered as follows.

Mr. Strachan assumes that there is some inherent difficulty in using Equation (20) to compute the loss of strength due to bending a rope made from different sizes of wire, around a given radius. The contrary is true, and as an illustration of the method, a computation is made of the loss of strength due to bending a $\frac{3}{4}$-in. wire rope around a sheave with a radius of 3 in. Fig. 16 illustrates the grouping of the wires in a $\frac{3}{4}$-in. Warrington, 6 x 19, regular lay rope, with a hemp center. Let the seven center wires of the strand (a, in Fig 16 (b)) be round and have a diameter of 0.054 in., and the outer wires, alternately, b = 0.042 in. and c = 0.058 in. There are six such strands, or 114 wires. The radii from the center of the strand to the center of the several wires are as shown in Table 13.



(a) Section of Rope

(b) Enlarged Section of Strand

Fig. 16.—Cross-Section of 6 x 19, Regular Lay Wire Rope, with Hemp Center.

---

[35] Cons. Engr., Denver, Colo.

The diameter of the strand is 0.288 in. and that of the rope, 0.796 in. Therefore, the diameter of the core is 0.220 in.; the lay of the wires in the strand is 1.815 in.; the lay of the rope is 4.94 in.; the angle of the wires in the strand is $\tan^{-1}\left(\dfrac{0.192\,\pi}{1.815}\right) = 18°23'$; and the angle of the strand in the rope is $\tan^{-1}\left(\dfrac{0.508\,\pi}{4.94}\right) = 17°54'$.

TABLE 13.—CHARACTERISTIC DIMENSIONS OF A $\frac{3}{4}$-INCH WARRINGTON WIRE ROPE WITH A HEMP CENTER

Item	Description	Wires, in Fig. 16(*b*)		
		a	*b*	*c*
1	Number of wires per strand	7	6	6
2	Diameter of wire, in inches	0.054	0.042	0.058
3	Distance from center of strand to center of wire, in inches	0.054	0.102	0.096

Applying Equation (20) to the wires forming the centers of the several strands: $r_1 = 0.254$ in.; $\alpha = 72°\ 06'$; $\sin\alpha = 0.95$ $\cos\alpha = 0.308$; and,

$$P_1 = \frac{\pi\,(0.054)^4 \times 28.5 \times 10^6 \times 11 \times 10^6}{16 \times 3.37 \times 0.254\,[2 \times 11 \times 10^6\,(1 + 0.90) + 28.5 \times 10^6 \times 0.0949]} = 13.94 \text{ lb.}$$

The pull on the six center wires (*a'*, Fig. 16(*b*)) at 13.94 lb per wire gives, say, 84 lb. Proceed to the first row of wires (*a*, in Fig. 16(*b*)) about these center wires. Since this is a regular lay rope the angle of the wires of the strand (except the center wire), with the axis of the rope is practically zero, and is so taken in this case. If it was a lang lay rope this angle would be the sum of the angles of the wires and strands, thereby demonstrating what Mr. Rairden so ably proves, that the loss of strength due to bending a regular lay rope is not the same as for a lang lay rope of the same diameter, and size of wire; thus, for Wires (*a*), Fig 16(*b*), $r_1 = 0.054$ in., and,

$$P_2 = \frac{\pi\,(0.054)^4 \times 28.5 \times 10^6 \times 11 \times 10^6}{16 \times 3.37 \times 0.054\,[4 \times 11 \times 10^6]} = 66.8 \text{ lb.}$$

The pull on thirty-six wires, at 66.8 lb per wire, gives 2 404 lb.

Then, proceed to the second row, and consider the six wires (*c*, Fig. 16(*b*)); thus,

$$P_3 = \frac{\pi \times (0.058)^4 \times 28.5 \times 10^6 \times 11 \times 10^6}{16 \times 3.37 \times 0.096\,(4 \times 11 \times 10^6)} = 48.76 \text{ lb.}$$

The pull on the thirty-six wires, *c*, at 48.76 lb per wire, gives 1 755 lb.

Finally, for the six wires, *b*, in Fig. 16(*b*):

$$P_4 = \frac{\pi \times (0.042)^4 \times 28.5 \times 10^6 \times 11 \times 10^6}{16 \times 3.37 \times 0.102\,(4 \times 11 \times 10^6)} = 12.6 \text{ lb.}$$

The pull on the thirty-six wires, *b*, at 12.6 lb per wire, gives 453 lb.

The total loss of strength due to bending the rope on a 3-in. radius (or, with a sheave ratio of $\frac{6}{0.75} = 8$), is the sum of these values or, say, 4 700 lb. If the breaking strength of the straight rope is 35 000 lb, the bending of the rope about such a sheave, statically, amounts to a loss of $\frac{4\ 700}{35\ 000}$, or 13.5% of its strength.

The following formulas for bending in wire rope should be added for completeness:

$$b = \frac{E\,d'}{D}\cos\alpha + \cos\beta \qquad \text{(59)}$$

$$b = \frac{0.44\,E\,d'}{D} \qquad \text{(60)}$$

$$b = \text{Equation (12)} \times \frac{2}{3} \qquad \text{(61)}$$

and,

$$b = \frac{E_r\,d'}{D_1} \qquad \text{(62)}$$

in which, in addition to the notation of the paper, $E_r = E'$ = modulus of elasticity of the rope, and D_1 = diameter of the bend of the center line of the rope. It is to be noted that Equation (60) is a variation of Equation (10).

Mr. Meals always writes well on any subject pertaining to wire rope, and its use, and his opinions are appreciated. The writer believes that little is gained in separating the center wire of the strand from its neighbors in estimating the strength of a wire rope.

The writer appreciates the comments of Mr. Deck and agrees with him concerning the importance of high frequency vibrations, and their effects, on stretched cables and wire ropes. This opinion is based on observations made of the performance of messenger cables in long-span transmission-line crossings of rivers and bays, such, for instance, as the great crossing of the St. Lawrence River, at Three Rivers, Que., Canada.

Messrs. Damon and Julian present a review of much that has been accepted as commonplace in discussions on wire rope and its bending stress, and, therefore, balance the discussion, and their remarks are accepted as a proper addition to it. From personal contact with the late Professor Swain, the writer is certain that he did not intend any sweeping generality, that may have been said concerning the constancy of the modulus of elasticity of steel, to apply to rope wire, because it is well known that the value may range between 23 000 000 and 30 000 000 lb per sq in.

The test data submitted by Mr. Rairden are most instructive in that they show conclusively, the difference in the loss of strength due to bending regular lay rope as compared with lang lay. This important fact has never been given the attention that it merits by writers on the bending stress of wire ropes, and, of course, is ignored in the simple generalities that pass for engineering formulas of merit.

There is need for more tests of wire rope to determine the loss of strength due to bending, statically and kinetically, and no doubt these tests will be made by competent authority, but until such tests are made, there will be many opinions concerning the service factors of wire rope. Sometimes, it seems to the writer that the design of wire rope is like that of a mansion of many windows, porches, and blinds, that are shuffled around at the owner's will. There are many styles of wire rope, but all are built on the same old foundations of a hemp or wire rope center. Since such centers have little or no resiliency, it is believed that the next step forward in wire-rope construction will be in the adoption of an elastic foundation for the strands.

LAKE CHAMPLAIN BRIDGE[1]

By Charles M. Spofford,[2] M. Am. Soc. C. E.

With Discussion by Messrs. Robert W. Abbett, Henry W. Troelsch, Jacob Feld, Clarence W. Hudson, and Charles M. Spofford

Synopsis

A chronological narrative of the planning, design, and construction of the bridge that crosses Lake Champlain from Crown Point, N. Y., to Chimney Point, Vt., is given in this paper. After an historical summary outlining the preliminary legislative steps necessary, the subjects of traffic counts, estimates, finances, and proposed toll rates are discussed.

A comparison of various types of bridges studied for this crossing and the reasons for adopting the continuous truss type are presented, followed by a description of the finished bridge itself, surveying methods of field location, specifications, loadings, materials, concrete, etc. Construction problems encountered on the substructure and superstructure are treated under separate headings.

Historical

Since early times Lake Champlain has been an important traffic route between the valleys of the St. Lawrence and the Hudson Rivers, and long before the construction of railways or highways the lake carried considerable freight traffic. During the struggle between France and England over control of the North American Continent the possession of the lake became of utmost importance both to the French and to the English, and strong forts were erected by both nations at Crown Point and at Ticonderoga. In Revolutionary times, equal importance attached to the control of the lake, and the capture by Ethan Allen and the "Green Mountain Boys" of Fort Ticonderoga by a night crossing of the lake forms a notable event in American history. While the lake has been a traffic route for centuries, it has also been a serious barrier to free intercourse between the State of Vermont, which was formerly a part of New York State, and New York State itself—a barrier, 120 miles in length, without a bridge. Communication across it has been by infrequent ferry lines operated in the season of open waters only, approximately 8 months per year. In many cases the ferries were not operated during the night and, in some cases, the approaches were hazardous. Occasionally, they were prevented from operating by bad weather. During the period between the formation of thick ice and its breaking up, occasional routes across the ice are available for vehicles.

---

[1] Presented at the meeting of the Structural Division, Boston, Mass., October 10, 1929.

[2] Hayward Prof. of Civ. Eng., Mass. Inst. Tech., Cambridge; Cons. Engr. (Fay, Spofford & Thorndike), Boston, Mass.

The bridge described in this paper is the first and only vehicular bridge crossing the lake in a distance of 120 miles. Its westerly approach is located a few miles above the Village of Crown Point, N. Y., at the Crown Point Reservation. The latter is a State Reservation containing the ruins of Fort St. Frederick and Fort Amherst, and the Champlain Memorial Lighthouse. It is being developed as a public park with bathing facilities, recreation piers, and park sites.

The bridge forms a connecting link between the main north and south highway routes on either side of the lake and also establishes a new traffic route between the Adirondacks, the White and the Green Mountains, and the Maine, New Hampshire, and Northern Massachusetts cities and coast resorts.

Popular demand for a bridge across the lake to replace the ferry-boat service, existed for a long time and finally "came to a head" in the Vermont General Assembly by the passing in 1923 of an Act creating a commission to inquire into the feasibility and possibility of joint action with New York State to bridge the lake. In February, 1925, the New York Assembly also established a commission to investigate such a bridge from the standpoint of New York and thereafter the two State Commissions acted together in making a preliminary investigation. The report[3] of this Joint Commission, submitted in 1926, discusses, in a general way, several possible bridge locations. It gives statistics as to traffic, points out the inconvenience of ferries, and recommends that the New York Commission be continued to complete its investigations and that additional funds be provided for borings and other studies. As a result, the New York Commission was continued and given a grant of $25 000. The Vermont Commission was automatically continued.

The 1927 report[4] of the Joint Commission contained data giving the results of borings at five possible locations, a report of the geologic conditions at these locations, and preliminary designs with estimates of cost of bridges at the proposed sites. The engineering features of this report were prepared by Roy G. Finch and J. A. L. Waddell, Members, Am. Soc. C. E. The geologic report was made by C. A. Hartnagel, Assistant Geologist of the State of New York.

---

[3] Legislative Document (1926) No. 93, of the State of New York, entitled, "Preliminary Report of the Joint Legislative Commission on Bridge Connections Between the States of New York and Vermont Across Lake Champlain."

[4] Legislative Document (1927) No. 59, of the State of New York, entitled, "Final Report of the Joint Legislative Commission upon Bridge Connections Between the States of New York and Vermont."

As a result of its investigation the Joint Commission finally recommended the immediate construction of a highway bridge crossing the lake from the vicinity of Fort St. Frederick, at Crown Point, on the New York shore, to Chimney Point, in the Town of Addison, Vt. (see Fig. 1), to be built, owned, and maintained jointly by the two States and the cost divided between the States approximately in proportion to the length of bridge located in each State, that is, 60% for the State of New York and 40% for the State of Vermont. It was recommended that the bridge be operated as a toll bridge and become free for the use of the public when the revenue collected should prove sufficient to pay the complete cost of construction, together with interest and maintenance charges. It was further recommended that necessary legislation be passed by both States to permit the two States to enter into a compact to carry out the project.

Following the recommendations of the Joint Commission the Legislatures of New York and Vermont early in 1927 passed the legislation necessary to establish a temporary Joint Commission to negotiate a compact between the two States to permit their joint action in constructing the bridge. The report of this Commission, which consisted chiefly of a proposed compact between the two States, was promptly approved by the Legislatures of both States, and the necessary legislation was passed by each. The compact was signed by the Commissioners on May 11, 1927, and was ratified by the Congress of the United States on February 16, 1928.

This compact creates the Lake Champlain Bridge Commission as a body, both corporate and politic, with full power to purchase, construct, own, maintain, and operate a highway bridge, including approaches, across Lake Champlain between the State of New York and the State of Vermont. It has power to make charges for the use thereof, and for any of such purposes to purchase, take, hold, own, and operate, real or personal property; and to borrow money and secure it by bonds or mortgages upon any property held or acquired by the Commission. In other words, this compact sets up an independent body similar to the Port of New York Authority.

In accordance with the terms of the compact a permanent Commission was appointed by the Governors of the respective States in the spring of 1927 and the Commission had its first meeting on June 20, 1927. On August 2, 1927, the writer's firm was appointed as Engineers, and proceeded immediately to make preliminary studies and estimates of various types of bridges and the necessary surveys required for construction, and to place contracts for additional borings. On November 15, 1927, and prior to the ratification of the contract by Congress in February, 1928, the final design was adopted by the Bridge Commission. After public hearings a license for construction was issued by the Secretary of War on March 23, 1928. Bids were received for the construction on May 8, 1928, and the contracts for construction of the main portions of the bridge and approaches were awarded on May 18, 1928. The bridge was opened to traffic on August 26, 1929, fifteen months after the award of the principal contracts. The appearance of the completed structure is shown by Figs. 2 and 3.

FIG. 1.—LAKE CHAMPLAIN BRIDGE: KEY MAP AND LOCALITY MAP.

Estimated Traffic

The estimates of annual vehicular traffic for the years 1930 to 1951 are given in Table 1. These data were based on the following considerations: Statistics of ferry traffic given by the Joint Legislative Commission in its reports on the Lake Champlain Bridge project show that for the five ferries from the bridge site southerly to the Wright's-Chipman Point Ferry the total traffic carried during the season, May to November, 1925, was "more than 75 000 automobiles." These same five ferries, together with the two ferries (Westport-Panton and Essex-Charlotte) next north of the bridge site, are known to have "carried over 80 000 automobiles during the six months' operating season" of 1926. The normally severe winters in this region cause ice conditions on the lake such that it is not possible for ferries to maintain open channels and to operate during the winter months. These conditions and the light patronage both contribute to limit the navigation season to about six months of the year, beginning approximately May 1, and ending about November 1, although under favorable seasonal conditions some of the ferries may continue operation into, and even through, the month of November.

TABLE 1.—Estimated Annual Vehicular Traffic for the Years 1930–1951

Year of operation	Year ending June	Number of vehicles	Annual percentage, increase	Triennia percentage, increase
1 (part)	1930	30 500	....	....
2	1931	60 000	....	....
3	1932	69 000	15.0	....
4	1933	77 500	12.3	....
5	1934	85 500	10.3	42.5
6	1935	93 000	8.8	....
7	1936	100 000	7.5	....
8	1937	106 500	6.5	24.5
9	1938	112 500	5.6	....
10	1939	118 000	4.9	....
11	1940	123 000	4.2	15.5
12	1941	127 500	3.7	....
13	1942	131 500	3.1	....
14	1943	135 000	2.7	10.
15	1944	138 000	2.2	....
16	1945	140 500	1.8	....
17	1946	142 500	1.4	5.5
18	1947	144 000	1.1	....
19	1948	145 000	0.7	....
20	1949	146 000	0.7	2.5
21	1950	147 000	0.7	....
22	1951	148 000	0.7	....

Nearly all the ferries operate only during daylight hours. Some, however, will give night service on signal at advanced rates. The ferries having the longer runs, as, for example, those operating out of Burlington, Vt., follow a regular schedule and this is true also of some of the short-run ferries. Other short-run ferries are operated only on signal. Ferry operation is subject to interruption and delay due to fogs, head winds, and rough water, and to occasional break-down of the motive power of the boats.

In view of the foregoing considerations had a bridge been available at the proposed site in 1926, it was estimated: (*a*) That of the more than 80 000

FIG. 2.—LAKE CHAMPLAIN BRIDGE FROM THE AIR.

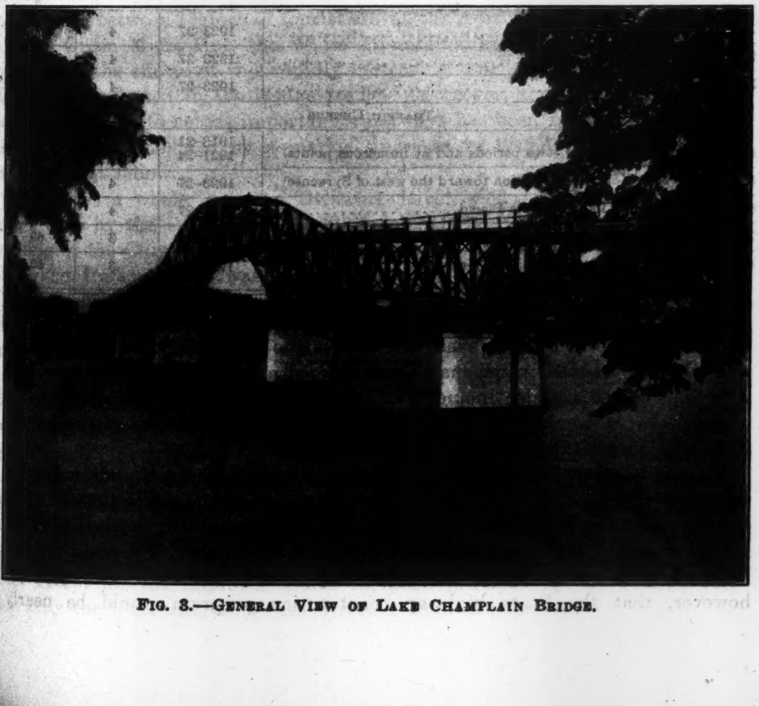

FIG. 3.—GENERAL VIEW OF LAKE CHAMPLAIN BRIDGE.

cars carried by these seven ferries during that operating season (all of which ferries are within about twenty miles of the bridge site), at least 60% or fully 50 000 cars would have used the bridge; (*b*) that other traffic would have been diverted from more distant points (the Burlington ferries and from around the ends of the lake) amounting to, at least, 10 000 cars; and (*c*) that 10 000 additional cars would have used the bridge during the winter and at other times when the ferries were not operating. Hence, a total of 70 000 cars was assumed as the probable traffic which would have crossed a bridge at the Crown Point-Chimney Point site in 1926; but to be conservative, 60 000 cars were taken in making up financial estimates as the number which would cross the bridge in its first normal operating year ending June 30, 1931.

No reliable data were available as to the growth from year to year of the ferry traffic across Lake Champlain. It was necessary, therefore, to base estimates of the probable growth of traffic upon statistics of traffic in general and in the districts bordering the bridge, and also to allow for effect of changed conditions resulting from the construction of the bridge.

TABLE 2.—GROWTH OF MOTOR VEHICLE TRAFFIC ON STATE HIGHWAYS

Item No.	Location	Years	Length of period, in years	Percentage increase
	MOTOR VEHICLE REGISTRATION			
1........	United States....................................	1923–27	4	53
2........	New York State..................................	1923–27	4	61
3........	Vermont...	1923–27	4	51
	TRAFFIC CENSUS			
4........	Massachusetts (two periods and at numerous points)..	1918–21 1921–24	3 3	66
5........	New York State (section toward the west of Syracuse)..	1923–27	4	63
6........	Saranac Lake to Lake Placid......................	1923–27	4	79
7........	Warrensburg to Chestertown.......................	1923–26	3	69
8........	Saratoga Springs to Lake George..................	1923–26	3	60

Table 2 shows the growth in automobile registration, and in traffic on the Massachusetts highways as well as on the New York State highways westerly of Syracuse, which may be considered as representing normal traffic growth. Values are also included in the tabulation for certain of the highways in the Adirondack Region which are more representative of the growth in tourist travel (Items Nos. 6, 7, and 8).

Statistics of traffic on the New York highways in the Adirondack Region must be viewed in the light of the fact that, during the years 1925 to 1930, extensive road construction brought about sub-normal traffic conditions in many instances and super-normal conditions in others. By the time the bridge was to be opened to travel, on September 1, 1929, it was expected, however, that the State highway construction program would be nearly finished; and that the automobile highway from New York City to Plattsburg, N. Y., and Montreal, Que., Canada, along the westerly shore of Lake Champlain, the most direct route from New York City to these northern points, would be entirely completed. It was assumed that these improvements would be reflected in an increased traffic in the districts served by the bridge and also on the bridge itself.

Another factor which was expected to have a decided influence upon the bridge traffic was the fact that the Crown Point Reservation—within which is located the New York approach to the bridge, and which contains the ruins of the historic forts, Amherst and St. Frederick—is being developed as an historic shrine and public park by the State Conservation Department. The development program provides for the building of a recreational pier and boat landing on the shore of the Reservation of the Champlain Memorial Lighthouse, the building of bathhouses and the improvement of the bathing beach, the extension of the museum, the construction of adequate buildings for the shelter of visitors, and provisions of ample parking facilities for motorists.

It was also confidently expected that the opening of the bridge would itself stimulate travel in this region such that the growth of traffic across the bridge would proceed, at least for the first few years, at a substantially higher rate than that on long established highways where for many years conditions have remained substantially unchanged. Tourist travel in general is increasing faster than normal travel, and as this bridge would form a connecting link between regions of tourist travel, the Adirondacks on the one hand and the Green Mountains, the White Mountains, and Maine resorts on the other hand, the effects of this rapidly increasing tourist travel would unquestionably be reflected in the bridge traffic. Moreover, the opening of a new and improved route across important waterways has been found in numerous cases to be accompanied by a marked increase in traffic, as shown by the examples that follow.

Traffic as a whole over the Delaware River was increased 70% in one year's time by the opening of the Philadelphia-Camden Bridge. With the opening of the Carquinez Strait Bridge across an arm of San Francisco Bay the bridge traffic of 1927 was 71% greater than the traffic on that important California highway route carried by ferry in 1926, whereas the normal growth in traffic over the 7-year period prior to the opening of the bridge showed an average increase of only 15.6 per cent.

At the Peace Bridge over the Niagara River at Buffalo, N. Y., where the ferry traffic had been 350 000 cars per year, the bridge traffic during the first year's operation was 1 407 272 vehicles, or four times the traffic on the ferry which the bridge replaced.

In the case of the Holland Tunnel beneath the Hudson River between New York and New Jersey, during its first year of operation ending November 12, 1928, it is estimated by the Chief Engineer that approximately 45% of the year's business was new traffic which would not have crossed the river except for the improved traffic facilities provided by the tunnel, and that only the remaining 55% was diverted from the ferries.

In view of the probable stimulation in traffic due to the foregoing causes, it was assumed that for a few years after its opening the travel over the bridge would increase rapidly and at a rate greater than the average increase in traffic on the highways generally of Vermont and New York. After a time this increase would be less rapid and in eight or ten years the increase might be expected to correspond more closely with the growth of traffic on the highway systems of these two States.

Financing and Insurance

The estimated and actual receipts and expenses from the time of opening the bridge to December 31, 1932, are shown in Table 3.

TABLE 3.— ESTIMATED AND ACTUAL TOLL RECEIPTS

Month	Actual Earnings by Month		Earnings as Estimated by Engineer*

* Engineer's report of May 24, 1928, used as a basis of financing.

Serial bonds, bearing interest at 4¼% and redeemable at any interest date upon thirty days' notice, at varying premiums, were issued to finance this project. They are legal and tax exempt in New York and Vermont for public officials and bodies of each State and of its municipal sub-divisions, for insurance companies, savings banks, and other fiduciary bodies. In the opinion of counsel they are also exempt from the Federal income tax.

Estimates of gross revenues and net earnings, together with payments of interest at the rate of 4% and retirement on the bond issue of $1 000 000, are shown in Table 4.

The revenues are based on an average toll of $1 per car, including all passengers. This rate is less than the average toll rate charged by the several Lake Champlain ferries. The estimates indicate that by 1952 the accumulated surplus will be sufficient to retire the bonds then outstanding ($420 000) and to pay principal and interest on the $200 000 advanced by the States of New York and Vermont.

TABLE 4.—ESTIMATED FINANCIAL SHOWING FROM BRIDGE OPERATIONS

Year ending June 30	Gross revenues from tolls	Operating expense	Net earnings	Bond interest and retirement	Bonds outstanding after retirement paid July 1 of year in question
1929	....	....	....	$40 000	$1 000 000

1952	149 000	25 500	123 500	....	....
Total	$2 669 500	$459 500	$2 210 000	$1 381 200	....

The bridge (except for its filled approaches) is insured for use and occupancy and for damages by fire, lightning, flood, tornado, earthquake, collapse, explosion, riot, malicious action, and other insurable hazards.

TYPE OF BRIDGE AND REASONS FOR ITS ADOPTION

While no limit was set upon the capital cost of the proposed bridge, in order to sell the bonds it was necessary that the bridge should show a probable revenue from tolls sufficient to cover carrying charges and also to amortize the investment in a reasonable time, which was fixed at thirty years by the Commission. The width of the roadway was fixed by the compact, and the clear width and rise of the channel span were determined by navigation requirements as established by the United States Army Engineers.

The Commission and its engineers were in agreement that the bridge should have as pleasing an appearance as possible consistent with the foregoing. The historic importance of the site and the fact that the bridge would be conspicuous for many miles on account of its height made its appearance of special importance. Borings and test piles disclosed that the soil overlying the bed-rock was extremely soft and that the bridge piers would have to be carried to bed-rock which over a part of the site occurs at a depth of 100 ft. below low-water level. After consultation with Army officials, it was decided to provide a vertical clearance at the channel span of 90 ft. above standard low water (Elevation 92.5) for a width of 186 ft., and a clearance of 73 ft. above the same level for a width of 300 ft. Fig. 4 shows the clearance at various points in the channel span. The total width of the lake at this water level is approximately 1 500 ft.

FIG. 4.—CHANNEL SPAN, LAKE CHAMPLAIN BRIDGE.

In selecting the type of bridge consideration was given to the relative advantages and disadvantages of the following types:

(*a*) End-supported truss bridge;
(*b*) Cantilever truss bridge;
(*c*) Continuous truss bridge; and
(*d*) Suspension bridge.

An arch bridge either of reinforced concrete or steel was not considered economically possible in view of the expense of carrying unbalanced arch thrusts to the bed-rock at its great depth below the arch springing lines.

In comparing the availability of the various types of truss bridges the method of erection had to be given careful consideration. Navigation requirements made it essential that the channel span should be erected without the use of falsework. In some truss bridges this has been done by erecting a complete span on a lighter and hoisting it in place, but such a method was not seriously considered for this bridge in view of the lack of suitably located anchorage basins in the vicinity of the site. In consequence, all studies of truss bridges were based upon erecting the center span by cantilevering each half of it from the adjoining span. This method would not involve special difficulty, or greatly increased expense in the case of the cantilever or continuous type of structure; but for an end-supported center span, some of the truss members would have to be increased in size.

Moreover, in the engineer's judgment, the end-supported type, if designed with due regard to economy (with a shorter center span than that actually used for the Lake Champlain Bridge), would prove much less pleasing in appearance than either the continuous or the cantilever type and, also, would require somewhat more expensive center piers, owing to the greater pier width necessary to provide landing space for abutting trusses than that required for the support of a continuous truss. If end-supported spans were to be given the same outline as the continuous spans adopted, the trusses would be far from economical in outline. A further complication affecting the appearance of a bridge with end-supported trusses was the gradient which would require deck trusses for part of the crossing and through trusses over the channel. The writer found it impossible to sketch any simple span design that was at all satisfactory in appearance.

A cantilever bridge of the usual statically determined type did not seem especially appropriate, particularly in view of the necessarily short suspended span which would be proportionably shorter than is generally considered advisable for cantilever bridges. Some study was given to this type, but it was not possible to discover any important advantages as compared with a continuous structure while it would have the disadvantage of additional expansion joints in the floor and of greater and more rapid deflection particularly in the center span. Noticeable deflection of any bridge, especially when the deflection occurs rapidly, is objectionable both from the standpoint of the users of the bridge (a particularly important factor in a highway bridge), and of maintenance. It was, therefore, the engineer's desire to produce as rigid a bridge as possible with due regard to first cost and maintenance charges. A cantilever bridge that is not statically determined, such as the Queensboro Bridge in New York City, is, in reality, continuous. The comparisons of this paper do not refer to such a bridge, but only to the usual type of statically determined cantilever bridge.

The continuous truss type has all the advantages of the cantilever type except that of statical determination, and is also economical of material, especially when the dead stresses are large compared with the live stresses as in the case of a highway bridge with a concrete floor and with spans as long as those of this bridge. The lack of statical determination requires additional mathematical investigations on the part of the designers, but involves no special theoretical difficulties, merely increasing the labor of making the necessary computations. The deflection of a continuous span is less in amount and occurs with less rapidity than that of a cantilever span, this being an important element in favor of the continuous bridge. Moreover, the continuous type can be given a more pleasing appearance, consistent with economy, than any of the other types of truss bridges.

One objection sometimes raised to continuous bridges is that settlement of foundations causes serious changes in truss stresses, but with piers supported on bed-rock, as in the Lake Champlain Bridge, this objection does not exist. Moreover, in the case of yielding foundations most of the settlement occurs during the construction of the piers themselves, and does not affect the truss stresses. Unequal settlement of the piers after the erection of the trusses and the establishment (by jacking) of the desired end reactions would affect only that part of the truss stresses due to the dead loads carried by the trusses at the time the ends are jacked. These loads would include the weight of the steel trusses and bracing and such portions of the floor system as might be found convenient for erection purposes; that is, unless the unequal settlement is so great as to leave the trusses suspended over one of the piers or abutments, a contingency which should be guarded against by proper design.

With both end-supported and cantilever truss spans rejected in favor of continuous truss spans, it became necessary to compare this type of structure with the suspension span type.

Detailed estimates were made of a continuous span structure and two suspension bridges. One suspension bridge had a center span of 700 ft., with two flanking spans of 350 ft. each and two 185-ft. approach spans, and the other had a center span of 1 000 ft., with two flanking spans each with a length of 350 ft. The estimated cost of the shorter of these suspension spans proved to be somewhat greater than that of the continuous truss type. Moreover, its appearance was not entirely satisfactory since the main structure, consisting of the center span and the two flanking spans, would not have sufficient length to extend from shore to shore at all stages of the lake level thus giving it the effect of not being quite long enough to accomplish its purpose. The Commission and the engineers agreed that such a structure would not look as well as the continuous span finally adopted. The other suspension bridge was long enough to extend from shore to shore without the use of approach spans, and would have made an attractive bridge, except for the fact that such a span appeared of unwarranted length. The cost of such a structure, however, would be so much greater than that of a bridge with continuous trusses that its adoption could not be considered.

A design involving the use of continuous span trusses for the greater part of the structure, therefore, was adopted finally with the approval of the Commission and the engineers. The writer and his associates believe that the structure as designed has a pleasing appearance, is economical, and will prove satisfactory in operation and maintenance. The outline of the trusses and the general dimension of the entire structure are shown in Fig. 5.

GENERAL DESCRIPTION

The bridge is a high-level structure approximately 2 190 ft. in length, of which 1 500 ft. more or less is over the water. The ascending gradients of 5½% upward from each end to the channel span are connected by a parabolic vertical curve. The main part of the bridge consists of one end-supported riveted-truss structure; two continuous riveted-truss structures

FIG. 6.—TRIANGULATION SYSTEM, LAKE CHAMPLAIN BRIDGE

(one with two spans and the other with three spans); and eight plate-girder viaduct spans (three on the New York shore and five on the Vermont shore), each having a length of approximately 50 ft. The girders of the viaduct spans were riveted together after the dead load was in place, making them continuous for the live loads, and certain of the columns supporting the viaduct spans are hinged at each end. The viaduct spans are reached by filled approaches, one approximately 400 ft. in length and the other approximately 300 ft. in length. The lengths of the main truss spans between centers of bearings vary from 270 to 434 ft., the latter being the length of the center span of the three-span continuous structure.

The width of the roadway on the bridge structure and on the greater portion of the filled approaches is 24 ft. between curbs. There are no sidewalks, but the curb construction gives footwalks with a clear width of 2 ft. 6 in. on each side, except for the short lengths opposite the web members of the through portion of the center span where these widths are reduced to 15 in. At each end of the filled approaches the roadway is widened for convenience in collecting tolls, giving four traffic lanes each 8 ft. 9 in. in width. The bridge is composed of deck spans except across the channel, where the trusses rise gradually from the floor level at each end to a height of 40 ft. above the floor at the center of the span. The distance from center to center of trusses of the end-supported span and of the two-span continuous structure is 18 ft., which is also the distance from center to center of girders on the viaduct spans. In the three-span structure the distance from center to center of trusses is 30 ft.

FIELD SURVEYS

The field surveys consisted of triangulation, leveling across the lake, topography, lake soundings, and current measurements. Wash and core borings were also taken after the preliminary location of the center line and the piers had been determined. The triangulation system used to determine the distance and relation between points on opposite shores of the lake took the form of a quadrilateral with three points on the New York shore and a fourth point at Chimney Point, Vt. (see Fig. 6). The three points on the New York shore were located so as to allow two sides of the quadrilateral to be taped precisely and used as base lines, checking one against the other. The taping of the base lines was done with a 100-ft. steel tape, supported near its center and having a 12-lb. pull applied by a spring balance at one end. Corrections were computed for the slope, temperature, and sag. Each base line was more than 1 000 ft. in length, and was measured twice with differences of 0.001 ft. and 0.012 ft. in the lengths obtained. Each angle was turned six times forward and six times backward with a transit, reading to 10 sec., first with the telescope direct and then inverted. These results were checked later by a different observer. The measured angles were adjusted to balance the various triangles, the usual correction being 1 sec. or 2 sec.

Reciprocal leveling with a precise level was used to transfer the elevations across the lake a distance of about 1 500 ft. The precise level used had three leveling screws and a bubble with an angular value of 7 sec. per division. Bench-marks were set close to each shore, at about the same elevation. The level was set near one of the bench-marks, and a series of readings were taken across the lake. The position of the level and target was then reversed, and another series of observations were taken in the opposite direction.

A self-reading home-made target, shown by Fig. 6 (*a*), was used for this work. It had four rows of alternate black and white spaces each 0.1 ft. high, the two outer rows being offset 0.05 ft. vertically from the two middle rows, thus aiding the observer in interpolating to hundredths. The two sets of measurements taken in opposite directions were then averaged to eliminate the effect of refraction and curvature of the earth. One set of rod readings was also taken on the surface of the water close to the instrument at each shore as a check on the results. The results from the readings on the water checked the average of the results from the reciprocal leveling more closely than the water level could be read without a hook-gauge. The latter was considered for use in place of the reciprocal leveling, but was not adopted owing to the uncertain effect of wind and the need of building a stilling-box at each shore. The curvature and refraction indicated by the readings were about 0.05 ft. during the morning readings, but this amount was reduced by afternoon. No check on the results of either the triangulation or the leveling has been made other than an approximate check made before the construction of the center spans and tests made by running lines across the ice which gave a check in both distances and elevations within a few hundredths of a foot.

Soundings were taken about 300 ft. to each side of the center line and near the shores and docks. These were located mostly by one transit cutting across range lines. The directions and velocities of the currents were determined by floats made from 2 by 2-in. wooden studs, 13 to 16 ft. long, weighted so as to float vertically and to submerge, except for approximately 1 ft.

LIVE LOADING AND UNIT STRESSES

The live loading used in the design of the main members of trusses and girders was Loading *H*-15 of the Standard Specifications for Steel Highway Bridges issued by the U. S. Department of Agriculture,[5] and as revised by mimeographed supplement. This loading gave a uniform load of 525 lb. per ft. per girder or truss, combined with a concentrated load of 24 500 lb. applied at a point where it would produce maximum stress in the member under consideration. The live loads used in the design of the floor system and columns or hangers supporting the floor-beams consisted of one 20-ton truck moving along the bridge in any part of the roadway, or two 20-ton trucks side by side moving in the same or opposite directions. The dimensions and load distributions of these trucks are those given in the specifications previously mentioned.

Impact and wind stresses were also computed in general in accordance with the foregoing specifications. The unit stresses used in the design of the main truss members were 16 000 lb. per sq. in. for axial tension and for bending on the extreme fiber, and $15\,000 - \frac{50\,L}{r}$ for axial compression, with corresponding values for other unit stresses. In designing the members of the floor system allowable unit fiber stresses of 18 000 lb. were used instead of the 16 000 lb. used for the main truss members.

---

[5] *Bulletin 1259*, U. S. Dept. of Agriculture.

MATERIALS

Steel.—Rolled steel, rivet steel, cast steel, and forgings were required to conform to the standard specifications of the American Society for Testing Materials for carbon steel, as follows:

Structural and Rivet Steel: Open-hearth (Serial Designation A7-24);
Cast Steel: Open-hearth, electric, or crucible (Serial Designation A27-24);
Steel Forgings: Open-hearth, or electric (Serial Designation A20-27);
Reinforcing Trusses for Concrete Floor: Open-hearth billet structural steel (Serial Designation A15-14); and
Other Reinforcement Bars: Either the same as for reinforcing trusses or rail steel (Serial Designation A16-14).

Paint.—Exposed metal work was given one shop coat of red lead and two field coats of tinted white lead. The coloring pigment used in the first field coat consisted of a small quantity of lampblack giving this coat a brown color. Considerable study was given to the second field coat to ensure a color that would harmonize with the landscape and prevent the bridge from being too conspicuous. The color finally selected was made by mixing from 13 to 13½ lb. of raw umber in oil with 100 lb. of white lead, and adding a small quantity of ferrite yellow until the exact color was obtained.

The red lead, white lead, linseed oil, and drier used in the paints were required to conform with the specifications of the Federal Specifications Board, as follows:

Red Lead: U. S. Standard Specifications No. 11, as corrected and revised by mimeograph circular of December 15, 1897, for grade containing not less than 95% Pb_3O_4.
White Lead: U. S. Standard Specifications No. 5.
Linseed Oil: U. S. Standard Specifications No. 4.
Driers: U. S. Standard Specifications for Liquid Paint Drier No. 20.
Turpentine: American Society for Testing Materials (Serial Designation D13-24).

Concrete.—Various grades of concrete were required for different parts of the work, and approximate parts by volume for these various grades were stated in the specifications as well as the maximum gallons of water, inclusive of the water contained in the aggregate per bag of cement. Slump tests for the various grades were also specified, depending upon the proportions of the mix, these tests to be made in accordance with the Tentative Method of Tests for Consistency of Portland Cement Concrete of the American Society for Testing Materials (Serial Designation D138-25T). These various requirements are stated in Table 5.

Coarse and fine aggregate used in the concrete came from iron mines at Mineville, N. Y., and were obtained at a depth of from 1 500 to 2 000 ft. below the surface. This material consisted of crushed stone from which the iron had been separated by a magnetic separator, less than 10% of the iron remaining in the rock after separation. The aggregate was transported to Port Henry by rail and thence to the bridge site in scows. Test cylinders of concrete were made regularly throughout the progress of the work and tested in the Cambridge Laboratories of the Massachusetts Institute of Technology. These tests showed the concrete to be unusually strong.

In view of the fact that much of the pier concrete had to be deposited in water at a considerable depth, the question arose as to what effect the hydrostatic pressure would have both on the time of setting and the strength of the concrete. An investigation of this question in 1928 and 1929 revealed that concrete similar to that used on this bridge, deposited in water at a pressure of 50 lb. per sq. in. (corresponding to a head of 115 ft.) develops a somewhat higher compressive strength in periods between 3 and 28 days than similar concrete setting under atmospheric conditions.

TABLE 5.—SLUMP TEST. REQUIREMENTS FOR VARIOUS CLASSES OF CONCRETE.

SUBSTRUCTURE

The character and depth of the material overlying the bed-rock are shown by the record of borings, given in Fig. 7. These borings were made in 1927. In addition, the data from borings made in 1926 were available to contractors, for examination. Five test piles were also driven. The overlying material was found to be so soft that a pile foundation would not be feasible; hence it was necessary to sink the piers to bed-rock, the depth of which reached a maximum of approximately 100 ft. below the low-water level of the lake.

Geological reports, core borings, and outcropping ledges showed the bed-rock to be of Chazy limestone formation of homogeneous structure and well fitted to carry any loads which could be put upon it by the bridge. The investigations indicated that the surface of the rock would be reasonably level and free from disintegration, and these conclusions were verified by the conditions found during construction.

All abutment piers and viaduct footings are of concrete. The piers and certain of the viaduct footings bear on bed-rock. The abutments and other viaduct footings are supported on good material without piling. The general type of all the piers (except Pier 9, which is on shore), is shown by the channel pier illustrated in Fig. 8. Pier 9 was laid "in the dry."

Piers 3 to 8, inclusive (see Fig. 5), had to be built in water, and it was specified that all of them, except the two channel piers (Piers 6 and 7), should be built by the open coffer-dam method. Bids were obtained for building the two latter piers by either the pneumatic caisson or open coffer-dam process.

DATA OF BORINGS

FIG. 7.—RECORD OF BORINGS MADE IN 1927, LAKE CHAMPLAIN BRIDGE

Lump-sum bids divided into several items were received for all piers, abutments, viaduct footings, and filled embankments at approaches, including a small amount of gravel roadway surface alongside the Vermont approach embankment. Eight bids in all were received from seven different contractors, varying from $385 000 to $441 000 for the construction of all piers by the open coffer-dam process, and from $433 490 to $577 320 for the construction of the channel piers by the pneumatic process and the other piers by the open coffer-dam process.

The itemized bids for Piers 6 and 7 showed a variation from $176 444 to $295 000 by the open coffer-dam process and from $249 340 to $349 000 by the pneumatic process. The accepted bidder's figure for these two piers was $220 653, approximately $27 000 lower than the lowest bid for the same piers by the pneumatic process. The second lowest bidder submitted the lowest bid for these two piers, but put in a much higher bid for the other piers, thereby making his total bid $4 485 higher than that of the accepted bidder. It should be noted that the lowest bid for Piers 6 and 7 by the coffer-dam method was $72 896 lower than the lowest bid for these piers by the pneumatic process.

Consideration of the bids for Piers 6 and 7 show clearly the financial advantages of the open coffer-dam process for the particular conditions which existed at these piers, namely, soft material overlying bed-rock at an approximate distance below extreme low water of 100 ft., and below extreme high water of 109 ft., in a fresh-water lake without rapid changes in water level and with comparatively little current. As far as the writer is aware, these bridge piers are the deepest yet constructed by the open coffer-dam process with a single-wall coffer-dam and with a deep concrete seal deposited under water.

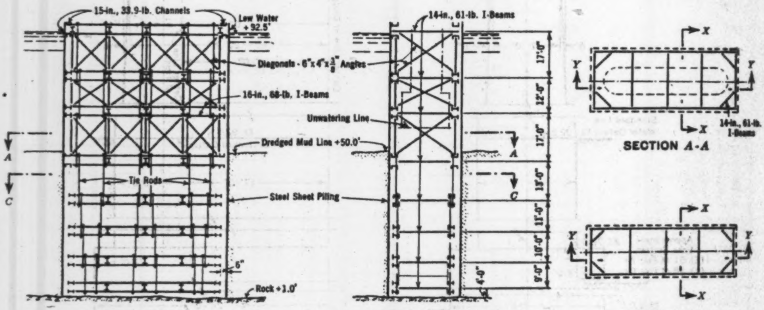
Fig. 8.—Dimensions of Channel Piers.

Wooden piles varying in length from 60 to 80 ft. were driven around the site of each pier and capped with 12 by 12-in. timbers placed approximately 8 ft. above the low-water level. On this capping a rough, working floor was placed. Waling pieces, 12 by 12 in., were fastened on this floor and similar ones were fastened approximately at the water level. These waling pieces served as guides for the steel sheet-piling forming the coffer-dam and were located horizontally so as to provide a clearance of approximately 4 ft. all around the concrete required by the plans for the portion of the pier below the lake bed. The sheet-piles formed a continuous wall weighing approximately 25 lb. per sq. ft. The individual piles had a width of 16 in. and a depth of 4 in. The maximum length of pile used was 98 ft., consisting of two pieces spliced by bolting in lengths of 40 ft. and 58 ft. Piling was driven to bed-rock without difficulty by a steam hammer weighing 7 000 lb. In no case were obstacles encountered, such as boulders or driftwood.

Inasmuch as such a coffer-dam would prove entirely inadequate to resist the external pressure due to water and mud, after the interior was dredged to any considerable depth, a system of internal bracing was devised by the contractor and approved by the engineers. This consisted of heavy horizontal frames braced transversely by three intermediate struts. For the part of the coffer-dam in which concrete was placed in the water no other bracing was used. In the remainder of the coffer-dam, that is, that part of it in which concrete was to be placed "'in the dry," diagonal bracing was used in the outer walls and also in three intermediate vertical planes. This bracing is shown in Fig. 9. The lower bracing consisted of rectangular frames of double 16-in., 68-lb. I-beams riveted together at the corners by knee-braces with three cross-struts in each frame, each consisting of a single 14-in., 61-lb. I-beam. The horizontal frames for the upper part of each coffer-dam was similar, but made of somewhat lighter members.



SECTION *Y-Y* SECTION *X-X* SECTION *A-A* SECTION *C-C*

FIG. 9.—COFFER-DAM BRACING, PIERS 6 AND 7.

Horizontal frames had to be left in place in the part of the pier in which concrete was laid in water. The 4-ft. clearance between coffer-dam walls and the specified dimension lines of the pier was sufficient to permit these frames to be placed entirely outside the required cross-section of the pier. The three cross-struts in each frame, however, passed through the piers.

For the upper part of the pier the horizontal frames were removed during construction, but the cross-struts and diagonals were embedded in the concrete. The diagonals, however, were cut off at the upper ends of each panel

The contractor's plan for placing the bracing below the mud line (which was accepted with slight modification for practically all piers), was as follows:

(*a*) After excavating approximately 12 ft. of mud from the coffer-dam, place all the horizontal bracing in this space in the form of a nest, and wedge the upper horizontal frame in place against the sides.

(*b*) Proceed with the excavation and, when conditions permit, lower the remaining frames until the upper one is at its desired level, and then wedge it in place. Proceed in this manner until all the bracing is in place, connecting the various sets of horizontal frames by tie-rods to act as suspenders and spacers during the process.

The foregoing plan proved satisfactory on the whole except that in the case of one of the piers the contractor excavated more than was planned before wedging one of the frames in place and, as a consequence, the sheet-piling buckled slightly—just enough to make it impossible to lower the remaining frames into place without cutting them apart and re-assembling them. This work had to be done in a considerable depth of water and required the services of six divers for several weeks. It would have been less expensive and the results would have perhaps been equally satisfactory had all the frames been assembled and bolted in place by divers.

The sheet-piling was easily pulled, except in the pier in which buckling occurred, where it was burned off under water at the mud-line. The mud was readily excavated by clam-shell buckets, except portions of it which adhered to the steel work of the coffer-dam and the bracing, which had to be loosened by jetting. After the removal of the mud, the water within the coffer-dam was found to be freer from sediment than the lake water outside.

Following the completion of the excavating and jetting, soundings were made within, and jet borings without, the coffer-dam to determine whether the bed-rock was reasonably level, not only over the site of the pier itself, but for a reasonable distance outside, and the bottom within the coffer-dam was examined by divers to determine whether it was clear of sediment and whether any of the upper surface of the rock required removal. The condition of the rock surface on all piers was found to be such that no further preparation of these surfaces was necessary. As a matter of fact the condition of these surfaces was especially satisfactory since they had been scored somewhat by glacial action and, in some cases, had pot-holes, thus ensuring good bond between concrete and bed-rock. In no cases were the surfaces tilted appreciably.

The concrete was placed in position by a patented, bottom-drop bucket with a capacity of 1 cu. yd. and made of ½-in. steel. At the bottom of the bucket double flap doors were attached to the bail by a chain. When suspended by the bail these doors were closed. When the bucket reached bed-rock, or the upper surface of the concrete previously laid, the bail would slide down, releasing the flap doors. This also released a clutch which engaged a lug on the side of the bail, preventing the doors from closing when the bucket was raised to permit the concrete to flow out. It was found that the cubic yard contained in the bucket spread on a level surface in a circle of 10 to 12 ft. in diameter.

Experience with depositing concrete in this manner shows that for the most satisfactory results the bucket should be level full; otherwise, when the bucket submerges, the rush of water will wash the cement from the upper portion of the concrete in the bucket. Moreover, the concrete should not be too dry. For the concrete in these piers a slump of 3 to 4 in., as determined by the standard slump test, was required. The concrete was laid from the center of each space between cross-braces toward the sides, in order to allow the laitance to flow toward the outer sides of the coffer-dam beyond the pier dimension lines.

After the under-water concrete that extended to grade, Elevation 72 (about 20 ft. below the low-water line), was placed, the coffer-dam was unwatered, and the remainder of the concrete laid "in the dry," the sheet-piling providing a satisfactory dam for this stage of the work.

SUPERSTRUCTURE

General Description and Unit Prices.— The superstructure consists of riveted truss and plate-girder viaduct spans all of carbon steel, supporting a concrete floor. The make-up of the various main members of the superstructure involves no unusual features and will not be described. The maximum stress in any truss member occurs in the bottom chord of the 270-ft. end-supported span. In the continuous spans the maximum stress in any truss member is tension and occurs over any intermediate pier.

Itemized bids for the steel, concrete floor, curbs, and broken stone on approaches were received. The bids on important items varied as follows:

Structural steel trusses, etc., erected and painted, per pound....	$0.06925	to	$0.084
Floor system, viaduct, etc., per pound...	$0.066	to	$0.0788
Bridge flooring complete	$98 000	to	$141 840

The successful bidder for the superstructure presented the lowest aggregate bid on the basis of estimated quantities, at $0.06925 per lb. for all structural steel and $98 000 for the bridge flooring.

The amount of structural steel as estimated by the engineers in asking for bids was 6 000 000 lb. The actual weight, as shown by final estimates for payment, was 5 883 727 lb., or approximately 60 tons less than the original estimate.

Stress Computations.—In designing the continuous trusses preliminary stress computations were made, using the values given in Griot's tables[*] of influence data for shear and moment for continuous beams of constant moment of inertia.

The principal dimensions of the structural members in Spans 6, 7, and 8, are shown in Fig. 10. For these spans, the values of the dead reactions, as obtained at Piers 5 and 8 from the preliminary design, were used as final values, a clause being introduced into the specifications stipulating that these predetermined reactions should be secured by the use of hydraulic jacks fitted with gauges and with the ratio between inches raised and reactions applied determined by actually raising the ends of the trusses before the laying of the concrete floor. Prior to the final establishment of the reactions by jacking, the Method of Least Work was used to determine the

(b) ELEVATION OF SOUTHERLY HALF OF TRUSSES, SHOWING GROSS AREAS OF MEMBERS IN SQUARE INCHES

FIG. 10.—PRINCIPAL DIMENSIONS, SPANS 6, 7, AND 8.

dead-load reactions due to the steel work and the temporary tracks and concrete forms which were on the span prior to the jacking. The method of least work was also used for a final determination of the live stresses, the irregular depth of the trusses in these spans making it seem advisable to obtain these stresses by a method more accurate than that used in the preliminary design. Fig. 11 shows an influence line for the stress in U_9 U_{11}, and also for the reaction, R_L at Point L_0.

Lateral Bracing.—The top and bottom lateral bracing in the truss spans consisted of riveted members throughout. In the three-span continuous structure the top lateral bracing had to be omitted in the panels over and near each of the intermediate piers where the trusses changed from "through" to "deck." The transfer of the wind forces from the top to the bottom lateral system was accomplished by means of portal bracing located in Panels 9–10 and 12–13 on the New York end of the bridge and corresponding panels on the Vermont end. Inasmuch as the top chord members in these panels were all in tension, they required no lateral support. The wind forces on the top chord in panels where the bracing was omitted, were transferred to the bottom chord by sway-bracing placed below the floor. Overhead sway-bracing was used at all other panel points.

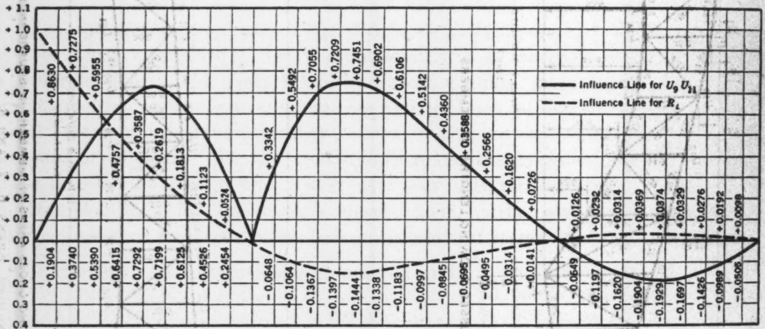

FIG. 11.—INFLUENCE LINES FOR HORIZONTAL COMPONENT OF STRESS IN U_0 U_{11}, AND FOR THE REACTION AT POINT L_0.

The top and bottom lateral bracing system in Spans 4 and 5 were continuous over both spans and had no features worthy of comment.

Floor-Slab.—The floor construction is shown by Fig. 12. It consists of a reinforced concrete slab upon which is laid the plain concrete wearing surface described later in this paper. The concrete slab is supported on transverse I-beams in the viaducts and on longitudinal I-beams in the truss spans. The dimensions of the slab, spacing of the I-beams, etc., are shown in the diagram. The floor was designed to carry 20-ton trucks. While the slab had sufficient strength in bending, with the depth used, it was found to be weak in shear; hence shear reinforcement was provided in the form of unit trusses. It was at first intended to use trusses with web reinforcement along the entire length of each unit, such as have been used in other bridges, but it was found that a material saving in cost could be made by omitting the diagonals in the central portion of the span where the concrete alone was of ample strength to carry the shear.

Concrete Wearing Surface.—The Commission decided in favor of a concrete roadway surface corresponding to the surfacing on the State roads at each end of the bridge. The question then arose as to the desirability of making use of the reinforced concrete slab itself as the wearing surface. This idea was abandoned, however, in order to protect the slab from wear, involving reduction in strength and possible exposure of the steel reinforcement. These factors seemed especially important for this bridge with its steep gradients and long periods of snow and ice, requiring the frequent use of chains on motor cars. After careful consideration it was decided to construct a special patented wearing surface. The Commission itself secured the right to use this surface and paid all royalties therefor, as well as the cost of special supervision of the laying by a representative of the owner. The wearing surface was made by obtaining a flush mortar upper surface on the concrete floor-slab and embedding in it (before it had acquired its initial set) a special cleavage fabric consisting of burlap with strands having a uniform spacing of not less than $\frac{1}{4}$ in., or more than $\frac{3}{8}$ in., small enough to prevent the large aggregate of the slab from bonding with the wearing surface. Then the concrete wearing surface was poured before the upper surface of the slab had obtained its initial set. The cleavage fabric was required to extend to within 2 in. of the curb, and lap-joints were not permitted. The object of the cleavage fabric is to permit the top layer to be removed if it wears out, without disturbing the integrity of the floor-slab.

FIG. 12.—CROSS-SECTIONS OF FLOOR, LAKE CHAMPLAIN BRIDGE

Curbs and Fencing.—In view of the height of the bridge above the lake every effort was made to safeguard automobiles from riding over the curb and through the fence. To that end the double curbs shown in Fig. 12 were provided. From abutment to abutment the fencing was made of steel wire mesh attached to wire cables at top and bottom, the cables being stretched into position between fence-posts. In addition, a structural steel channel top rail was used, this being connected to the fence-posts, except in the through portion of Span 7 where it was connected to the truss web members. The writer believes that the protection afforded by the double curb and the wire fencing and cables is ample to protect cars from going off the bridge, although a car so out of control as to run over the curb would very likely be overturned.

The height of the fence received careful consideration, in order to prevent the attractive view of lake and mountains from being cut off from the occupants of cars crossing the bridge. To that end the line of sight of occupants

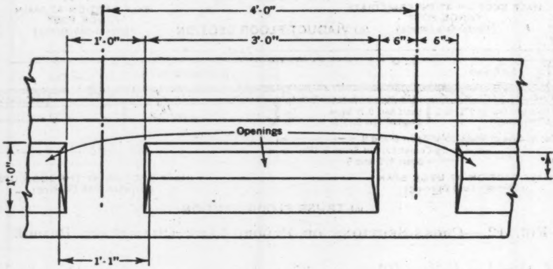

FIG. 13.—ELEVATION SHOWING TYPICAL CURB ELEVATIONS.

of motor cars of average height was studied, and the decision was finally reached to locate the top of the rail at a height of 4 ft. 6 in. above the concrete curb, with the top of the fencing 14 in. below the top of the rail, thus affording a clear space between bottom of rail and top of upper cable of approximately 11½ in. Views can also be obtained through the meshes of the fence. The fencing is of the chain-link type and consists of a fabric of galvanized aluminum wire slightly less than No. 6 gauge, with 2-in. mesh and with both edges knuckled. The shop coat of paint was applied by dipping the fencing while still warm from galvanizing.

Drainage and Snow Removal.—In view of the fact that the curb which also forms a footwalk on either side of the bridge would add considerably to the weight of the bridge if solid, the curb openings shown in Fig. 13 were provided. These serve not only to reduce the weight of curb and amount of concrete, but they also give ample provision for drainage and improve materially the appearance of the bridge as seen in side view. It is also expected that they will help keep the bridge floor free from snow which, if not too damp, will to some extent be blown off the bridge through these openings. The openings were made uniform in size throughout the length of the viaduct and the truss spans to simplify the form work. Unit quantities in the floor are as given in Table 6.

Expansion Joints.—Because of the continuity of the truss and viaduct spans, it was possible to reduce the number of expansion joints (which are always troublesome in highway bridges) to four in all in a total length of 2187 ft. from abutment to abutment. These joints were located at each abutment and over Piers 5 and 8, the maximum expansion occurring over Pier 8 where a total clearance of 15 in. is provided. The same expansion is provided (although it was not necessary) over Pier 5. Fig. 14 shows the details of the expansion joints at these two points. Attention may be called to the fact that the expansion plates consist of flat plates roughened by transverse strips welded thereto instead of the checkered plates commonly used.

Rocker and Roller Bearings.—In order to reduce the friction in the truss bearings and to prevent rusting, the rollers and rockers are enclosed in steel boxes filled with Albany grease and with sides that can be removed for replacing the grease if this becomes necessary. This method of protecting the rollers was used on the Queen City Bridge across the Merrimac River at Manchester, N. H., and an examination several years after its construction showed that the Albany grease had not hardened and that no rusting of the rollers had occurred. Fig. 15 gives details of one of the rocker nests on Pier 7.

Erection.—In designing the superstructure it was assumed that Spans 4, 5, 6, 8, and 9 would be erected on falsework and that the projecting ends of Span 7 would be cantilevered out until they met. The sizes of all the truss members were determined on this basis, with the specification provision that if the contractor wished to use another method of erection requiring any of the members to be increased in size the additional material would have to be furnished at his own expense. This method of erection was followed, except in the case of Span 5 which the contractor decided to erect by cantilevering out from Span 4 for a distance of six panels (162 ft.), at which point a pile bent was built and used for jacking up the outstanding end until the top chord members connecting Spans 4 and 5 were relieved from stress. The remainder of Span 5 was then erected as a cantilever. At the conclusion of this stage in the erection the outstanding end of Span 5 was above its true position, due to the raising of the span by jacking at the falsework bent. The jacks were then lowered until the end of Span 5 was supported on its appropriate pier. The final position of this end was then established by jacking at the pier. This method of erection involved an increase in the size of a few of the main members of Span 4, but the cost of this additional material was comparatively small.

SECTION B-B

FIG. 15.—LAKE CHAMPLAIN BRIDGE, ROCKER NEST AT PIER 7.

The method of erection adopted for Span 7 required careful computations of the horizontal movements of Panel Points U_{17} and L_{16} at the cantilevered ends of Span 7 due to cambering and to the weight of steel and erection track. The deflection due to the traveler when located at one of the projecting ends was also determined. Computations also had to be made of the position of the bottom panel point, L_{34}, under varying conditions of load and temperature to determine the proper location of the rocker nests at this point with the rockers vertical. These computations were made by the contractor, and the decision was reached to set the rockers at this pier vertical and 2 in. forward (south) of their position under dead load and normal temperature.

The horizontal deflections of Panel Points L_0 and L_{34} were also computed to determine the proper position of the base plates at these points, which were specified to be located so that the roller nests should be central at mean temperature. The horizontal movements of U_0 and U_{34} were also computed to determine the amount of expansion to be provided in the expansion joints at these points.

The rollers, wedges, and shims provided at L_0 and L_{34} of Spans 6, 7, and 8 were temporarily omitted, and the truss shoes were supported directly on the base plates, planed surfaces being required for the sole plates on the shoes and the base plates to permit sliding during erection. In consequence, these panel points were located 20 in. below their final height. Panel Point L_{34} was also located 3.25 in. forward (south) of its final position.

For closure, Panel Points L_0 and L_{34} were both raised by jacking, and Span 8 with the projecting end of Span 7 was moved forward horizontally. As these processes were carried out it became possible to insert the previously omitted truss members in an unstressed condition. After these members were in place, L_0 and L_{34} were raised farther by means of calibrated jacks, until the calculated end reactions due to the steel trusses, bracing, and floor members, together with the erection track and such concrete forms as were in place to time of jacking, were obtained.

LIGHTING AND OTHER ELECTRICAL WORK

The bridge is lighted by incandescent lamps which are alternated on the two sides and are spaced longitudinally from 100 to 150 ft. apart. From the standpoint of traffic, lights on the bridge seemed even less needed than on the country highways giving access to it. The bridge is straight—horizontally at least—and every reasonable precaution has been taken to prevent vehicles from going over the side. Lights were necessary, however, at each end of the bridge to facilitate the collection of tolls and navigation lights are required by law; the Commission decided, therefore, to light the entire length of the bridge partly for advertising purposes.

Current is received at the New York end of the bridge at 2 300 volts and transformed to voltage suitable for lighting units. Two sets of navigation lights were originally installed—electric and oil—the latter for emergency use only. It was found, however, that the oil lights could not be readily lighted in a high wind, and these have been changed to electric lights operated by a storage battery, to prevent interruption in case of line or station trouble; these lights have proved entirely satisfactory.

Steel lamp posts consisting of 6-in. I-beams bolted to the structural steel fence-posts are used on the truss and viaduct spans. Reinforced concrete posts are used on the approach spans. The lamps in both cases are supported on structural steel brackets consisting of a single 4-in. car-building channel with flanges turned upward.

Toll Collection and Rates

The facilities for toll collection are on the approach at the New York end of the bridge. The traveled way is here divided, by an island 8 ft. wide, into two roadways, each 20 ft. 6 in. wide. A shelter for toll collectors, with signs giving the rate of tolls, is provided on this island. By means of smaller islands, each of these two roadways is again divided, through a small portion of its length, into ways 8 ft. 9 in. wide for the passage of single lines of vehicles. Any or all of these four narrow ways may be shut off by structural steel roadway gates, and each is equipped with a pavement unit, electrically connected to a counter in such a manner that the passage of a vehicle over any one of the pavement units is recorded and a substantially correct traffic count is made automatically. The toll collection area is well lighted and "mushroom" pavement lights and headlight reflecting signals are used where needed. The toll rates are as follows:

Passenger automobile (including passengers)	$1.00
Foot passengers and bicycles	0.25
Motorcycle, or passenger car trailer	0.50
Trucks, tractors, and trailers:	
1-ton, or less, truck or trailer (carrying capacity), or tractor (by weight)	1.00
1-ton to 2½-ton truck or trailer (carrying capacity), or tractor (by weight)	1.25
2½-ton to 5-ton truck or trailer (carrying capacity), or tractor (by weight)	1.50
5-ton truck or trailer (carrying capacity), or tractor (by weight)	2.00
Motor buses:	
Motor bus, seating capacity 16 passengers, or less	$2.00
Motor bus, seating capacity more than 16 passengers	3.00
Horse-drawn vehicles or saddle horses	0.50

Steam rollers, steam shovels, cranes, traction engines, and unusual vehicles of all descriptions, as well as cattle, sheep, and small animals, are permitted on the bridge only upon application to the Toll Collector, and at rates of toll published by the Commission or fixed by the Toll Collector.

A lighted sign is provided at the Vermont end, giving the toll rates, and a guard is stationed there during periods of considerable traffic. A private telephone line connects the two ends of the bridge.

The tolls may be collected at any of four points—the easterly side of the approach, each side of the large island, and the westerly side of the approach, and, at times of heavy travel, collectors are stationed at these four points. When traffic is light, it may be diverted to two lanes, or even to one lane if desired. At each collection point a pedestal is provided upon which a toll register may be placed for the use of the collector in recording tolls. These toll registers record the number of tolls taken by each collector under each of several classifications, and show to the traveler, at time of registering, the amount of toll paid. Different registers are used for northbound and eastbound traffic. The receipts are taken from the collectors by bank messengers at regular intervals.

At the easterly side of the New York approach is the toll collector's dwelling, in which are located living quarters for the collector and an office from which a view of the bridge to the north and of the New York approach to the south may be had. The switchboard from which all navigation and street lights are controlled is in the office. The dwelling also contains an office for the Commission in which is located the electric traffic counter, enclosed and under lock and key. By means of the roadway gates all vehicles can be diverted, if desired, to the lane immediately adjacent to the dwelling; hence, during the winter and at other times of light travel the toll collector may remain in his dwelling, stepping to the curb to collect tolls when a vehicle approaches.

Total Cost

The total construction cost of the bridge, including foundations, superstructure, approaches, lighting, toll houses, and equipment, was $967 800. Other items, including interest during construction, administration, legal and engineering charges, and real estate damages brought the grand total up to $1 149 000.

The contract included an allowance by the foundation contractor of $100 per day for failure to complete abutments, viaduct footings, and Piers 3 and 4 on or before October 20, 1928, and the entire work on or before December 1, 1928. It also provided a penalty or bonus of $250 per day for the superstructure contractor for every day lost or saved in the work to or after August 24, 1929, with the provision that the maximum amount thus deducted or added should not exceed $15 000. While certain details, including the final coat of paint on the part of the superstructure below the floor, was not completed by August 24, it was possible to open the bridge to traffic on the date assigned for its dedication, Wednesday, August 26, 1929, and no penalty was imposed upon the contractor.

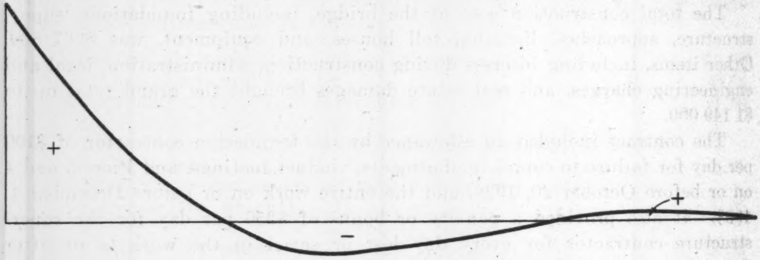
Acknowledgments

The effect of hydro-static pressure in depositing concrete at considerable depths, as reported in this paper, was studied in a series of tests by Mr. J. Wayne Couter, at the writer's suggestion.

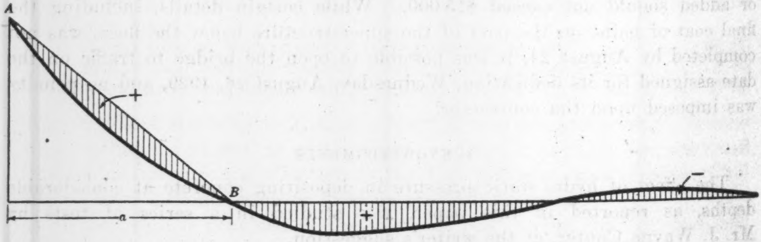
The Merritt-Chapman and Scott Corporation was awarded the contract for construcing the piers. The contract for the superstructure was awarded to the American Bridge Company.

DISCUSSION

Robert W. Abbett,[7] Assoc. M. Am. Soc. C. E. (by letter).—The author is to be commended for his thoroughness and originality in planning the Lake Champlain Bridge. It stands as another monument to the death of what has been a bugaboo to American bridge engineers for the past century. Continuity in bridge construction has been scrupulously avoided in design and vigorously attacked by many of the most eminent designers for several reasons; notably because it is statically indeterminate and because a slight pier settlement has been thought to introduce critical stresses in various parts of the structure. That the weakness and inaccuracy of these reasons have been recognized is proved by the increasing popularity of this type of construction, and by the large number of continuous trusses that have been built since Gustav Lindenthal, Hon. M., Am. Soc. C. E., proposed the Sciotoville Bridge.



THE ELASTIC CURVE FOR LAKE CHAMPLAIN BRIDGE



INFLUENCE LINE FOR STRESS IN U_9-U_{11}

Fig. 16.—Influence Line for Lake Champlain Bridge.

The layout of the Lake Champlain Bridge is most ingenious. The writer can think of no other arrangement which would have provided the necessary clearance at mid-span with such economy in approaches. In the high-level viaduct from Newark to Jersey City, N. J., a somewhat similar layout was necessary for the river spans. Here, however, the cantilever principle has been used with comparatively long suspended spans. Since the approach conditions for the two sites are quite similar, the writer cannot hold with the author in his unsupported statement that a short suspended span was necessary in the cantilever type. An economic comparison between the continuous truss, as built, and a cantilever truss with a longer suspended span similar to the Hackensack and Passaic River Bridges, would be interesting.

---

[7] Asst. Prof., Bldg. Constr., Thompson-Starrett Foundation, Dept. of Civ. Eng., Union Coll., Schenectady, N. Y.

It appears to the writer that the method of consistent deflections might have been utilized in the stress analysis to some advantage over the method of least work. This method seems to be more simple and less laborious. The elastic curve for the truss may be found by removing the redundant, R_L, and drawing the deflection diagram for a unit load at its point of application. The influence line for the stress in any member in an end span is easily constructed using the elastic curve as a foundation. Thus, the influence line for Member, U_9–U_{11} is constructed by simply drawing a straight line across the elastic curve from A to B (Fig. 16) and multiplying each ordinate of the resulting diagram by $-\frac{a}{r}$, in which, $r =$ the lever arm of Member U_9–U_{11} about its center of moments in the truss, and $a =$ the distance of R_L from the same center of moments. For members in the central span the construction of influence lines is a more lengthy process, but fundamentally it is no more complicated.

HENRY W. TROELSCH,[8] M. AM. SOC. C. E. (by letter).—Some of the circumstances encountered in carrying out the field work in connection with the erection of this bridge should be of general interest.

The spans erected on falsework were supported at alternate panel points on towers, each of which consisted of two bents braced together. The erection travelers, running on the floor of the bridge, were used to place the falsework and to erect the spans in one pass, working from the shore to the middle of the through span.

The mud of the lake bottom was very soft, and no difficulty was encountered in driving piles to a bearing on the underlying rock. In some cases, however, the rock was 100 ft. below the water level, and piles, 140 ft. long, were required. The piles consisted of 12 by 12-in. timbers, and were spliced by four angles, 4 by 4 in. by $\frac{5}{16}$ in., fastened with $\frac{3}{4}$-in. through bolts. Squared timber piles, being free from the initial curvature usually present in round piles, are less subject to bending from column action. They also have a larger area than round piles of the usual dimensions, and can carry a greater load, especially when they are driven to bearing on rock. They can usually be withdrawn, and have a high salvage value.

The piles were driven by a steam hammer suspended from the boom of the traveler. No leads were used; instead, wooden guides were lashed across cables extending from the completed part of the span to the next pier.

The closing of the through span was simplified by the shape of the structure and by the presence of a roller shoe at the north intermediate support, L_{24}. The end supports, at L_0 and L_{34}, were erected 20 in. below their normal position, which was equivalent to rotating the two halves of the structure about the intermediate supports, L_{10} and L_{24}. Since the closing joints, U_{17} and L_{18}, were well above the centers of rotation, the rotation caused a separation of the two halves of the structure at these points, leaving a gap at each closing joint. The gap in the upper chord was about an inch larger than that in the lower chord.

---

[8] Designing Engr., Am. Bridge Co., New York, N. Y.

The closing operation consisted of rolling the north half of the structure southward until the gap in the lower chord was closed, and then jacking up the end supports, L_0 and L_{34}, until the upper chord was closed. The closure was thus accomplished without temporary or adjustable members, such as are ordinarily used in closing cantilever bridges, and without drilling any of the connections in the field. No special equipment was required other than four 300-ton hydraulic jacks.

Jacob Feld,[9] Assoc. M. Am. Soc. C. E. (by letter).—The writer is chiefly interested in the description of the substructure design and construction. Although given in great detail there are several questions which might be answered in the closing discussion to complete the record.

The contractors were asked to bid on the construction of all piers by the open coffer-dam process with an alternate choice of constructing the channel piers by the pneumatic process. In accordance with information shown by the borings, with approximately 50 to 60 ft. of fine uniform soft materials to penetrate, it seems that a design of pre-cast concrete or steel-shell caisson might have proved just as economical, if not more so, than the open coffer-dam. Such a design would have given a better concrete surface than can be guaranteed to result from concrete placed under water in spite of all precautions that were taken.

There is no mention of any special precautions in protecting the surface of the piers at the water-line to take care of ice pressure and wear during the winter seasons. Undoubtedly, this item was considered in the design, and the omission of special protection for the concrete, an unusual procedure, must have resulted from definite reasons. It would be interesting to have those arguments on record.

An item often overlooked in the preparation of construction procedure for such piers is the accumulation of laitance on the top of each pour of under-water concrete. In Piers 6 and 7, the total height of under-water concrete was approximately 60 ft. A considerable thickness of soft material must have been exposed after unwatering. The chemical tests of this soft material in a number of projects has shown that the quantity of cement removed from the concrete is between 10 and 15%, so that the total amount of soft material which can be expected is about one-twenty-seventh the total height. In these piers the amount of soft material on top of the under-water concrete should have been somewhat more than 2 ft. It would be interesting to know what depth of soft material was actually removed from the top of under-water concrete, and whether any tests were made as to the strength of the concrete below the removed material.

---

[9] Cons. Engr., New York, N. Y.

Clarence W. Hudson,[10] M. Am. Soc. C. E. (by letter).—This paper is valuable for several reasons. It gives a comprehensive description of the engineer's service to his client from the inception of the project to its completion; it describes the work of the engineers preliminary to their actual engineering service; it begins with certain traffic statistics, from which estimates of traffic on the proposed bridge and of the financial returns from such traffic were made; and the amount of money that could justifiably be spent for the construction of a bridge was determinable from the estimated return from traffic.

The following comments apply to the various subjects described by Professor Spofford:

(*a*) The author describes the service of the engineers after the financial feasibility of the project was established.

(*b*) The description of the field survey is very concise and yet comprehensive and clear.

(*c*) The engineer's conclusions with respect to the type and details of the structure to be adopted, were sound.

(*d*) The reasons given for the elimination of simply supported and cantilever type truss spans, from their design for the central portion of the structure, the writer believes are correct.

(*e*) The writer does not believe, however, that the difference in cost due to using simple truss spans, cantilever spans, or continuous spans, for the principal part of a structure, would, in general, be large enough in itself to be a controlling factor as against a better appearing or more satisfactory structure inherent in any one of the types, for use in a definite location.

(*f*) The description of the method of building the deep piers is excellent and the word or two with reference to the engineer's effort to eliminate the harmful effect of laitance (which the writer has always found to be existent) in concrete deposited under water, is evidently good.

(*g*) The writer feels, however, that the longitudinal grade adopted was about the maximum permissible and that the use of higher unit stresses in the floor system than in the main trusses is a variation from general practice.

(*h*) The resulting structure is very pleasing in appearance.

Charles M. Spofford,[11] M. Am. Soc. C. E. (by letter).—The writer has been gratified by the favorable comments on this paper, and takes this opportunity to express his thanks for such comments.

As stated by Mr. Abbett the method of deflections might have been used advantageously in computing the stresses in the trusses. Many years ago, in connection with an investigation made in behalf of the Comptroller of the City of New York, the writer used the method of deflections in computing the stresses in all the members of the Queensboro Bridge. This is a continuous structure statically indeterminate to the second degree (as is the Lake Champlain Bridge). Later experience in dealing with statically indeterminate structures has convinced him that the method of least work is simpler to apply, largely because the signs of the various expressions take care of themselves, requiring the computer to give attention to the numerical computations only. As a matter of fact, both methods are identical when reduced to their simplest terms.

[11] Hayward Prof. of Civ. Eng., Mass. Inst. Tech., Cambridge; Cons. Engr. (Fay, Spofford & Thorndike), Boston, Mass.

As far as graphical methods go the writer's experience indicates that analytical methods are more satisfactory in cases where the computations may be divided among several staff members. One of the chief advantages of an analytical method is the fact that the results may be checked with more precision than by any graphical method known to the writer, thus giving a greater feeling of security than would otherwise be the case. At all events the computations form such a small factor as far as the expense of designing goes that any theoretically correct method may be applied without affecting materially the expense or time required for the design.

With respect to laitance in the concrete piers, the concrete was properly proportioned, thoroughly mixed, and carefully and continuously placed in position by bottom dump 1-yd. buckets. As the pouring progressed the upper surfaces of the piers were inspected by divers from time to time, who reported little or no laitance. At the conclusion of pouring, the amount of laitance that had to be removed was a matter of only 2 or 3 in. instead of the 2 ft. suggested as a possibility by Mr. Feld. Whether the strength of the concrete was reduced by the formation of laitance during pouring was not investigated, but tests of the concrete as it came from the mixer showed it to be of high strength; and as the stresses to which it was subjected were not severe, no doubt existed as to its having adequate strength. Inspection of the character of concrete deposited in sea water in the piers of the Charlestown Bridge, in Boston, Mass., was made after the concrete had been in place for several years. Samples were taken by diamond-drill borings, under the direction of Frederic H. Fay, M. Am. Soc. C. E. This inspection showed the concrete to be of excellent quality throughout the depth of the pier.

In reply to the query by Mr. Feld as to the reason for not protecting the pier concrete against abrasion and deterioration, it may be pointed out that the piers are in a fresh-water lake with little current and are practically free from danger of abrasion from ice and floating objects. The concrete piers of the Queen City Bridge, across the Merrimac River (designed and constructed in 1922 at Manchester, N. H., under the supervision of the writer's firm), which are located in fresh water and a short distance below a dam, have undergone no deterioration, either from the action of the current or from other causes, as far as the writer knows. Had the Lake Champlain Bridge piers been built in tidal water, granite encasement between high and low water would have been used in accordance with the writer's usual practice.

As to the relative cost of piers constructed in open caissons as compared with those built by the pneumatic process, the writer can only judge by the actual bids received, which were mentioned in the paper. The specifications stipulated that the design of the caissons should be left to the contractor who might use timber, steel, or concrete, and presumably some of these contractors bid on caissons designed with either pre-cast concrete or steel shells, if they found such a construction economical as suggested by Mr. Feld.

In reply to Mr. Hudson's comment on the longitudinal gradient, it should be borne in mind that the bridge is in a country where steep hills are frequent and where the $5\frac{1}{2}\%$ gradient used in the bridge is moderate and substantially less than that on some of the main highways in the vicinity. No difficulties from the gradient have yet been reported to the engineers.

As stated in the paper, the bridge was designed for the *H*-15 loading given in the Standard Specifications for Steel Highway Bridges of the U. S. Department of Agriculture, with the exception that 20-ton trucks were used instead of the 15-ton trucks specified in the loading. The engineers believe that, in view of the probable infrequency and possible non-appearance of such trucks on the bridge, it was entirely logical to apply a higher unit loading for the floor system than had the 15-ton trucks conforming to the *H*-15 loading been used.

CONSTRUCTION PLANT AND METHODS FOR ERECTING STEEL BRIDGES.[1]

BY A. F. REICHMANN,[2] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. HOWARD P. TREADWAY, BENJAMIN WILDER GUPPY, R. A. VAN NESS, J. G. TRIPP, A. A. EREMIN, AND A. F. REICHMANN

SYNOPSIS

This paper is concerned with the erection, only, of steel bridges, and, in consequence, classification of the structures will be made more from a standpoint of the problems facing the erection engineer than from type of structure. The physical conditions at the site, time permitted for erection, particular season during which erection is to take place, quantity of river flow, and similar factors have a greater bearing on the way the structure is to be handled than the type of structure itself.

In general, the construction plant for erecting a steel bridge is determined by the type and size of the bridge and the method by which it is to be erected. In consequence, the problems involved by the type and size, which determine the method of erection, will be discussed before the equipment necessary to develop this method of erection, is taken up.

MAJOR CONDITIONS TO BE ANALYZED

The method of erection depends upon so many conditions that it is impossible to use any set plan of procedure for a given type of structure. Each project should be considered by itself, and the choice which is the simplest and which requires the least equipment is a problem for an experienced erection engineer. In attacking the problem of erection, it might, at first thought, be considered possible to divide the structures into two general classes; that is, railway and highway. However, there is such a wide divergence in both classes of structures, from light single-track railroad structures to the most up-to-date three and four-track railroad bridges, and from the small 20-ft. highway span to the tremendous structures built in the larger cities of the country, that the two classes are interlocking so far as erection problems are concerned. Both highway and railway bridges might be divided into groups as to type of structure. The more important of these types are I-beam spans, girder spans and viaducts, simple truss spans, arches, cantilever spans, continuous spans, suspension spans, and movable bridges. In determining and developing problems of erection and in attempting to arrive at the proper method of procedure, it will be found that the following major conditions will require consideration and analysis:

---

[1] Presented at the meeting of the Construction Division, New York, N. Y., January 16, 1930.

[2] Asst. Chf. Engr., Am. Bridge Co., Chicago, Ill.

1.—Type of Structure.

2.—Location of Structure:
  (*a*) The character of the terrain to be crossed.
  (*b*) The distance from the center of supply for labor and materials.
  (*c*) Available space for storage yards and necessary shops.
  (*d*) Connection with railroad facilities.
  (*e*) Power and fuel supply.
  (*f*) Height above the water or ground.

3.—Maintenance of Traffic:
  (*a*) River.
  (*b*) Railroad or highway beneath the structure.
  (*c*) Railroad or highway on the structure proper.

4.—Effects of the Elements:
  (*a*) Floods and high water.
  (*b*) High winds.
  (*c*) Extremely hot or cold weather.

5.—Time Allowed for Construction:
  (*a*) As provided in the contract.
  (*b*) As governed by the seasonal effect on the work.
  (*c*) As governed by schedule of foundation construction.

TYPE OF STRUCTURE

In attempting to discuss the various problems listed in the foregoing outline, it will be found that in a great many cases the items are "interlocking" and cannot be treated independently. If the bridge consists entirely of I-beam spans, girder spans, or viaducts, no great consideration need be given to many of the subdivisions following. However, in cases of most other types of structures—especially truss spans that will require a temporary supporting structure—consideration of conditions beneath the latter must be given.

Practically all types will require consideration of the traffic over the bridge, accessibility for delivery of materials, etc. For that reason, no further discussion of the type of structure under that particular heading will be considered, but the various types as affected by conditions under the other following classifications will be mentioned.

LOCATION OF STRUCTURE

The first consideration under this subject will be the character of the terrain to be crossed. The amount of attention to be given to this problem depends on the type of structure. If the type of bridge is such that no temporary supporting structure is required, little consideration will be necessary. For truss spans of every description, this particular condition will be of major importance. If the structure is over dry land or shallow water, it will probably be found simplest to use timber falsework as a support; if it is over a deep stream, subject to wide variations in flow, where there is danger of driftwood, scour, and ice, or if there is river traffic to be considered, it may be found impracticable to use much, if any, temporary supporting falsework, and the bridge can best be erected by cantilevering, regardless of whether or not it is the intended permanent type. The erection of light girder spans and viaducts and of suspension bridges does not require major consideration under this heading as, in most cases, the supporting structure is eliminated.

When giving consideration to the problems connected with the distance from center of supply for labor and materials, all types of structures will be involved. If the structure is a railroad bridge, the problems in general entering into the delivery of materials will be simple because only in rare instances are attempts made to erect railroad bridges before the roadbed and track are completed up to the site. In highway bridges, however, the reverse is the case; and the question then develops as to whether it is most economical to build a temporary track to the site, or to arrange for transportation of equipment and materials by the use of trucks or teams. Under this consideration comes also the question of labor supply. If housing conditions are available only at a considerable distance away, it must be determined whether to supply this housing close to the job by the construction of labor camps or to supply transportation for labor to and from the available housing facilities. The latter is of considerable importance in the erection of steel bridges for the reason that the major part of the organization is made up of semi-skilled workers, and to be able to maintain an efficient organization, these workers must be kept satisfied as to living conditions.

Available space for storage yards, office, and shops will require consideration. In general, it is found that the bridges will be approached by earth fills through low lands, or in the case of bridges in cities, by streets in congested districts. Consequently, it is frequently necessary to arrange for yards, shops, etc., along the fills or streets, and often very little space is available, so that careful planning is necessary to take care of supplies and equipment. Otherwise, it may require going a considerable distance away from the structure for this space, with consequent increased cost of handling and transportation.

The subject of available railroad facilities is to a certain extent connected with the preceding discussion regarding distance from center of supply and conditions at the site and affects this consideration very materially. There may be good railroad facilities at one end of the bridge, but due to the nature of the stream, the method and order of placing the foundations, traffic under the structure, etc., it may be necessary to start the construction of the bridge from the opposite end, in which case it may be a saving to transport the material from the point of delivery on the railroad by hauling, by ferrying in barges, or by transfer on cableways. On some of the larger streams, such as the Ohio River and the Mississippi River, recent developments in transportation have sometimes made it possible to eliminate the railroad problem entirely by delivering the material from the fabricating plants directly to the site by water. Where this can be readily arranged, it is of considerable advantage in many cases because it puts the material directly under the point where it is to be erected and saves one or more handling charges.

As a rule, the question of available power and fuel supply does not have any great bearing on the method of erection. Its greatest effect will be on the equipment used. If there is electrical power connection, electrically driven machinery is usually found to be most economical. This condition, however, is rather rare, and usually it is found that power must be supplied by the contractor, in which case, steam-driven or gasoline-driven units can be provided to best advantage. The question of whether steam or gasoline will be selected depends on the available water supply, the facilities for obtaining fuel, and sometimes the type of structure, as, in general, gasoline equipment is somewhat lighter in weight and more easily transported than steam-driven units.

The height of the structure above the water or ground is of major importance and will not only affect the method of erection; it goes even further back than the erection itself, and often affects the design of the structure. When it comes to consideration of the method of erection after the design is definitely decided upon, then this question of height determines whether falsework will be used or whether necessary alterations in the design can be economically made to permit of cantilever erection. As the height of the structure increases, the cost of temporary falsework increases very rapidly, due to extreme wind loads which require additional main supports and much extra bracing. Often, if the structure is low, it is possible to erect truss spans at remote locations more advantageously and then float them on barges to their final location. This will especially merit consideration if the structure is close to the surface of the water, and the water is excessively deep at that point.

MAINTENANCE OF TRAFFIC

Under this heading, the maintenance of river traffic is of first importance for the reason that traffic on navigable streams in the United States is controlled by the Federal Government, and in case of interference thereto, permission from the United States War Department is necessary. In many cases there is only one available channel for river traffic, and, therefore, no supporting structure can be placed in the river at that point. As a consequence, it may be necessary to arrange for the erection of the span by cantilevering or by floating the structure in place, or by some such means, although other considerations would indicate that falsework would be most economical. In the northern part of this country it is sometimes possible to arrange the time of erection, so that the setting of steel over channels can be prosecuted when navigation is closed by ice. In any cases where it becomes absolutely necessary to do any construction that in any way affects river traffic, arrangements must be started for this well in advance of the time it is needed because the Federal Government, in granting permission to do this, will require various transporting companies to be notified and warned of any obstruction to navigation that may be contemplated, and, in addition, notices must be published in local newspapers.

In the case of railroad or highway traffic beneath the structure, it is usually possible to restrict this traffic partly, by narrowing the lanes of traffic, so that they can be crossed without great difficulty. If this cannot be done, it may be possible to detour the traffic temporarily, so that this problem is not of as great moment as the maintenance of river traffic.

The maintenance of traffic over the structure may be very important, as in the case of replacing an old span. In a problem of this kind, the maintenance of traffic will have a great bearing on the method of erection. In some cases it will be found possible to carry the traffic on the old structure while building the new one around it, or it may be possible to place temporary supporting falsework and carry traffic on this falsework at the same time a new structure is carried on it. It does not have as great effect on the method of erection as it does on the cost. Where there is any traffic to be maintained, it will have considerable effect on the cost of the work for the reason that it cannot fail to cause many interruptions, and consideration should be given to a method which will involve the least interruption to the progress of the work by traffic. The maintenance of traffic over the structure is usually more easily arranged than that under the structure because, in arranging this traffic, the erector is dealing with parties vitally concerned with the completion of the structure, and, in consequence, can more easily arrange for the necessary interruptions in traffic.

EFFECTS OF THE ELEMENTS

The most important considerations under this heading are floods and high water. In erecting bridges over most of the major streams of the United States, it will be found that it is of most importance to place temporary supporting structure during the periods when low water may be expected. Therefore, from necessity, the entire program will be predicated on the time when the water will be low. Even if the fluctuation between high and low water is small, the periods of high water will bring down driftwood or floating ice, or it will cause scour in the river bottom that may prove disastrous.

A high wind must be anticipated at any time and provision must be made for it. This means consideration of extra bracing and guys to the structure. There are localities in the United States where, at certain times of the year, high winds are especially prevalent, which may affect the time when the work is to be prosecuted. This requires consideration not only from a standpoint of safety, but also from a standpoint of economy. However, there may be long periods when it is impossible for men to work on a high structure due to the wind.

There are few localities in the United States where extremes of hot or cold weather will be a great problem, except as it affects the cost of the structure. It will not be necessary to suspend work entirely on account of hot or cold weather, but progress may be seriously impaired, with consequent increase in cost.

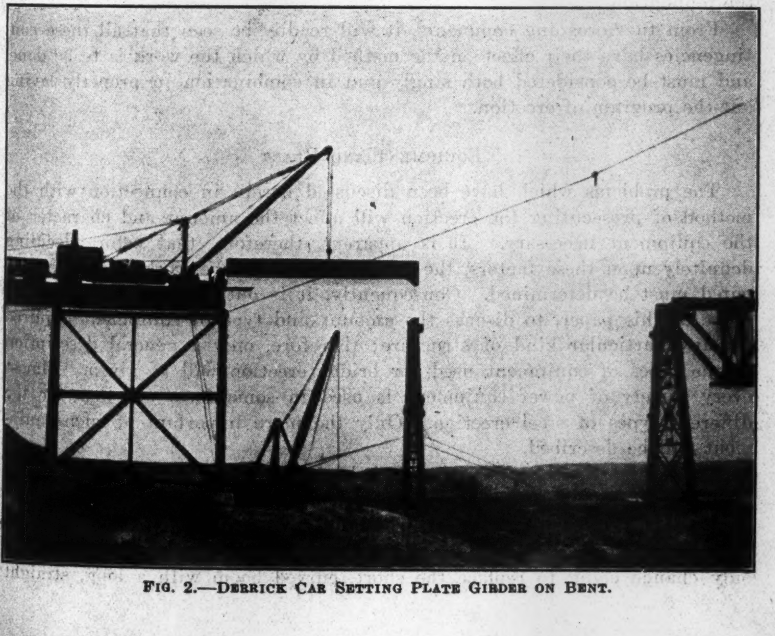

Fig. 2.—Derrick Car Setting Plate Girder on Bent.

TIME ALLOWED FOR CONSTRUCTION

The time allowed to complete the work, as provided in the contract, may be of vital importance in determining how it is to be done. It may be advisable from a standpoint of economy to erect the structure from one end, but the time allowed may require that the work be prosecuted from both ends It is often necessary, therefore, to decide whether to work from one end of the structure only, and work long hours with consequent extra expense for overtime; to work in night shifts, with consequent great reduction in efficiency; or to work from both ends of the structure, with consequent increase in force, equipment, and materials. Often the date of completion of the contract will require the bridge builder to prosecute the work at a time when it is extremely hazardous on account of risks from high water, ice, etc.

There are certain seasons of the year when one can almost be assured that he must contend with ice, driftwood, current, scour, etc., and it is, therefore, often necessary to arrange and schedule the work so that certain parts of it, which may be seriously affected by these contingencies, can be prosecuted at a time to avoid undue risks. In order to meet this condition on even a small portion of the work, the schedule of the entire project is often affected. The same problems that face the steel erector in connection with river conditions very often affect the foundation contractor, so that he may be unable to alter his foundation schedule and it will be imperative, therefore, for the steel erector to adapt his schedule of erection to fit that of the foundation.

From the foregoing comments, it will readily be seen that all these contingencies have their effect on the method by which the work is to be done, and must be considered both singly and in combination in properly laying out the program of erection.

EQUIPMENT AND PLANT

The problems which have been discussed herein in connection with the method of prosecuting the erection will affect the amount and character of the equipment necessary. It is apparent, therefore, that before deciding definitely upon these factors, the method by which the work is to be prosecuted must be determined. Consequently, it is out of the question in the scope of this paper, to discuss the amount and type of equipment required for any particular kind of structure; therefore, only a general description of the types of equipment used for bridge erection will be given. Almost every variety of power equipment is used in some form or other for the different types of steel erection. Only the more important of such equipment will be described.

Locomotive Erecting Cranes.—Probably the most universal type of equipment used for erecting bridges is the locomotive crane (see Fig. 1). This is an adaptation of the machines originally designed for wrecking cranes for use by the railroads. Originally, the railroad wrecking cranes were used, the only change being to replace the short, curved boom with a long, straight boom. Later, these cranes were developed more specifically for erection work by the addition of special auxiliary hoists, increased counterweights, etc. These locomotive cranes consist of a short, heavy railroad car carrying a heavy steel body mounted on a turn-table so that it will rotate 360° in either direction. This heavy cab contains the power plant and all the hoisting machinery. In addition, the hoisting engine is connected through proper gear trains to the trucks of the carrying car so that the car is self-propelling. It is from this feature that it gets its name, "locomotive crane". In order to increase the radius at which heavy loads can be handled by these machines, they are equipped with jack-beams at each end of the car body. These jack-beams are heavy I-beams which can be pulled out of the frame of the car (usually a distance of about 8 ft. from the center line of the track) and when blocked up, give the crane a base of about 18 by 24 ft. These cranes are usually also provided with booms so made that when handling excessively heavy lifts a short boom is used, while for setting lighter loads at a greater height above the track, additional sections can be added.

Due to the fact that these locomotive cranes—in order to have stability for handling loads at any advantageous distance from their center of rotation—must be excessively heavy, their use on bridge erection is confined to those structures which, by their design and method of construction, will support heavy loads. In the case of I-beam spans, girder bridges, and viaducts within their capacity, and truss spans the dead weight of which requires heavy falsework, these machines make ideal rigs for erecting. Due to their rotating features, they can be used with equal readiness at all points of the compass from where they are located. In most cases of truss spans erected by cantilevering and of suspension bridges and for all highway bridges, except the unusually heavy ones, these cranes are not economical because their excess weight would require too much additional material for the structure to make it capable of carrying it.

Derrick Cars.—The derrick car (Fig. 2) consists of a rather long heavy frame car on the front of which is mounted an A-frame for providing the mast of the derrick rig, and on the back end the hoisting equipment and sufficient additional counterweight to take care of the uplift. In addition, it is often augmented by a "counterweight car" behind it, to provide stability against extraordinary uplift. It has the advantage, therefore, over the locomotive crane in that it will pick heavy loads at a greater distance in front of the car; but it has the decided disadvantage in that the swing of the boom is limited to slightly less than 90° each side of the front.

The derrick car, like the locomotive crane, is usually provided with proper driving mechanism so as to make it self-propelling. Its principal use is for the erection of I-beam and girder spans, viaducts, etc., the character and size of which make the loads to be handled and the distance to be reached beyond the capacity of the locomotive crane. It is particularly advantageous for setting heavy girder spans 80 ft. long, or more, which, under present-day railroad traffic, often run from 75 to 100 tons in weight.

Derricks.—These are stiff-legs or guy derricks made in various designs and capacities. The difference consists in the bracing of the mast. If there are two stiff legs, the derrick is a "stiff-leg derrick"; if braced with guy ropes, it is a "guy derrick". A combination derrick has one stiff leg braced with guy ropes at right angles.

Derricks can be used for practically every type of structure, but as they are usually difficult to move from place to place, they are not often used except for the erection of small isolated structures, or for handling the steel from cars to storage at the storage yard. They are, however, often of distinct advantage for the erection of bascules which are to be built in open position and for the towers of vertical lift bridges. In both cases, this amounts to erecting a truss span standing on end, and, consequently, the structure is not spread over a great deal of ground and is readily reached without moving the equipment. Derricks are often mounted on barges forming derrick boats which are particularly serviceable for the placing of temporary supporting structures for bridges, such as driving piles, setting falsework, etc., and if the permanent structure itself is not too high above the water, they can be used to advantage in erecting the steel.

Travelers.—Briefly, travelers may be described as derricks with their hoisting equipment mounted on a movable platform. They are of almost every conceivable type and are usually designed and built to fit the requirements of each individual structure. Depending on the particular type of structure for which they are designed, they may be operated on the floor of the bridge or span from one truss to the other on the top chords. If they are operated on the floor of the bridge, some special provision usually has to be made to move the material either through them or around them in order to get it within reach of the booms. They are of particular advantage when the material is to be delivered to the site by water; therefore, the question of getting the material through or around them does not enter into the problem. They have a further advantage in that as they operate over the floor of the bridge, there is no special provision necessary to get them from one span to the other as the erection progresses over a series of spans. This is offset by the disadvantage of having them sufficiently strong and heavy to carry the long boom necessary to reach to the upper parts of the structure.

If the travelers are operated on the top chord of the structure (Fig. 3), they must be constructed to span from one chord to the other and require the necessary special construction on the trusses to permit moving them from one span to the next. Offsetting this they have the advantage, since they are entirely above the steel to be erected, that the booms may be much shorter, permitting lighter construction. Furthermore, placing them on the top chords leaves the floor system entirely unobstructed for bringing forward the materials required.

Travelers are used for the erection of almost every type of bridge (see Fig. 4). In cases where truss bridges—either due to their type or to some of the conditions heretofore discussed—are to be erected by cantilevering, some type of traveler is ordinarily used because less weight is involved for their capacity than with cranes or derrick cars. They can be modified in innumerable ways to adapt them to special needs. In the case of towers for suspension spans and extra long bascule spans to be erected in the open

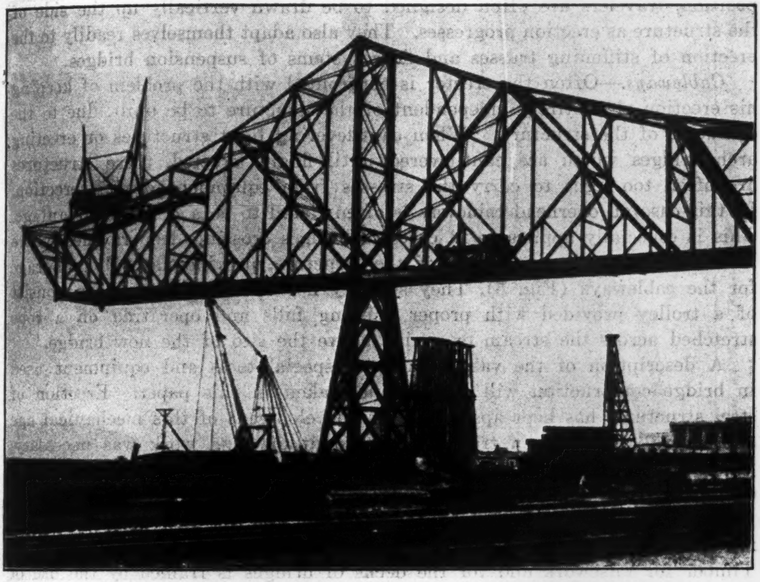

Fig. 3.—Top Chord Two-Boom Traveler, Cantilever Erection.

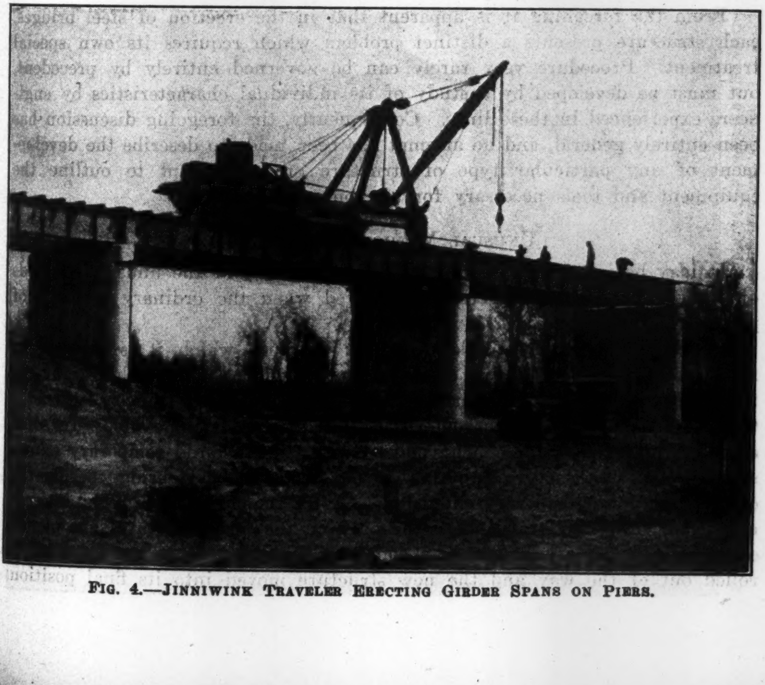

Fig. 4.—Jinniwink Traveler Erecting Girder Spans on Piers.

position, travelers are often designed to be drawn vertically up the side of the structure as erection progresses. They also adapt themselves readily to the erection of stiffening trusses and floor systems of suspension bridges.

Cableways.—Often the erector is confronted with the problem of keeping his erection rig entirely independent of the structure to be built, due to the character of the structure. When cantilevering light structures or erecting arch bridges which are cantilevered until finally erected, these structures are often too light to carry the stresses from equipment during erection. In this case an overhead cableway is often found to be a distinct advantage. This is especially applicable in cases of bridges crossing deep ravines where hillsides, adjacent to each end of the structure, provide natural anchorage for the cableways (Fig. 5). They scarcely need description as they consist of a trolley provided with proper hoisting falls and operating on a rope stretched across the stream or ravine above the site of the new bridge.

A description of the vast number of special tools and equipment used in bridge construction will not be undertaken in this paper. Erection of steel structures has kept apace with the development of this mechanical age and where, years ago, a tremendous amount of hand work was necessary, practically all operations are now done by mechanical appliances. For example, rivets are now almost universally driven by air or electricity; and the oxy-acetylene cutting and welding flame and the electric arc are used for the removal of old structures and for alterations to new ones in the field. Timber for falsework and for the decks of bridges is framed by the use of electrically and air-driven portable tools.

From the foregoing it is apparent that in the erection of steel bridges, each structure presents a distinct problem which requires its own special treatment. Procedure very rarely can be governed entirely by precedent, but must be developed by a study of its individual characteristics by engineers experienced in these lines. Consequently, the foregoing discussion has been entirely general, and no attempt has been made to describe the development of any particular type of structure or to attempt to outline the equipment and tools necessary for any one type.

UNUSUAL METHODS OF ERECTION

It may be interesting to touch briefly on a few of the unusual methods of erection which are sometimes employed when the ordinary methods of procedure will not apply.

Generally, when the traffic over the structure which it is planned to replace is exceedingly heavy, every effort is made to change the alignment for the new structure so that it may be built without interference with traffic. Often, however, physical characteristics will make this impossible. In some cases of this kind, arrangements have been made to build temporary extensions to the substructure and then to construct the new bridge beside the old one on these temporary extensions. After the new structure is entirely completed ready for traffic, both the old and the new structures are placed on a rolling system and, within a comparatively short time, the old span is rolled out of the way and the new structure moved into its final position

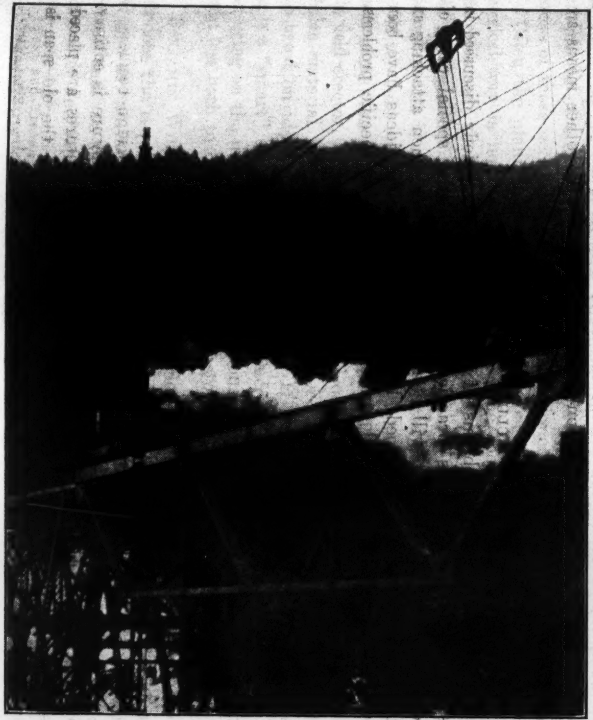

FIG. 5.—ERECTING TRUSS WITH CABLEWAYS; LOCOMOTIVE CRANE IN BACKGROUND SUPPORTING ONE END OF TRUSS.

FIG. 6.—HYDRAULIC JACK RAISING SPAN TO RELEASE FALSEWORK.

ready for service. To handle a structure in this way requires—in addition to the rolling system—some means of raising the structure to release the rollers. For this purpose, hydraulic jacks (Fig. 6) have been developed with capacities as high as 2 500 tons per jack. Water is generally used to operate them except during periods of low temperature when mixtures of alcohol in water or even pure alcohol are used.

In the erection of permanent cantilever spans, it is usually possible to erect the suspended span by temporarily cantilevering one-half of it from each permanent cantilever arm. Occasionally, however, the stresses developed by this method make it impractical to extend the cantilever beyond the permanent cantilever arm. In a few cases, therefore, the suspended span has been erected at a remote location, transported on barges to the site, and raised into final position. In some cases the span has been raised by the use of hydraulic jacks; in others, where the height was considerable, the suspended span has been raised by the use of cables running over sheaves mounted on the ends of the cantilever arms. To reduce the power required to lift the span, counterweights are used to balance the lifted span.

The erector will sometimes be confronted with the problem of constructing a single truss span, where, because of exceedingly deep water, swift current, or because of navigation, it is an impossibility to place any supporting structure under the span. In such cases it has been found necessary to erect temporary anchor arms at each end of the structure in order to make a temporary cantilever of this simple truss span. Such a method requiring, as it does, the erection and later removal of a large quantity of material, is, of course, expensive and is only resorted to where no other means are available.

CONCLUDING REMARKS

The more important problems of erection are only briefly discussed in this paper, because there is practically no limit to the special cases of erection and equipment that will confront the engineer when attacking an individual problem. It is hoped, however, that sufficient ideas have been advanced to serve as a general guide in the solution of specific problems.

DISCUSSION

Howard P. Treadway,[3] M. Am. Soc. C. E. (by letter).—This paper is a distinct addition to the literature on the subject of construction plant and methods for erecting steel bridges. It is a comprehensive general statement of this interesting subject, and, as such, little can be added by way of discussion. It naturally leads, however, to a discussion of details entering into the various problems at hand and could very well be used as the opening statement of an extensive treatise on definite problems that have been solved.

It is quite probable that almost any steel bridge can be erected by several different methods of procedure and by using different types of erection equipment. Ordinarily, the designing engineer submits, to erecting contractors, plans showing a finished structure, and it is then the problem of the erecting engineer to determine the most economical plan for the field work. Usually, it is only the cheapest one that ever has any publicity, because under ordinary circumstances it is the cheapest procedure that warrants the awarding of the contract. Occasionally, there are conditions in which special service or responsibility of the contractor is considered, and a more elaborate scheme submitted by such a contractor is given the preference at a higher price.

The erecting engineer makes a careful study of the plans, the location, and local conditions, as set forth by Mr. Reichmann. It frequently happens that he has to re-design certain members of a proposed structure in order to erect it safely, because the designing engineer has overlooked the fact that during the process of erection his structure will have stresses in these members in excess of those occurring in the finished balanced structure.

Often the plant necessary to do the work in the easiest and most economical way is not available, or it may be too expensive to acquire, and the equipment that the erector has on hand has to be adapted to the problem. All these conditions having been considered a scheme is worked out, and an estimated cost is made, which bid is submitted to the customer.

If the field engineer develops a method that is safe under all conditions he is more than likely to be a high bidder. Therefore, it often happens that the field erector, in considering the flood conditions of a stream or the foundation material for the falsework, takes a long chance and offers to do the job based on ideal weather conditions. If these weather conditions prevail he is a "smart" man, and his performance is applauded. If, however, he is bordering on the unsafe side and conditions go against him, he possibly incurs great loss both to himself and to the customer.

Benjamin Wilder Guppy,[4] M. Am. Soc. C. E. (by letter).—The author mentions the requirement for the maintenance of traffic when replacing an old span as one factor that determines the method to be adopted for erecting the new one. In such a case it is necessary to remove the old span and sometimes alter and repair the existing substructure.

[3] Pres. and Treas., Kansas City Bridge Co., Kansas City, Mo.

[4] Engr. of Structures, B. & M. R. R., Boston, Mass.

The type of superstructure to be removed and its condition and the repairs and alterations required to adapt the substructure to carry the new span and the heavier loads are factors that must also be considered in determining the erection method to be used. The writer recalls one case—the renewal of the superstructure of an important double-track railroad bridge over a wide river—where these were found to be the governing factors for determining the method to be used for the erection of the new superstructure and also for developing its design.

R. A. VAN NESS,[5] M. AM. SOC. C. E. (by letter).—The author has compiled a paper which condenses the subject in such form as to make it of real value as permanent information for the files of interested engineers, as well as educational matter for structural student engineers. To those who are closely in touch with bridge erection in one field or another, the paper revives a general appreciation of the entire subject.

The Company with which the writer is connected has maintained a steel bridge erection plant for many years. At present (1932), it comprises rolling equipment to house a normal force of 30 persons; one derrick car capable of setting a 106-ft. Cooper E-65 girder ahead; one locomotive crane with a capacity of 75 tons; two gasoline-operated air compressors, capacity 310 cu. ft.; one two-unit, electric arc (300 amperes) welding machine; an oxy-acetylene torch; and miscellaneous small equipment.

Most of the Company's bridge steel is erected with this plant, and no work is contracted except that which must be erected before Company forces would be available and other work of such magnitude that it requires a large outside plant for the most economical erection.

J. G. TRIPP,[6] M. AM. SOC. C. E. (by letter).—Only one addition is suggested for Mr. Reichmann's paper. The author does not stress sufficiently the fact that the solution of construction and erection problems should precede the design of a bridge. Mr. Reichmann follows this practice in his organization, but too often such considerations are passed by and left for the erector to make the best of poor "construction symmetry"—that ogre of the construction man. For example, it is not an uncommon occurrence in inaccessible territory to be faced with the fitting of the design to such a simple thing as the available plant of the hauling contractor in order to determine the sizes that can be handled into the location of the structure. Natural obstructions, road grades, etc., often cause complications difficult to overcome. Such structures as the Marble Canyon Bridge, in Arizona, is a case in point. The designers well knew that their problem was not so much stress, strain, and connections, but such simple things as maximum sizes of pieces to be transported from the railroad to the job, a matter of 120 miles over rough terrain. Design must accommodate erection methods and available plant to obtain economical results.

---

[5] Bridge Engr., A. T. & S. F. Ry. System, Chicago, Ill.

[6] Constr. Mgr., Merritt-Chapman & Scott Corporation, New York, N. Y.

Mr. Reichmann's tabulation of erection conditions is particularly well stated. In the writer's opinion, he might have added:

"6.—Specification Limitations:
(*a*) Eight-hour laws.
(*b*) Inspection routine."

If the specifications are inelastic and their effect unweighted in the estimate to erect, costly results and even defeat of the plans based entirely on the other five major conditions might follow.

As the author states, equipment and plant types are legion. The writer has found that little refinements on standard equipment pay big dividends. Simple devices enabling men to reach into difficult places; tool kits in basket slings; visual and manual signal assistance; proper power cord attachments, etc., are examples. Special refinements in cableway control apparatus and power take-ups on stay-lines pay handsomely.

In the design of structural steel falsework—another bridge problem—an important point is to build something that is easily dismantled without injuring the value of the dismantled parts. In this case, the study of erection methods and plant is paramount, and the design of the members is hedged in with limitations rarely found in permanent structures. In such cases all Mr. Reichmann's conditions must be evaluated for choice of method and plant, but final selections are tempered by considerations for easy and quick dismantling. For example, it might prove economical to erect a set of concrete arch-bridge centering from a cableway, but it might also be very expensive to dismantle such centering with the same tool. The net result would be to develop some plan, such as trestle and locomotive cranes, or floating equipment and jacks, to displace the cableway. If the only consideration was to erect for permanence, the cableway might be chosen without further thought as being the most economical for the case in hand.

Mr. Reichmann's conclusion that there are no limits to the special cases of methods and equipment used in bridge erection, is fully seconded by the writer. If the designer, as well as the erector, will follow Mr. Reichmann's condition chart, few, if any, mistakes in judgment will result.

A. A. EREMIN,[7] ASSOC. M. AM. SOC. C. E. (by letter).—With the advancement in modern bridge design considerable attention is generally given to the problem of erection. Often the equipment available and the economic considerations of the erecting methods decide the selection of the type of bridge.

An interesting type of semi-permanent bridge with a half-through truss of uniform depth was developed by M. Pigeaud,[8] for the French Army, during the World War, which deserves careful consideration of military engineers.

Parallel cables are swung over some steel-framed square towers, which are composed of members that can easily be handled. Cross-beams are suspended from the cables, and tracks are placed on top of the beams. The trusses are made in sections about 15 ft. long which are rolled into position in the span by means of a car. After completing all connections the entire span is raised with jacks to release the cables and is lowered on the bridge seats. This method of erection is applicable to a half-through bridge with any number of spans. From November, 1914, to May, 1919, 152 bridges of this type were constructed in France.

[7] Asst. Designing Engr., Bridge Dept., State Highway Com n., Sacramento, Calif.
[8] *Le Genie Civil,* June 14, 1919.

The Ludwigshafen-Mannheim Bridge over the Rhine River, in Germany, was designed to be erected in two steps:[9] (1) Erect the bridge as a three-span, through-type structure with the trusses of uniform depth and continuous over the intermediate piers; and (2) construct a steel arch over the three spans, and reinforce the trusses, and suspend them to the arch. The result, after removing the intermediate piers, is a steel arch bridge with stiffening trusses, which forms an exceedingly graceful structure.

Mr. Reichmann has given a valuable summary of the construction plans and methods used in erecting steel bridges.

A. F. REICHMANN,[10] M. AM. SOC. C. E. (by letter).—The discussion has added some interesting cases of specific erection problems to a paper which was limited to a generalization of major considerations in the determination of the most feasible and economical equipment and methods of erection.

Paper No. 1841

FULTON STREET, EAST RIVER TUNNELS, NEW YORK, N. Y.[1]

By Miles I. Killmer,[2] M. Am. Soc. C. E.

With Discussion by Messrs. H. J. King, S. M. Swaab, Jacob Feld, Ole Singstad, John F. O'Rourke, H. H. Hatch, and Miles I. Killmer

Synopsis

This paper treats the specific problems encountered by the contractors in constructing the two tubes of the Fulton Street, East River Tunnels, in New York, N. Y. Useful information is given concerning the size and general types of equipment necessary and the manner of using it to the best advantage. The paper supplies a general picture of the contractor's power house, required on a job of this scope, and the assembly and erection methods of various phases of the work, especially the shields, are described in detail. The paper closes with an interesting account of construction problems met during the building of the High Street Station.

Introduction

A description of the plant used on the Fulton Street Tunnel, which is situated on what is known as Route 101, Section 1, of the new subway of the City of New York, is given in this paper. The contract began at Church Street about 100 ft. south of Park Place in Manhattan (see Fig. 1). Local and express tracks run south on Church Street to Fulton Street, where the local tracks terminate at a station next to the Hudson Terminal Building. The two express tracks turn east, pass under the southbound tube of the Brooklyn-Manhattan Transit (B. M. T.) Company in a short section of concrete tunnel, and continue east in separate cast-iron tubes to the end of the contract at Jay and Nassau Streets, in Brooklyn, N. Y. Following the cast-iron tubes from west to east, one passes under the northbound "B. M. T." tube, St. Paul's Churchyard, Fulton Street, the East River, Cranberry Street, High Street, and under private property to the end of the job.

The tubes were constructed by the shield method under compressed air. The working shafts were at Fulton and Front Streets, Manhattan, and on

Furman Street, Brooklyn. Shields started east and west from each of these shafts in each tunnel, making eight shields in all. From January until May, 1929, all eight of the shields were under way together. In Brooklyn, the ground pierced by the shields was mostly sand, gravel, and boulders. In Manhattan, it was a fine sand with clay admixture and was very favorable for tunneling. The Manhattan shields passed under the tracks of the Interborough Rapid Transit (I. R. T.) Company, in William Street and in Broadway, and the easterly "B. M. T." tube near Church Street; and the Brooklyn shields passed under the east approach to the Brooklyn Bridge. Along "the line of march" through Fulton Street were many tall buildings the footings of which were close over the shield, vertically, and only 2 or 3 ft. away from the outside of the tunnel, horizontally. These buildings were not underpinned. The air pressure used in driving the shields and in putting down the mid-river sumps ranged all the way from normal to 48 lb. per sq. in.

FIG. 1.—GENERAL PLAN OF FULTON STREET, EAST RIVER TUNNELS.

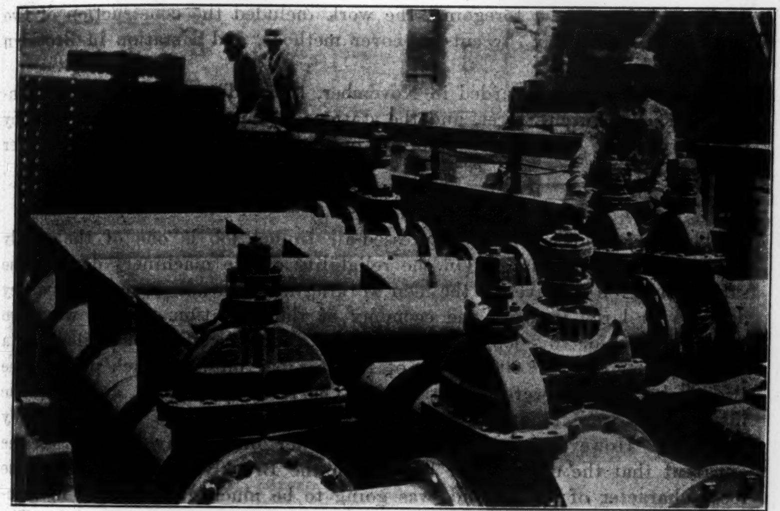

FIG. 2.—MANIFOLDS AND VALVES AT TOP SHAFT IN MANHATTAN.

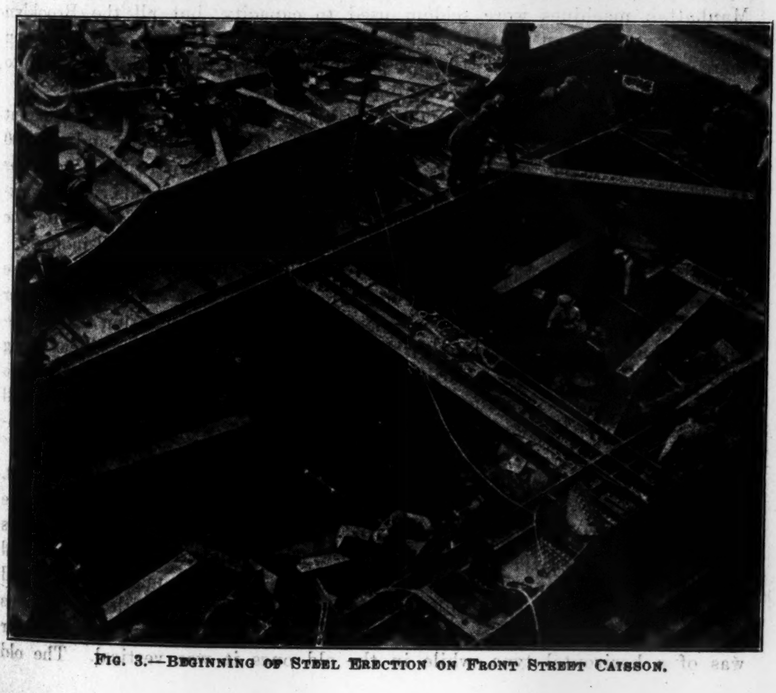

FIG. 3.—BEGINNING OF STEEL ERECTION ON FRONT STREET CAISSON.

In addition to the foregoing, the work included the construction of two stations in Manhattan, by cut-and-cover methods, and a station in Brooklyn by tunneling.

The contract was awarded in November, 1927. The two shafts, the open-cut work on Church Street, and the station on Fulton Street, were built by sub-contractors. This paper describes only the plant used on the remainder of the contract.

POWER HOUSES

The power house on a compressed-air tunnel job is one of the vitally important items of plant. On the reliability of the machinery depends the safety and even the lives of the men working in the heading; on its adequacy depends in large measure the economy of the operation. There were two power houses for this job, one at each end. The specifications called for a low-air capacity of 28 000 cu. ft. of free air per min. for each plant. The two plants as built were almost alike. The low-air, high-air, and hydraulic installations were identical, but the electrical installations were necessarily different. However, the work was no sooner under way than it became apparent that the demand for low air on the Brooklyn side, because of the loose character of the ground, was going to be much greater than in Manhattan. This condition persisted throughout the duration of the job. The Manhattan machines were seldom used to capacity, but all the Brooklyn machines were almost continuously being pushed to their limit, and even then there were times when it was not possible to keep up the air pressure to what was desired in the river headings.

All the machinery was operated by electricity. In Manhattan, the current was received at the power house at 13 200 volts from one feeder and at 7 500 volts from the other two feeders, and it was stepped down to 2 200 volts for the larger motors and to 220 volts for smaller power demands. In Brooklyn, the current was received at 4 300 volts and used at that voltage for the large machines; it was stepped down to lower voltage for the small motors.

Power was supplied by two commercial companies as sub-contractors. The electric current reached each power house by three entirely independent feeder lines, coming from three different sub-stations. This precaution was necessary, of course, to insure power in the event of a break-down or accident along one of the feeders. The power-house engineer and electrician always had to be on the alert. In a number of instances, break-downs did occur and all machines came to a stop. It usually took from 3 to 5 min. to start the compressors again.

In each power house there were five low-air machines of 5 600 cu. ft. capacity. Four in each plant were new, and one was a used machine. The new machines were 29 by 29 by 21 in., and were operated by synchronous motors of 625 h. p., for 2 200-volt, 3-phase, 60-cycle current with a full-load speed of 180 rev. per min. The motors on the Brooklyn machines operated at 4 300 volts. The used machines were 28 by 28 by 24 in., with synchronous motors of 600 h. p., at 164 rev. per min. In the new machines the after-cooler was of a horizontal type, while in the old ones it was vertical. The old

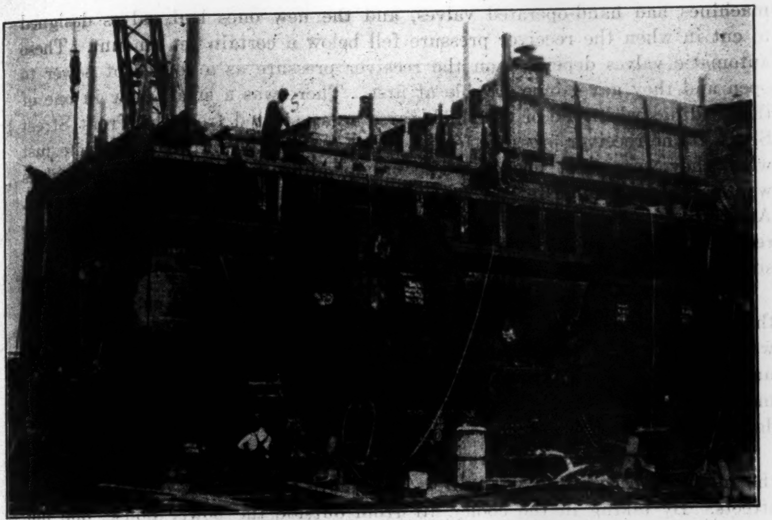

FIG. 4.—STEEL ERECTION AT LATER STAGE.

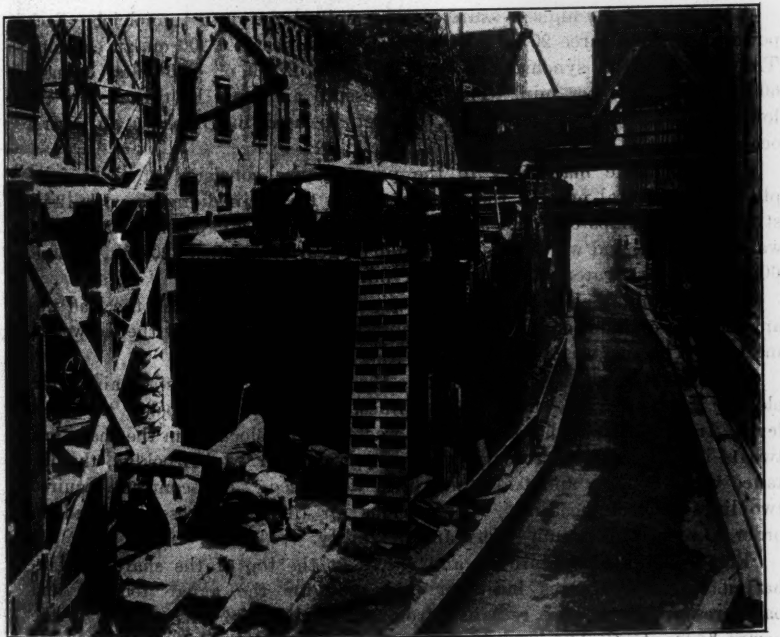

FIG. 5.—SINKING FURMAN STREET SHAFT.

machines had hand-operated valves, and the new ones had valves designed to cut in when the receiver pressure fell below a certain set amount. These automatic valves depended on the receiver pressure as a source of power to open and they gave some trouble at first. There was a small blow in one of the headings when one of the shields was being started from the Front Street Shaft. The receiver pressure fell so low that the valves failed to operate just when they were most needed. The old machine with hand-operated valves was started and sufficient air was obtained from it to meet the emergency. After this incident, all the automatic valves were connected to a separate receiver which was kept supplied with the necessary air at the desired pressure by one of the high-air machines.

The compressors gave admirable service; the operators, as well, proved their mettle; dramatically, on one occasion, when the Brooklyn power house was struck by lightning and less conspicuously through many months of unfailing service. In Brooklyn, there were weeks and weeks when all five machines were compressing air at maximum load, 24 hours per day and 7 days per week.

The air for the compressors was taken in above the roof. In Manhattan, the inlets were equipped with filters to remove some of the dust of the city streets. By taking in the cooler air from outside the power house, one not only secures better air, but better compression economy.

The demand for high-pressure air is usually large on a tunnel job. Each power house had three 20 by $12\frac{1}{2}$ by 14-in. machines of 1 300 cu. ft. capacity. The motors were synchronous and rated at 225-h. p., 220-volts, 3-phase, 60-cycle, 257 rev. per min. The high-pressure air could be turned into the low-air lines if need be and was, in fact, so used in Brooklyn on several occasions.

The hydraulic machinery in the power house consisted of three four-plunger horizontal pumps; the plungers were $1\frac{3}{4}$ in. in diameter with 12-in. stroke. The pumps operated at 50 rev. per min., had a capacity of 24 gal. of water per min., and were driven by 100-h. p., gear-connected, 220-volt, 3-phase, 60-cycle motors, rated at 700 rev. per min.

The accumulator was of the hydro-pneumatic type in which the load was applied by a cylinder charged with compressed air instead of by the old weight method. The size was 8 by 42 in.

The power houses were connected to the shafts by the necessary air, water, electric, back-pressure, and telephone lines, laid in trenches below the street level. In Manhattan, the power house was only one block from the shaft, and two 14-in. lines sufficed to carry the low-pressure air. In Brooklyn, the distance was 1 600 ft., and two 16-in. lines were used. The contract required two lines to each heading. The various air lines are cross-connected, in order to secure maximum safety and flexibility.

Fig. 2 shows the manifolds and valves at the top of the shaft in Manhattan. A shanty was built on this spot for the gauge tenders, and back-pressure lines were returned from all headings to this shanty, to the power house, to the engineers' office, and to the superintendents' office.

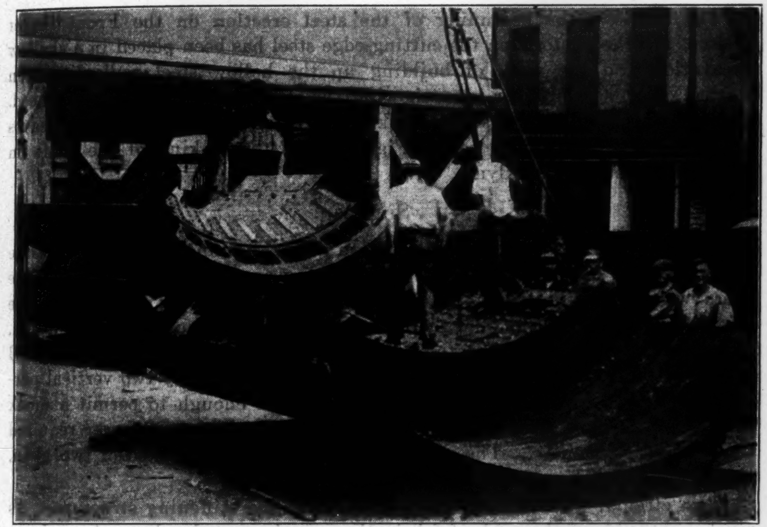

FIG. 6.—TWO SECTIONS OF SHIELD.

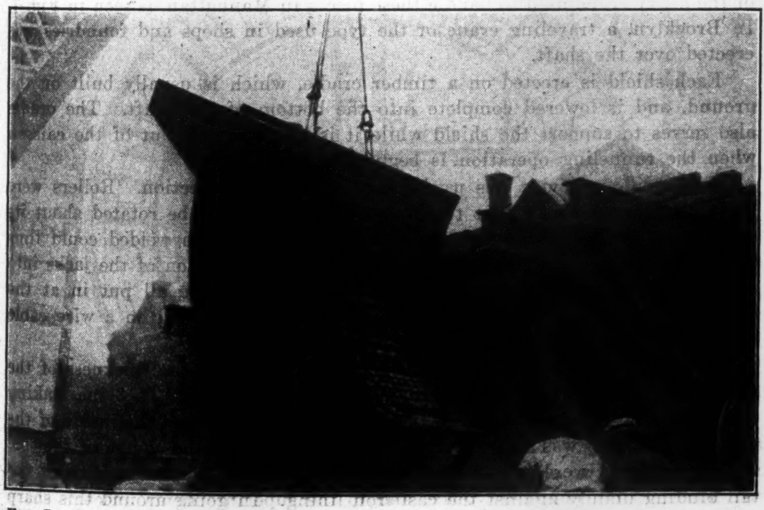

FIG. 7.—ONE OF LOWER-QUARTER SECTIONS OF A SHIELD IN THE SLINGS OF A HEAVY DERRICK, READY TO BE LOWERED.

CAISSONS

Fig. 3 shows the beginning of the steel erection on the Front Street caisson. In the photograph the cutting-edge steel has been placed in a shallow excavation and the work of building up the hollow steel walls has been started. Fig. 4 is another view showing the steel erection further advanced. The circular openings (closed by bulkheads) through which the shield leaves the caisson can be plainly seen. Fig. 5 shows the sinking of the shaft on Furman Street, in Brooklyn.

SHIELDS

The contract required the construction of eight tunnel shields. Since the material to be encountered in all the tunnels was sand or gravel and, since there was no possibility of "shoving blind" at any stage of the job, the shields were entirely open, and there were no unusual features in their design. One platform extended across the horizontal diameter. The spaces above and below the platforms were each divided into three pockets by two vertical partitions. The lower middle pocket was made large enough to permit a muck car to pass through to the face, but the conditions of the job never required the use of this facility. The skin-plates of the shield consisted of two 1¼-in. plates, riveted and welded together.

Two circular girders or diaphragms formed the stiffening structure. As much as possible of the work of fabrication was done at the shop. A quadrant of the skin and quadrants of the stiffener girders with cutting-edge or hood castings attached, were riveted together in the shop. Fig. 6 shows two of these sections. The largest of them weighed about 20 tons. Part of the boom of the heavy crane used to handle these pieces in Manhattan, is seen in Fig. 7. In Brooklyn, a traveling crane of the type used in shops and foundries was erected over the shaft.

Each shield is erected on a timber cradle, which is usually built on the ground, and is lowered complete into the bottom of the shaft. The cradle also serves to support the shield while it is being shoved out of the caisson when the tunneling operation is begun.

An ingenious device was used to speed up shield erection. Rollers were built into the cradle so that the assembled shield could be rotated about its axis. The seams along which the skin-plates were to be welded could thus be brought "into the clear" for easier access. The insertion of the jacks into their places was made much simpler, because they were all put in at the bottom. The shield was rolled by the derrick which pulled on a wire cable wrapped several times around the outside.

The outside diameter of the shield was 18 ft. 10 in., the thickness of the skin was 2½ in., and the outside diameter of the tunnel, 18 ft. 3 in., making the theoretical clearance between the outside of the iron and the inside of the tail 1 in., radially. This clearance served very well in the course of the job. In Manhattan, two shields went around curves of 335-ft. radius without the tail binding unduly against the cast-iron lining. In going around this sharp curve, special efforts had to be made to build the iron so as to overcome the

FIG. 8.—TYPICAL CROSS-SECTION OF RIVER SHIELD.

tendency of the tail of the shield to shorten the horizontal diameter. The tail was long enough to lap over two rings and 6 in. on the third ring. This is the minimum length of tail that will permit the removal of a broken segment in a ring after a shove has been completed.

The shields were very heavily constructed and stood up well for the duration of the job. On the Brooklyn side, boulders were of very common occurrence; in some cases, pieces were broken out of the cast-steel hood segments by hidden boulders. Both land and river shields were equipped with hoods extending 2 ft. 10 in. farther ahead than the cutting-edge; the hoods on the land shields reached to 1 ft. below the springing line on either side, while those on the river shields reached only to a point 1 ft. above the springing line. The total length of the shield along the bottom was 15 ft., of which 6 ft. 6 in. was in the tail, 5 ft. 2 in. was between the rear diaphragm and the front diaphragm, and the remainder made up the forward part of the shield consisting of the cutting-edge castings and the steel structure to which they were anchored. Fig. 8 shows the dimensions in the cross-section of a river shield.

Hydraulic Equipment.—The hydraulic equipment on each shield consisted of shoving jacks, table jacks, and the erector. The shoving jacks were 10 in. in diameter and were equipped to be pushed out or pulled back by hydraulic power. With a pressure of 6 000 lb. per sq. in., the eighteen jacks were capable of exerting a forward thrust of 4 000 tons. The shoving jacks had the usual offset foot so that the pressures exerted by them were transmitted to the web of the cast-iron segment and not against the flange. In spite of this design, there were many instances in which tunnel segments were broken by the jacks during a "shove." To reduce the number of such breakages, steel shoes were made in the blacksmith shop and fastened to each jack. These shoes were designed to limit the area over which the thrust was exerted against the segment, and also to overcome the tendency of the moving part of the jack to twist.

Of course, each jack had its own control spindles by which it could be pushed out, exhausted, or pulled back. There were eighteen jacks on each shield, eight above the springing line and ten below. This arrangement proved satisfactory in controlling the moving of the shield.

The jacks stood up well throughout the course of the job and there was only a small amount of repacking required to keep them all in working order. This work was done on Sundays and it can be stated that throughout the entire job, every shield averaged 90% of its rams in working order.

Three tables were provided in the horizontal platform, one in each of the three pockets. They were of exceptionally heavy construction and lasted in the land headings for the duration of the job. In the river headings, they were put out of commission after the shields had passed the river bulkheads.

The erector was mounted at the edge of the horizontal platform of the shield on the axis of the tunnel. The motion of rotation (extending to about 380°) was effected by a pinion on the erector shaft, moved by a rack above it just under the operator's platform. The erector arm was extended or withdrawn by a hydraulic cylinder within the erector itself. Fig. 9 is a view

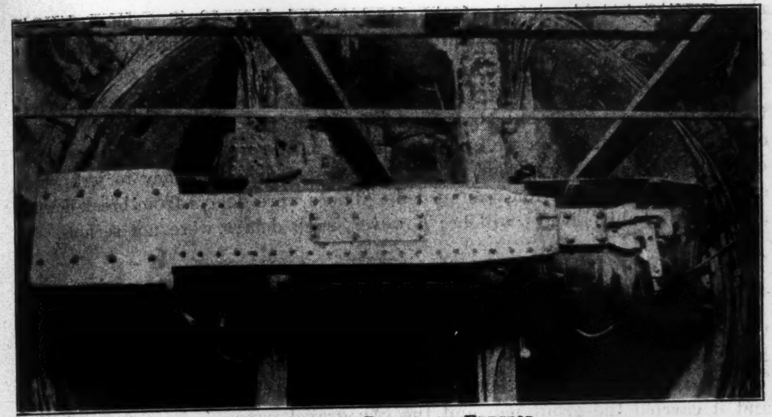

Fig. 9.—Outside Detail of Erector.

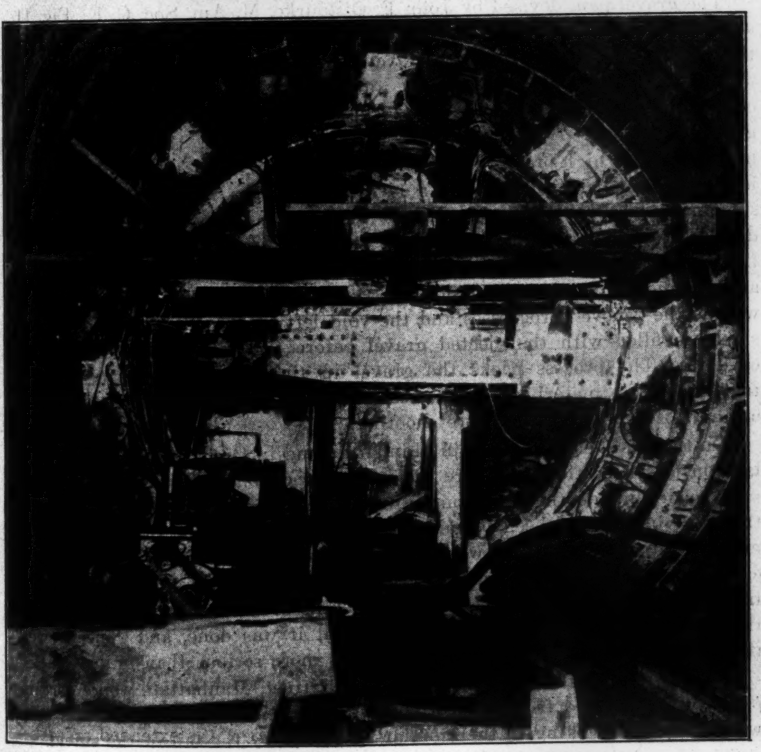

Fig. 10.—North River Heading in Manhattan.

showing the outside detail of the erector, and Fig. 10 is a more general view showing erector, jacks, shield platforms, and the tunnel rings in the foreground.

The erectors were built to operate at the same pressure that it was planned to use for shoving the shields, namely, 5 000 lb. per sq. in.; but this system offered disadvantages as well as advantages. The wear and tear on erector control valves was very high, and the erectors had a tendency to jerk when a slow and definite motion was needed. There were delays from break-downs, as there probably always will be; however, such delays were not serious.

Tunnel Plant in Rear of Shield

The traveling platform was dragged ahead by the shield and slid on the tie-rods, just above the springing line of the tunnel. It was originally 20 ft. long, but was extended in the field; it was the full width of the tunnel. The traveler served as a bolting platform in re-tightening the back rings, and it carried the grout pan and the two gravel pans.

The gravel pan, devised by John F. O'Rourke, M. Am. Soc. C. E., Fig. 11, was used for ejecting pea gravel outside the cast-iron lining, although in the photograph it is not on a traveling platform. It is a tank holding about 33 cu. ft. of gravel, with a nipple and valve at the bottom of its conical floor. There is an air-tight trap-door at the top through which the gravel is loaded. When the tank has been charged, the door is closed by admitting high-pressure air to the tank. Below the bottom nipple is a tee, on one side of which is a 1½-in. hose with a valve and on the other side an armored rubber hose leading to the grout hole in the segment. Immediately after the valve in the air line is opened, the valve at the bottom of the tank is opened. The gravel falls into the air jet and is carried along the armored hose and ejected outside the tunnel lining. This process is under way as the "shove" progresses and the void left by the advancing tail of the shield is filled with the ejected gravel before the ground has a chance to cave in. The process packs the gravel in tightly and almost cements it together. The material may be ejected dry or the charge in the tank may be inundated with water before shooting.

On the land headings, both in Manhattan and in Brooklyn, great stress was laid on this operation to insure the instant and complete back-filling of the void made outside the cast-iron lining by the advance of the shield. Had the overlying ground been permitted to fall into this space, disastrous settlement of adjacent buildings would have resulted. In fact, the success of the entire tunneling procedure was linked to the success of this operation. It is impossible, in this paper, to go into the details of the campaign waged to get this work done quickly and thoroughly; but it was done, and done so well that no building settled or suffered injuries more serious than minor cracks.

Fig. 12 is a photograph taken at Nassau Street, Manhattan, where certain plates were removed from the bottom of the cast-iron lining. It shows very well the gravel packing in the annular space left by the tail of the shield.

FIG. 11.—VIEW SHOWING GRAVEL PAN.

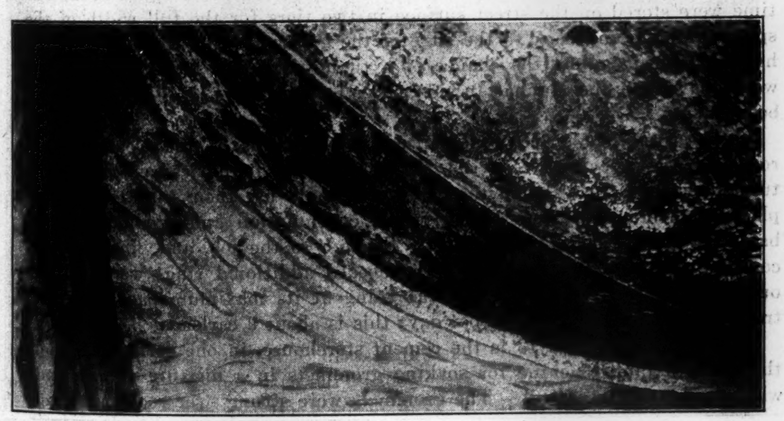

FIG. 12.—GRAVEL PACKING UNDER BOTTOM OF CAST-IRON LINING.

The ejection of grout outside the cast-iron lining is a second line of defense in the prevention of settlement and is no less important than the gravel process. While graveling is done in the first ring behind the tail, grouting is done seven to twenty rings back. Grout penetrates farther than gravel. It spreads out into seams that may have opened up in the overlying ground. It sometimes spreads out in such a seam over a wide area and, being under pressure, can actually lift up the ground that has slumped down. The grout pan is practically the same as that used in the construction of the Pennsylvania Tunnels.[8]

The machine is nothing but a tank into which sand, water, and cement are dumped. These ingredients are mixed by paddles turned by a small air motor at the end of the machine. The liquid grout is ejected by admission of compressed air after the tank has been closed.

Tunnels are grouted to check the loss of air while the shield is passing through loose ground even when the question of settlement of buildings does not enter. Thus, grouting was extensively used in passing under the dock bulkheads and, also, out under the river. Fig 18 shows typical shoring beneath an elevated railway structure in Brooklyn, which was required while the tunnel was passing beneath it. The ground settled about 1 in. and the columns were jacked up and held by wedging.

DOCK PLANT AND GANTRIES

Practically all the materials used for construction were delivered to the job by water transportation and excavated material was disposed of in the same way. The right to use certain property on the East River was given in the contract. In Manhattan, a gantry was built from the shaft, east along Fulton Street to South Street, thence east along the northerly half of Pier 16 (see Fig. 1) to dumping boards erected along the edge of the pier.

The dock space available in Manhattan for handling segments, grouting sand, pea gravel, and cement is shown in Fig. 1. Tunnel segments at one time were stored on the street surface in two tiers for the full width of the space available and back to the edge of the gantry. This iron was kept on hand to guard against the chance of a tie-up of harbor transportation. It would have kept the Manhattan side going for four days if all deliveries had been cut off.

A large storage space was utilized in the yards of the Central Railroad of New Jersey, in Greenville, N. J. When the foundries were producing tunnel segments faster than the contractor could use them, the surplus was placed in storage in New Jersey; when consumption and production were balanced, the segments came directly through to the job, and, finally, when consumption exceeded production, the needed additional rings were ordered out of storage. When the work was going at its maximum pace, the contractor erected about 48 rings per day; this is about 9 carloads.

At the right in Fig. 13 is the cement storehouse, in one corner of which there was a tank machine for soaking grommets in a mixture of red lead, white lead, and linseed oil. The grommets were strung over rods that fitted

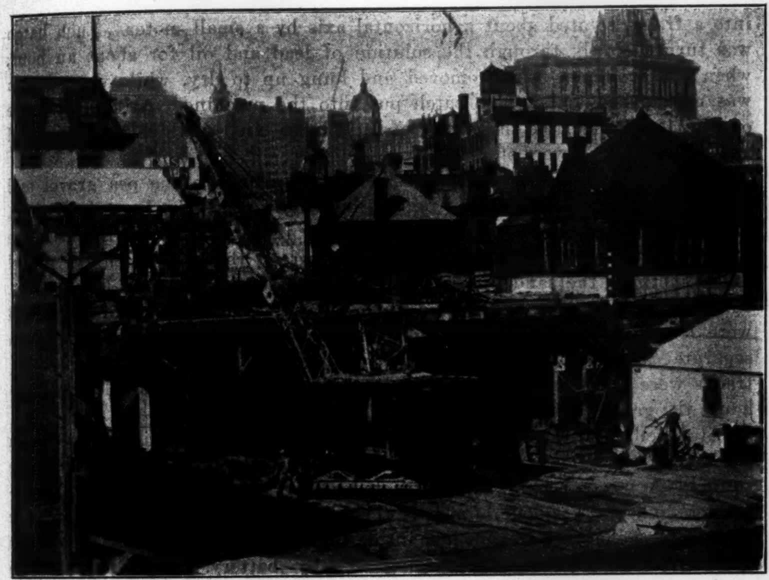

FIG. 13.—STORAGE YARD AT BULKHEAD IN MANHATTAN.

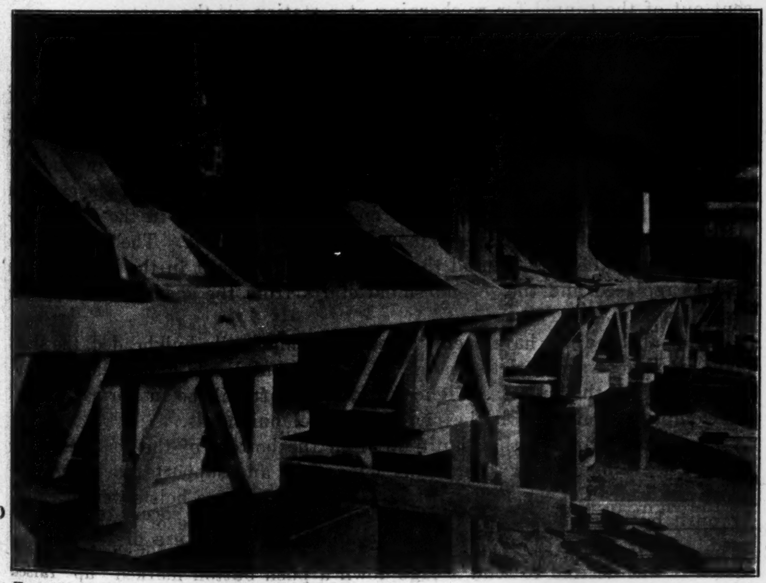

FIG. 14—HOPPERS FOR SCREENING, MEASURING, AND BAGGING GROUTING SAND AND PEA GRAVEL, IN MANHATTAN.

into a frame rotated about a horizontal axis by a small motor. Each batch was turned slowly through the solution of lead and oil for about an hour, when the grommets were removed and hung up to dry, while the solution was replenished and a new batch put into the machine. At the left edge of Fig. 13, one can see the corner of the timber bins in which the pea gravel and grouting sand were stored.

The detail of the measuring hoppers through which the pea gravel and grouting sand were drawn off from the bins and bagged, is shown in Fig. 14. The storage bins were equipped with steam coils for winter conditions. The measuring and bagging device included a screen through which the gravel and sometimes the sand was passed. It was essential to avoid large stones, which choked the hose and caused much delay. The bagged sand and gravel were loaded into muck cars which were elevated to the gantry level in a separate cage constructed near the cement shed. In Brooklyn, the gantry tracks were laid through the third floor of a warehouse. Outside the warehouse the gantry extended out on Pier 6 (see Fig. 1).

Storage-battery locomotives were used throughout the entire job—both on top and in the tunnels. In Manhattan, the batteries were re-charged in the tunnel. A power room was constructed at the top of the shaft with transformers and a motor-generator set. The direct current was carried down the shaft to a re-charging station just inside the locks in each tunnel. Automatic devices prevented the overcharging of any battery. In Brooklyn, the re-charging was handled differently. The batteries were put on flat cars and sent out of the tunnel for re-charging at a station on the gantry.

Shaft Plant

The shaft plant on a tunnel job is required to take care of two very different shaft conditions. There is, first, the period when the shields are being started from the shaft. The deck is in place in its upper position and the space below is under compressed air. All materials pass in and out through locks above the caisson deck. After one tunnel has been extended about 150 ft. from the shaft, a concrete bulkhead is built in the face of the shield, and the air pressure is removed from the heading. The deck is then removed from the caisson, and the second shield is built in the bottom. The deck is replaced and the second shield starts from the shaft in the opposite direction.

After all headings have been started and temporarily bulkheaded, the shaft plant undergoes a complete change. Concrete bulkheads with locks are constructed in all the tunnels. Henceforth, the shaft will be in normal air and the compressed air will be beyond the tunnel bulkheads.

Steel framework is then built up from the bottom of the shaft to above the gantry level. This frame forms a hoistway and supports the cage hoists above the well. On the Fulton Street Tunnels, the cage hoists were operated by push buttons. This was the first time that this type of equipment was used, and it worked out very well. The cages were of the usual design. When it was desired to send a cage down a push button marked "up" raised the cage about 1 ft., freeing the "landing dogs." The "down" button was

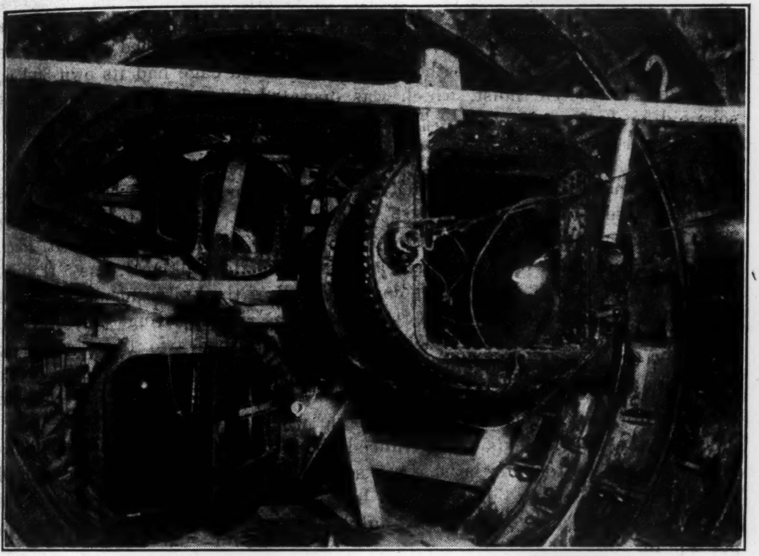

FIG. 15.—BULKHEAD AND LOCKS IN RIVER HEADING.

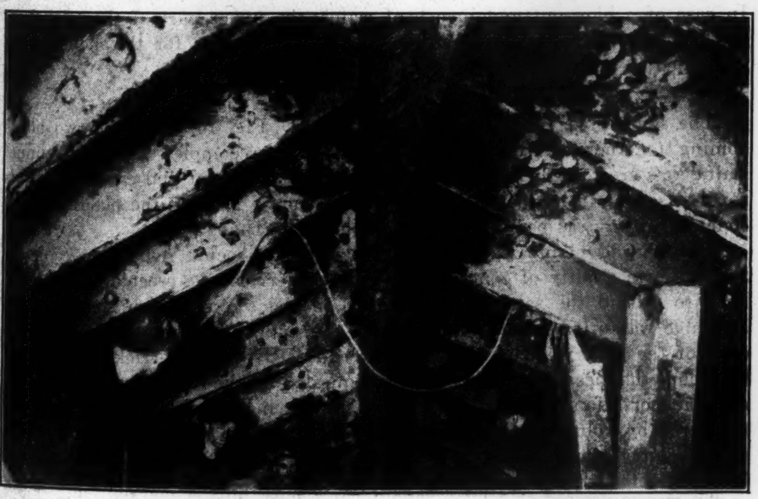

FIG. 16.—MEETING OF TWO HOODS, MAY, 1929.

then pushed and the cage descended to about 2 ft. above the bottom where it stopped automatically. A second button was then pushed and the cage was slowly "inched" down to the final level. Each cage had its own 30-h.p., single-drum, electric hoist, which was operated by a slip-ring motor, with solenoid brakes on 220-volt, 3-phase, 60-cycle current at 860 rev. per min.

Tunnel Bulkheads and Safety Screens

The tunnel bulkheads presented no novel features. Because of the large sized cars used, the muck locks had to be 8 ft. 6 in. in diameter. They were 38 ft. long. The man locks were 6 ft. 6 in. in diameter and 34 ft. long. The emergency lock, placed as high as possible in the bulkhead, was 5 ft. 0 in. in diameter and 20 ft. long. The concrete wall of the bulkhead was 6 ft. 6 in. thick in the land headings and 8 ft. thick in the river headings (see Fig. 15).

In addition to its locks, each bulkhead contained two 10-in. air lines; two 6-in. blow lines; one 4-in. high-pressure, air pipe; one 3-in. water line; two 1½-in. hydraulic lines; a back-pressure pipe; and several iron conduits for electric cables and telephone wires.

After the river shields had advanced about 1 000 ft. from the tunnel bulkhead near the bottom of the shaft, a second bulkhead was built close behind the shield. After this bulkhead had been put in use, the air pressure in the section of tunnel between the two bulkheads was maintained at about 15 lb. per sq. in.

The safety screen was required, by specification, in the river headings after the shield had passed the river bulkhead. This is an air-tight bulkhead closing the upper part of the tunnel. Two were used in each river heading so that one would always be in place while the other was being moved ahead. In case of a blow-out and inrush of water, the upper part of the tunnel on the landward side of the screen would be a safe haven for the men if they succeeded in reaching it.

Completion

The south river shields met in May, 1929. Fig. 16 shows the two hoods coming together. After all the excavation was completed and all tunnel lining was erected, there was the big job of cleaning out and caulking. This work was done in normal air. Toward the end of August, the placing of the concrete lining was begun; it was completed in June, 1931.

The mixing plants were carefully planned to secure maximum economy and uniform quality of concrete. A stiff-leg derrick was erected at the bulkhead to unload the sand as it came in on the scows. Such space as was available was utilized for storage piles. A mixing plant was set up near the edge of the gantry. The aggregates were raised by the derrick to a storage bin about the measuring hoppers. As requested by the engineers of the Board of Transportation, the aggregates were measured by weight. The water was measured by volume. The mixer discharged into a car which was elevated to the gantry level and then taken to the form in a train of two or three cars. The concrete cars were made by substituting a concrete body on the muck cars. The mixing plant and methods of placing were about the same in Brooklyn as in Manhattan.

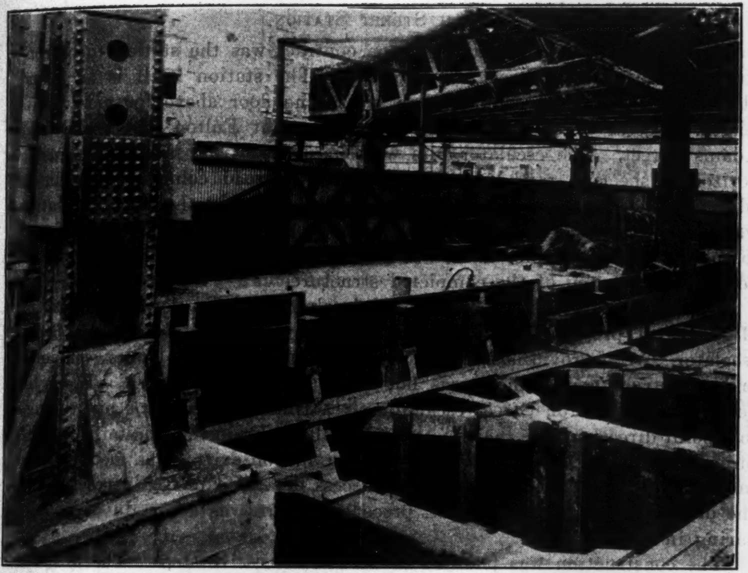

FIG. 17.—EXCAVATION FOR ESCALATOR PITS, HIGH STREET STATION, BROOKLYN.

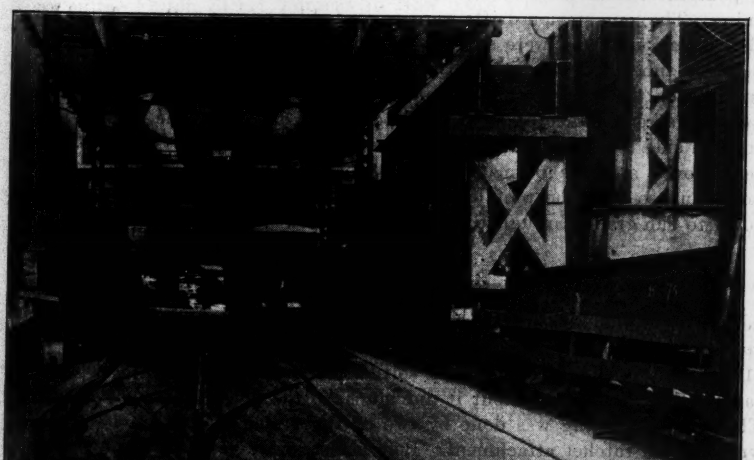

FIG. 18.—SHORING UNDER ELEVATED RAILWAY ON HIGH STREET, BROOKLYN.

HIGH STREET STATION

A somewhat unusual feature of the contract was the station to be constructed under High Street, in Brooklyn. The station itself is an island platform about 700 ft. long, with a mezzanine floor above for most of its length. Access to the station is by escalators at Fulton Street and near Adams Street. The escalator pits were excavated from the surface, using horizontal sheeting methods. The elevated railroad columns immediately adjoining the pits were underpinned to sub-grade before the main excavation was made. The column in the foreground of Fig. 17 was first underpinned to sub-grade, but the pier had to be partly removed and the column given a new bearing on top of the completed structure.

Fig. 18 shows the shoring of the steel columns of the elevated railway on High Street preparatory to making the excavation for the Adams Street escalator. After providing for such column shoring, and for trolley, vehicular, and pedestrian traffic, there was not much room left to work. From the bottom of the Fulton Street escalator pit a timbered drift was put through to a point directly above the two cast-iron tubes. From the sides of this drift, mining gangs broke in and started the long station drift. The methods used in this work were new. Since their success depended on the correctness of the designer's figures and not on precedent, there was a certain element of daring in them.

The construction was planned in several successive steps. The first was to pour the tunnel inverts and erect thereon timber bracing for the cast-iron lining. The long station drifts were excavated by miners. Pressed-steel liner plates were used and were supported by arch ribs resting on the tops of the cast-iron tubes and strengthened by a bowstring. The first heading was large enough for the central or bowstring section of the arch rib; side headings followed at a distance of 50 ft. and permitted extending the arch rib down on each side to a firm bearing on the cast-iron tubes. All posting could then be removed and the permanent steel erected. The arch ribs were finally jacked up so that the roof load was taken from the tubes and transmitted down to sub-grade through the permanent steel.

CONCLUSION

The foregoing covers the major items of plant used on this work. Several new items would be welcome, but have not yet been devised. A number of attempts have been made to develop a bolt-tightening machine but, to date (1930), this problem had not been solved. A small, air-driven tightener that ran up the nut was used, but it did not have the power to complete the job. The final tightening was done by two or three men pulling on a 5-ft. hand wrench with ratchet attachment. Belt loaders were used for a time, but the available space was so small that the advantages of the loader were outweighed by its disadvantages.

ACKNOWLEDGMENTS

The construction work described in this paper was done by the Mason and Hanger Company, Incorporated.

DISCUSSION

H. J. KING,[4] M. AM. SOC. C. E. (by letter).—While comparatively few engineers are faced, during their professional careers, with the problem of driving tunnels under such difficult conditions as those described by Mr. Killmer, nevertheless this extremely valuable contribution can be studied with great profit by tunnel men engaged in work in normal air.

The writer is acquainted with several tunnels driven under more or less populous centers over which subsequent subsidence of the ground surface has been the basis of actions brought to recover losses for heavy damages to adjacent buildings and other improvements. In certain types of ground this subsidence may not be evident for several years after the completion and acceptance of the tunnel by the owner.

In the writer's opinion the application of the apparatus for ejecting pea gravel, so clearly and interestingly described by Mr. Killmer, could well be extended to include many liner tunnels driven under areas where surface subsidence is objectionable. In many cases the gravel treatment alone would be entirely sufficient to prevent subsidence, and the necessity for the more costly grouting treatment could be obviated.

S. M. SWAAB,[5] M. AM. SOC. C. E. (by letter).—The work done by Mr. Killmer on the Fulton Street Tunnels in New York City represents the highest development of the art of subaqueous tunneling. While shield tunneling is an English invention and the first shield-driven tunnels were built in England, still the art has received its maximum development in methods, safety, and economy, in the region of the Port of New York since the date of the building of the Hudson and Manhattan Tunnels by the late C. M. Jacobs and J. V. Davies, Members, Am. Soc. C. E.

On each of the several tunnels as it was built, certain innovations were made until the process of building subaqueous tunnels can now be said to be fairly well established, the size of the tunnel and the nature of the ground being the same.

On the Fulton Street Tunnels there has been made the most consistent, and, at the same time, the greatest and best progress (except that made on those tunnels where the material of the face practically flowed into the tunnel through the openings in the shield, or where the shield merely displaced the material) on any of the subaqueous tunnels in the neighborhood of New York; and for workmanship, alignment, and grade, they have not been surpassed.

The specifications issued by the Board of Transportation for this work left to the contractor the choice of electric or steam power for the operation of the compressor plants, and the contractor chose to use electric power. This was made possible by improvements in compressor machinery. The plate valves used to-day are lighter in weight and, at the same time, provide greater area for the air to pass through and cause less restriction than the poppet-valves formerly used. Consequently, the machines can be operated at much higher speeds than formerly, being, in fact, direct-connected to the motors and operating at full motor speed without restriction. However, in adopting electric power, one has to be alert because of accidents to the feeder lines to which there is always some liability (such as that to which Mr. Killmer calls attention), even if the power lines come from different sources. Proper protection of the circuits by lightning arrestors can readily be provided at comparatively little expense. The expense of supplying this protection is, in fact, so small that one cannot readily afford to be without it.

---

[5] Cons. Engr., Philadelphia, Pa.

The automatic valves for controlling the output of air from the low-pressure compressors were, undoubtedly, designed to be operated by moderately high, low-pressure air. Consequently, when the low-pressure air was reduced materially by a blow-out in one of the headings, there was not sufficient pressure available to operate the valves. Mr. Killmer immediately overcame this by cutting into the line of the old compressor with hand-operated valves, and the pressure was thus boosted to provide for the emergency. Subsequently, a recurrence of this condition was prevented by taking the air supply for valve operation from a receiver connected with the high-pressure machines.

The plant which is described in detail in Mr. Killmer's paper was ample for the purpose. Three of the low-pressure compressors would have been sufficient, at times, on the Manhattan side, and six might have been used on the Brooklyn side to advantage, owing to the fact that the material on the Manhattan side held the air better than that on the Brooklyn side of the river.

The connection between the high-pressure and the low-pressure air lines is very advantageous and, as Mr. Killmer states, was availed of several times in connection with this work.

The shields which were used on Fulton Street fulfilled every purpose and stood up so well that in the subsequent work done by Mr. Killmer on Rutgers Street, this same shield design was used without any substantial change.

The innovation made in the method of tunneling under atmospheric air in the station on High Street was, undoubtedly, a very desirable one, since there has been no material left in the ground which, in the nature of things, will deteriorate.

The method of tunneling in soft ground without air (previously used on the stations built in connection with the several subaqueous tunnels, prior to the building of the Fulton Street Tunnels), permitted a large quantity of heavy timber to remain in the ground, but in the substitute method used by Mr. Killmer, this is not so. The advantages of this method over that formerly used on similar work are readily recognizable and have been highly satisfactory. In any event, it is quite possible that there will be less disturbance of the utility structures, buildings, and street paving, in the future than has occurred in connection with any of the other work heretofore built.

In Fulton Street, Manhattan (which is about 55 ft. in width between the houses), the tunnels were driven under compressed air through sand below the level of the ground-water, in many instances below, and in all cases extremely close by, the foundations of the buildings, without causing injury worthy of the name, and, in fact, without appreciable settlement. This was done in advance of the building of the station between Broadway and William Street. The latter work was done from the surface after the tunnels had been driven. It was originally intended to underpin the buildings on both sides of the street in advance of the driving of the tunnels. This was not done, however; but for the purpose of protecting and securing the buildings during and after the construction of the station, permanent bulkheads, built piecemeal, in isolated sections, in individual pits, were constructed in front of them on either side of the street and just beyond the station walls, in advance of the building of the station. These bulkheads, when completed, were solidly braced across the cut provided for the station, as the excavation was made, and the station itself was subsequently built within the lines of the bulkheads thus provided.

The work on the station in Fulton Street, Manhattan, which was one of the most difficult operations to be performed in connection with this contract, was distinctly illustrative of what could be done by way of tunneling in close proximity to high and heavy buildings. After the completion of the tunnels and immediately over them, the earth prism between the surface and the top of the tunnels was removed in a bulkhead-protected trench, without permanent injury to any of the buildings, and with a minimum of disturbance during their occupancy. Incidentally, there was as little or possibly less settlement of the individual buildings than would have occurred had they been previously underpinned.

The method of following up the erection of the iron close by with pea gravel and of subsequently injecting into this cement grout had the desired effect of preventing surface settlements to the largest extent that they have ever been prevented in any work of this character in New York City, or elsewhere.

Indeed, it would be difficult, to say the least, for one to conjecture what might possibly happen on work of this character. One must always be on the alert. For the ordinary things that happen, a man may be, and is to some extent, prepared. It requires an ingenious, resourceful, and quick-witted man, however, to be prepared to meet unexpected contingencies as they arise, and then there must be a liberal allowance of "good luck," or its equivalent, no matter by what name it is called. In addition, a good organization properly directed, adequate financial resources, and a properly designed plant, such as was here available, are required to complete a contract, such as this, successfully.

JACOB FELD,[6] ASSOC. M. AM. SOC. C. E. (by letter).—The author has omitted mention of the methods for checking line and grade in the two sections of each river tunnel by which such remarkable coincidence as that shown in Fig. 16, was obtained. The writer has given line and grade in rock and earth tunnel construction under structures, and appreciates how much detailed work is required in providing accurate control points in blind headings to permit accurate meeting of such headings. The same operation must be considerably more difficult in tunnels under water, because of the longer sections and because of the movements which must occur in each section due to such conditions as change in tide levels and possibly motion of the soil surrounding the tunnel shield.

OLE SINGSTAD,[7] M. AM. SOC. C. E. (by letter).—This paper is a concise and well prepared account of an important and interesting construction job, well executed. Two outstanding features of this work are most impressive: (1) The rapid progress attained in shield driving, which has established a new record for subaqueous tunneling in this kind of ground; and (2) the driving of the shields through Fulton Street below and very close to the foundations of buildings of considerable height, without underpinning the buildings and without causing serious settlement or damage to them. This result, of course, could not have been attained without the effective measures taken, as described in the paper, to insure the instant and complete backfilling of the void created outside the cast-iron lining in advancing the shield.

It is also interesting to note certain improvements over previous practice in the details of the plant, such as the use of automatic or push-button elevators in hoisting materials up and down the shafts (an arrangement which no doubt was prompted by the scarcity of labor and the high wages paid at the time); and the use of a simple mechanical device for saturating the hemp grommets with red lead. This device not only effected a saving in labor, but unquestionably resulted in a more thorough saturation of the grommets, thereby improving their water-proofing properties.

The erection of the shield on a cradle equipped with rollers also is a novel feature, resulting in greater ease in erecting and equipping the shield and a saving in the time required for this work.

The rapid progress made on the work and the excellent results obtained are due largely to the fact that the contractor, as well as the City, had organizations of construction men and engineers in charge, with extensive experience in tunnel work, and that the job was equipped with an adequate and up-to-date plant.

JOHN F. O'ROURKE,[8] M. AM. SOC. C. E. (by letter).—In addition to this paper there are only two papers[9] in the publications of the Society on the subject of under-river shield tunnels and their approaches. The papers are all well written, fully illustrated, and treat the subject from two different points of view; namely, that of the owner's engineers who supervised the work in the field and that of the engineer who was in actual charge of the work for the contractor. It would be well if descriptions of the construction record of the numerous other shield tunnels under the Hudson River and the East River had been published by the Society so that the growth of the art of shield tunneling in New York City could be followed from one to another, including the views of the engineers and contractors. At any rate the facts concerning them are generally known and short references to some of them may be of value in showing the successive improvements by which shield tunneling has reached the high state of development disclosed in Mr. Killmer's extremely lucid and important paper.

[9] "The New York Tunnel Extension of the Pennsylvania Railroad—The North River Tunnels," by B. H. M. Hewett and W. L. Brown, Members, Am. Soc. C. E.; and "The East River Tunnels," by J. H. Brace, Francis Mason, and S. H. Woodard, Members, Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXVIII (1910), pp. 152 and 419, respectively.

The first under-river shield tunnels in New York City were the two under the Hudson River (The Hudson and Manhattan Tunnel) from Morton Street, Manhattan, to Jersey City, N. J. (begun in 1874). These were started as brick tunnels constructed without shields by the Haskins System, which were later changed to shield tunnels lined with cast iron. The brick tunnels were driven through the clay river bed with 34 lb. of compressed air by excavating the neat size of the brickwork and lining the roof and sides of the excavation, as it progressed, with light steel rings, 30 in. wide, in 3 and 6-ft. segments, that broke joints with those of adjoining rings. This steel lining was braced radially with timbers from a pilot tube at the center, 6 ft. in diameter, which was driven a few feet in advance of the heading. The 24-in. brick lining was built as each 15-ft. length of excavation was completed. The muck from the next 15-ft. length was filled into the last length of brickwork to a little below the springing line (upon which the construction tracks were extended), after which the remainder of the excavation for the length was completed and hauled to the shaft in muck cars drawn by mules. It is significant that the material from the heading was sufficiently firm to support the construction track and give a footing for the mules without planking, and confirms what follows on that subject.

A paper[10] on this tunnel by the late Arthur Spielmann and Charles B. Brush, Members, Am. Soc. C. E., relates to the work at the beginning and before the method of construction described herein had been fully developed. However, the paper has many facts concerning the steel-plate rings. The material of the river bed through which the tunnel passed, is described as so stiff under the air pressure that it could be cut in benches, with steps rising from one bench to the other. Another paper[11] by the late William Sooy Smith, M. Am. Soc. C. E., gives further information regarding the river bed and describes the Haskins tunneling methods in detail. This comparative solidity of the so-called silt, which is in reality a sedimentary deposit of clay in horizontal layers, was subsequently confirmed by Messrs. Aims and Fitzgerald, Resident Engineer and Superintendent, respectively, in numerous personal interviews which contained a wealth of corroborative detail, and also by the writer's own observations in front of a shield where these tunnels were being driven through part rock and clay near the New York side of the river. He also had opportunities to observe the clay of the river bed at the Pennsylvania Railroad tunnels; at Haverstraw, N. Y., where the clay for brick-making is taken in great quantities from behind coffer-dams in the river, the clay banks being like those on shore; and also at the Poughkeepsie Bridge during the sinking of the pier foundations. In all these cases the clay was similar to that previously described, through which the Hudson and Manhattan Railroad Company's tunnels were driven so that the entire river bed from New York to Poughkeepsie may be said to consist of a fairly firm and dependable clay with a shallow covering of mud where the clay has been disturbed. Attention is called to these facts as showing the reliable nature of the bed of the river where undisturbed for the firm support of tunnels and other structures with properly designed foundations, because there is a widespread belief that the river bed is soft and affords only insecure support. The direct opposite is true, particularly as to tunnels, which weigh less than the material they replace, so that the clay beneath them has less load on it than before their construction.

---

[10] "The Hudson River Tunnel," *Transactions*, Am. Soc. C. E., Vol IX (1880), p. 259.

[11] "The Hudson River Tunnel," *Transactions*, Am. Soc. C. E., Vol. XI (1882), p. 314.

It is a fact that at both the Pennsylvania Railroad tunnels and the Holland Tunnel the clay surrounding the tunnels directly behind the shields became soft and slushy for a few feet out from the tunnel lining and that some settlement as well as flotation of the tunnels occurred. This was occasioned by the ground not closing in on the lining at the tail of the shield, but maintaining itself for some time as a dirt tunnel of the diameter of the shield. The weight of the overlying ground and water caused arch stresses in the surrounding parts greatly in excess of the ordinary compression stresses when directly supported from below, and squeezed the firm clay composing the face of the dirt tunnel into a watery mud.

This same clay when forced during shoves into the tunnel through openings in the bulkheads, by hydraulic pressures exceeding 100 lb. per sq. in. on the heading in front of the shield, required a foot on the spade to cut into it during removal. This shows how firm the clay surrounding the tunnels naturally is and that if immediate support were provided for the tunnel and surrounding ground as the shield was shoved (as can easily be done), the destructive arch stresses would be prevented and the tunnel would be as free of either settlement or flotation as were the brick tunnels in the same kind of ground, where immediate support by the steel lining plates preserved the firmness of the clay unchanged.

The Hudson and Manhattan Railroad Company's tunnels are also of interest because in them cast-iron shield tunneling was introduced in New York City through the advice of the late Sir Benjamin Baker, Hon. M. Am. Soc. C. E. Certain London bankers retained Sir Benjamin to report on these tunnels when they were considering a loan to the Tunnel Company. He learned that on two occasions when the air pressure in the northerly brick tunnel, extending from Jersey City to the middle of the Hudson River, was reduced from 34 lb. to 20 lb., because of trouble with the steam boilers, the heading began to move into the tunnel. This was stopped both times by rapid and effective bracing. The possibility that, on some future occasion, when the air pressure might be lowered or lost, the bracing might fail and the tunnel be filled with silt, seemed to Sir Benjamin too great a risk to ignore, and he advised the bankers to make the use of shields a condition of the loan, which was done. This involved abandonment of the brick lining and the substitution of cast-iron lining, which was the only kind known at that time that could resist the thrust of shield jacks. The existing brick tunnels were entirely satisfactory in his judgment and subsequent events have justified this opinion. The northern tunnel (the western half of which was built of brick at that time and the eastern half subsequently built of cast iron) has been in constant and satisfactory use to its full capacity for twenty-three years (since 1907), and the brick and cast-iron parts are both in equally fine condition.

The next shield tunnels undertaken (1903) were for the Rapid Transit Commission of New York from South Ferry, Manhattan, to Joralemon Street, Brooklyn, with approaches in Battery Park, Manhattan, and Joralemon Street, Brooklyn. These tunnels were of cast iron, as are all subsequent river tunnels and approaches in New York at the present. Shield tunneling being still quite undeveloped, there were difficulties and stoppages of work, but after some delays and much discussion, the troubles were corrected, the tunnels were finished, and have been giving satisfactory service for more than twenty years.

The tunnel construction along Joralemon Street in Brooklyn caused immediate settlement of the street over the tunnels as the shields advanced, a little later followed by settlement of the stoops and areas, outward from the buildings. Later, the fronts of the buildings began to settle and crack, the settlement of the ground under them progressing slowly to the rear for several years, until the angle of rupture of the ground was finally reached when the settlements stopped. By this time some of the buildings had moved out several inches into the street, spur shores against the fronts were frequently used until the settlements stopped, and a number were so badly cracked that the front walls had to be rebuilt. After years of litigation, the Court of Appeals affirmed the verdicts for damage to the buildings and disallowance of the much larger claims for contingent damages, such as losses of rentals and interference with business. The opinion stated in support of this that the work had been done without negligence, that the grout used to minimize settlement, while it was the best known method, had not entirely succeeded in doing so, and that the damages were incidental to the character of the work. This means that the best known method of preventing settlement must be used if consequential damages are to be avoided.

The shield tunnels undertaken after the Pennsylvania Railroad tunnels, were those across the East River, two from Whitehall Street, Manhattan, to Montague Street, Brooklyn, and two from Old Slip, on the New York side, to Clark Street, in Brooklyn. It was on these contracts that the writer introduced gravel packing to fill the space left around the tunnel lining by the shields. The contracts specified grout for this purpose, paid for per barrel of cement used. After gravel packing had been tried for a short time and was found to prevent visible settlement of streets or buildings the contracts were modified to substitute it for the grout used immediately behind the shields.

The gravel packing was first used in the river headings from the shaft at Old Slip and Front Street on the New York side. Figs. 19 and 20 show Old Slip on January 29, 1916, about two months after the tunnels were driven beneath. Gravel packing was supposed to be used from the beginning, but the street settled about 6 in. for nearly 75 ft. When the writer went into the tunnel it was found that, although the blowing apparatus and pea gravel were provided, the men did not understand the method and had confined their activities to grouting. The writer instructed them in getting the apparatus in working order and in blowing the gravel into the space around the tunnel at the rear of the shield, so that in a few hours the tunnel and ground at the rear of the shield were firmly supported for the length of a ring. When the next shove was made the operation was repeated and from that time on gravel packing the space left by the shield was started with the shove and continued until the entire space was packed, in the order of top, sides, and bottom, and there was no further settlement.

In Fig. 19 a white arrow shows where the settlement was stopped at the tail of the shield. The line marks the end of a piece of curb where the shield had not moved, of which the other end had settled 5 in. From this point the curb did not settle perceptibly, as the gravel packing was regularly used with a success that was warmly appreciated by the tunnel men, many of whom had worked on the Joralemon Street tunnels and believed shield tunneling and settlements to be inseparable.

Fig. 20 is a view from the corner of South Street looking backward to the shaft at Front Street, Manhattan. The sidewalk and roadway in this picture as far as the white arrow, remained without settlement. The line of the curb shows this, and any unevenness in the sidewalk and pavement was there before the tunnel was driven. Neither view shows settlement in the adjoining building as its pile foundations were carried on solid rock.

The same successful avoidance of visible settlement followed the construction of the Brooklyn approaches on Clark and Montague Streets where the gravel packing was faithfully performed. There was equal success in preventing settlements in driving the tunnels on Fulton and Willoughby Streets, Brooklyn.

Grout was used in all these tunnels from one to three days after the gravel packing had been placed. The gravel packing was so dense that grout could not be forced through it and a hole had to be punched through the gravel at each grout hole before the grout hose nipple was attached. In excavations subsequently made around the tunnels for inter-track stations, the grout was usually found in large lumps in the ground where it emerged through the gravel as there were no holes or cracks into which it could flow. It appeared that when the grout came in contact with the surrounding ground that the water was filtered from it, the sand and cement forming a lump that grew in size until the resistance of the ground to further expansion of the lump caused a refusal of flow from the grout mixer under a pressure usually about 100 lb. per sq. in. These lumps greatly compacted the ground surrounding them.

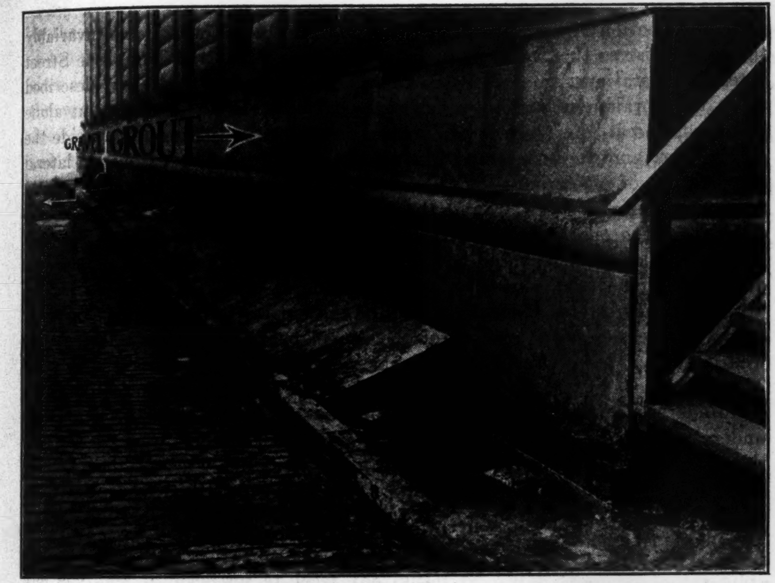

Fig. 19.—North Side of Old Slip, Showing Where Grout Was Used Outside of Lining Allowing Settlement of Street Over Tunnel.

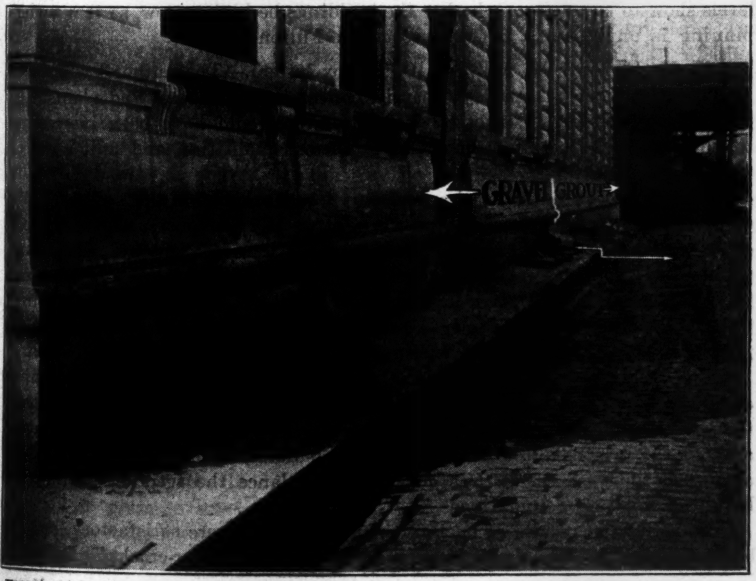

Fig. 20.—North Side of Old Slip, Showing Where Gravel Was Used Outside of Lining Preventing Settlement of Street Over Tunnel.

The collection of grout into lumps around the tunnel, which was invariably the case so far as the excavations disclosed at the Clark and Montague Street inter-track stations, goes far to explain the settlements already described when the Joralemon Street tunnels were driven. In that case grout alone was used, and it must have made pockets for itself in the ground outside the grout holes and formed lumps like those described. The extent of lateral compression of the ground by these lumps was limited, so that the greater part of the empty space around the tunnels was left unsupported. In any event were the character of the ground to permit the entire empty space to be filled with grout, it would be too soft for at least an hour to support the overlying ground which usually starts to settle at once.

Mr. Killmer states that the success of the entire tunneling procedure was linked to the successful placing of the gravel packing, and that this was so well done that only a few minor cracks were caused in driving the tunnels. This latter fact is very important regarding that contract as none of the high buildings was underpinned, while all buildings of seven stories or more were underpinned before the Montague and Clark Street tunnels were driven past them, because the security afforded by gravel packing was not then known. An examination to-day of underpinned buildings and those adjoining them on Montague Street would show the joints between them to be undisturbed although in some cases the walls of the small buildings extend only 10 ft. below the streets while the underpinning of the high buildings near the river extends 100 ft. below the street. The fact is that gravel packing prevents all but a very slight settling of the ground as a whole along the tunnels, which levels show to be uniform whether the buildings be high or low, so that underpinning is unnecessary, as was proved on Fulton Street.

H. H. Hatch,[12] M. Am. Soc. C. E. (by letter).—The author has covered his subject-matter thoroughly; that is, contractors' problems and plants. In connection with his instructive description, it would have been interesting to know also about the engineering problems, quantities, and unit costs of this work.

It always pays to make the necessary precautions for the safety of life and the expedient progress of the work, especially in constructions of more or less risky nature. Sometimes a contractor tries to "get by" with plant on hand and without making the necessary preparations for emergency. At times, he succeeds, and often he has "hard luck" which results in loss of life, time, and money. Mr. Killmer, however, seems to have taken the necessary precaution for any emergency with respect to his equipment and personnel.

It is interesting to note that the many tall buildings near-by the tunnel could be held in place without settlement and without any support other than a maximum air pressure of 48 lb. per sq. in. Disregarding the disturbance of the original ground in driving the shields, it means that a force of about 3.5 tons per sq. ft. was sufficient to balance the reaction of the tall buildings on their foundations.

Evidently the results of back-fill with pea gravel were satisfactory, as "no building settled or suffered injuries more serious than minor cracks." It occurs to the writer, however, that the more uniform the material sizes the higher is the percentage of voids; and that if there is any variation in the particle sizes of the gravel, or if pea gravel is mixed with sand, before being shot into the openings outside the shield, the back-fill would become more compact due to a smaller percentage of voids. It is desirable to know the maximum and minimum pressures used in shooting the pea gravel back of the shields.

---

[12] Engr. in Chg., Cobble Mountain Reservoir, Springfield Water-Works, Westfield, Mass.

More information on the grouting would have been welcome. Practical experience on various tunnel and foundation grouting has proved that better work can be obtained with neat cement than with an admixture of sand. The thinner the grout the farther is its penetration. Often, with sand-cement grout it appears that the sand, being heavier, will stop short during the discharge of the grout and let the fluid travel past it. This process gradually will form sand pockets near the discharge of the grout pipe and eventually will prevent the passage of more grout.

In a rock tunnel with concrete lining, it is possible to compute the minimum quantity of grout necessary to fill the voids back of the concrete. To this amount, of course, should be added the estimate of grout necessary to seal up the rock seams, if any. It has been found that the grout will shrink and that the excess water, especially in thin mixtures, will occupy space, provided the pressure does not drive it away. Often it is this excess water that will find weak spots in the concrete lining and seep through, thus guiding the engineer in locating at least the outlet of water from voids for additional grouting. It is questionable whether, in shield tunneling, the quantity of grout can be estimated in advance. It would be instructive to know just what methods were used to make positively sure that the grouting was complete. Were there any investigations or attempts to determine whether additional grout could be forced back of the shields after the completion of the first grouting?

MILES I. KILLMER,[13] M. AM. SOC. C. E. (by letter).—Mr. Feld comments on the omission of any description of the methods of running line. This phase of the work was done by the engineers of the Board of Transportation of the City of New York. It involves triangulation, base-line measurement, dropping line down the shafts, prolonging line through the lock bulkheads, and many other special methods. It is an extensive subject, and it could not be treated adequately, except in a separate paper. The work was done with great accuracy by the Engineers of the Board, and the Manhattan and Brooklyn survey lines checked at the junction of the shields within $\frac{1}{4}$ to $\frac{1}{2}$ in.

The discussion by Mr. Hatch requires some comment. The air pressure in a sand heading does not support the ground. The pressure used is such as to balance the head of ground-water at the bottom of the tunnel and is not influenced by the presence or absence of near-by building loads. The actual pressure in the land headings was generally not more than 18 lb. The 48-lb. pressure was required only in putting down the sumps below the tunnels at the lowest point under the river. The ground is supported by the cast-iron tunnel lining surrounded by its envelope of ejected pea gravel and grout, by the exterior of the skin on the shield, and, at the face, by breast-boards held in place by braces against the shield. When the shield is to be advanced, vertical timbers ("soldiers") are placed against the breast-boards. From these "soldiers," horizontal stretchers extend back through the pockets of the shield to cross-timbers ("walking sticks") wedged into the last cast-iron ring erected. The braces that had originally supported the breast against the shield are then knocked out, and the shield can be advanced without disturbing the support of the face. Under certain conditions, the horizontal tables can be used to support the face. They are shoved out by means of their rams until they make contact with the "soldiers." When the shield is advanced the hydraulic pressure behind the rams is released slowly, and the tables come back as the shield goes ahead.

---

[13] Mgr., Mason & Hanger Co., Inc., New York, N. Y.

All the foregoing applies to a sand or gravel heading. If the face is of semi-plastic clay, a condition arises in which the pressure of air in the tunnel may be utilized to support the face, or at least to supplement other methods of supporting it.

The possibility of using sand with the pea gravel to secure an enveloping back-fill having a smaller percentage of voids, is mentioned by Mr. Hatch. This idea was successfully put in practice in the construction of the traffic tunnel from Boston to East Boston, Mass., recently completed. It was found that about one-third sand could be used with the pea gravel; a larger percentage caused stoppages in the tank or in the hose. In the Boston Tunnel, the surrounding ground was a stiff clay that did not fall into the void left by the advancing tail of the shield. It is the writer's opinion that where the surrounding ground is sand or gravel and tends to fall almost immediately into the annular space, pea gravel without sand will prove more effective as its granular nature makes it more fluid or mobile. The air pressure used in ejecting the gravel was the same as that used in grouting, that is about 80 lb.

Mr. Hatch also suggests the use of neat-cement grout to secure greater penetration. This was tried on a subsequent job with which the writer was connected. In driving two shields up Jay Street, Brooklyn, a very loose running sand and gravel was encountered. Some heavy buildings had to be passed. The quantity of 1 to 1 grout ejected was not fully satisfactory and neat-cement grout was resorted to for a distance of several hundred feet. The computed volume of the grout actually ejected, proved to be about equal to the computed volume of the 1 to 1 grout previously ejected, per foot of tunnel. In this case, therefore, the extra expense was not warranted. Of course, in grouting rock seams, neat-cement grout would probably be superior to the 1 to 1 mix.

Although the question of supporting buildings along a street seems to have been solved from an engineering point of view, there still remains the problem of defending suits brought by owners who, in many instances, will seize upon the occasion of the presence of a contractor to bring suit even when the physical damages are so slight as to require magnifying glasses to be seen.

WIND-BRACING CONNECTION EFFICIENCY

By U. T. Berg,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. David Cushman Coyle, William R. Osgood, O. G. Julian, Harold S. Richmond, Robins Fleming, L. E. Grinter, C. R. Young, C. H. Sandberg, N. A. Richards, Jacob Feld, Dana Young, A. J. Wilcox, R. D. Dalton, John J. Gould, W. C. Huntington, and Paul Nielsen, A. Toriggino and Erle L. Cope, R. A. Caughey, and U. T. Berg

Synopsis

This paper is intended as a warning, especially on wind connections in which negative moments due to gravity loads are neglected. Very high stresses in the connection members may be relatively harmless in themselves, but dangerous as far as the tension rivets are concerned, especially under alternate loading, where a gradual loosening may result.

Introduction

Wind resistance in structures is divided between resistance exerted by steel, walls, partitions, etc., in an unknown ratio. The mass inertia creates additional resistance against gusts of wind. The modern tendency toward increased height and relatively lighter weights intensifies the deflection and brings the question of rational design to the front.

What is the use of providing thousands of rivets that can not possibly do the work expected, and other rivets stressed to such a point that a few years of service will loosen them and increase the sway? To make architects "kneebrace-minded" would go far toward increased strength, as a conscientious design of the present-day types of connection meets many difficulties due to the large number of rivets required.

The term, "educated moments," is sometimes used in reinforced concrete design to denote that the reinforcement is placed more to suit the practical condition than the elastic theory can justify. Instead of providing for a

support moment, $\frac{W\,L}{12}$, a smaller value, such as $\frac{W\,L}{16}$, or $\frac{W\,L}{24}$, is substituted, assuming that a re-adjustment of stresses will take place.

Tests substantiate the claim that, at working stresses and intermediate stages, re-adjustments take place only to a slight degree, but, at ultimate loads, re-adjustments become very marked.

Fig. 1 illustrates the relations between computed and measured moments obtained from tests[2] on continuous beams. The conditions are that the beams are completely fixed at the ends; 47% of the bottom reinforcement steel is extended over the support. Steel designers generally take for granted that stresses will be distributed according to the connection; that the weaker parts will "give;" and that there is a balancing of stresses from the weaker to the stronger member. This practice may be justified within certain limits.

A beam with standard connections, as shown in Fig. 2, is designed as simply supported. If the column is unyielding, the connection angles must be sufficiently elastic to permit the beam ends to rotate. Angles, $\frac{3}{8}$ in. thick, with 4-in. legs, will readily satisfy this requirement. The computed stresses in the angles are high, but harmless, because at no time is there any danger of excessive pull on the rivets. However, if the legs are made very thick the rivets, which are generally considered as taking shearing stresses only, will be called upon to take heavy tensile stress in addition, due to the increased strength of the connection.

TENSION RIVETS

It is logical to base the design on the stage in which the initial tension is reached on the rivet, and to express the factor of safety, as follows:

$$\text{Factor of safety} = \frac{\text{Initial tension value of rivet}}{\text{Total tension stress on rivet}}$$

It is readily seen that the I-beam stub connection (Fig. 3 (*a*)), with a tension force of the value, 2 *S*, cannot deform as illustrated in Fig. 3 (*b*). The initial tension in rivets would have to be overcome to permit the rivets to elongate. A force, $R - S$, is developed which maintains the edge in position as shown by Fig. 3 (*c*). When the initial tension is reached, it is not unreasonable to assume that the force, $R - S$, is distributed as a triangular load, zero at the rivet center, and maximum at the edge. This would locate the center of gravity of the force at a distance equal to $\frac{2}{3}$ *C* from the rivet center. (Actually the pressure diagram is parabolic due to the deformation of the plate. However, the corresponding shorter arm is compensated for by the fact that the rotation due to the variation of pressure between the plates reduces the fixing moment at the rivet.)

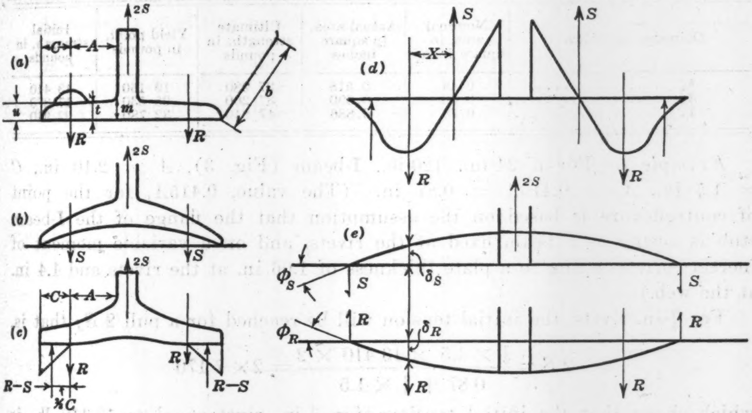

FIG. 3.

If *X* denotes the distance from the point of contraflexure to the rivet center, the following equations can be written:

$$S X = (R - S) \tfrac{2}{3} C \dots\dots\dots\dots\dots\dots\dots (1)$$

or,

$$R = \frac{S(X + \frac{2}{3} C)}{\frac{2}{3} C} \dots\dots\dots\dots\dots\dots\dots (2a)$$

$$S = \frac{\frac{2}{3} C R}{X + \frac{2}{3} C} \dots\dots\dots\dots\dots\dots\dots (2b)$$

Reliable tests are available on tension rivets.[8] For red-hot driven rivets, the ultimate strength was found to be 54 000 lb. per sq. in.; the yield point,

---

[8] *Bulletin No. 210*, Eng. Experiment Station, Univ. of Illinois, by Wilbur M. Wilson, M. Am. Soc. C. E., and William A. Oliver, Assoc. M. Am. Soc. C. E.

37 000 lb. per sq. in.; and the initial stress at least 70% of the yield-point strength, or 25 900 lb. per sq. in. Table 1 gives the foregoing values applied to the rivets commonly used.

There is some element of doubt relative to the value, C, in Equation (1). It is possible that a reduced value of the distance from rivet center to the effective bearing edge should be entered in the equation when used for thinner plates, so that $C_{\text{max.}}$ is a function of the thickness of the plate plus one-half the diameter of the rivet head. However, in most practical cases, the plate thicknesses are such that this question does not have any importance.

TABLE 1.—DIMENSIONS AND STRENGTHS OF RIVETS

Diameter, in inches	Nominal area, in square inches	Actual area, in square inches	Ultimate strength, in pounds	Yield point, in pounds	Initial strength, in pounds
¾	0.44	0.518	27 980	19 160	13 410
⅞	0.60	0.690	37 260	25 530	17 870
1	0.78	0.886	47 840	32 780	22 940

Example 1.—For a 24-in., 120-lb., I-beam (Fig. 3), $A = 2.10$ in., $C = 1.5$ in., $X = 0.415A = 0.87$ in. (The value, $0.415A$, for the point of contraflexure is based on the assumption that the flange of the I-beam stub is acting as a beam fixed at the rivets, and on a variable moment of inertia corresponding to a plate thickness of 1.06 in. at the rivets and 1.4 in. at the web.)

For $\frac{3}{4}$-in. rivets, the initial tension will be reached for a pull $2\,S$; that is,

$$2\,S = \frac{\frac{2}{3} \times 1.5 \times 13\,410 \times 2}{0.87 + \frac{2}{3} \times 1.5} = 2 \times 7\,170$$

which shows that the initial tension of a $\frac{3}{4}$-in. rivet equal to 13 410 lb. is overcome by the application of a force of only 7 170 lb. acting as described in this example.

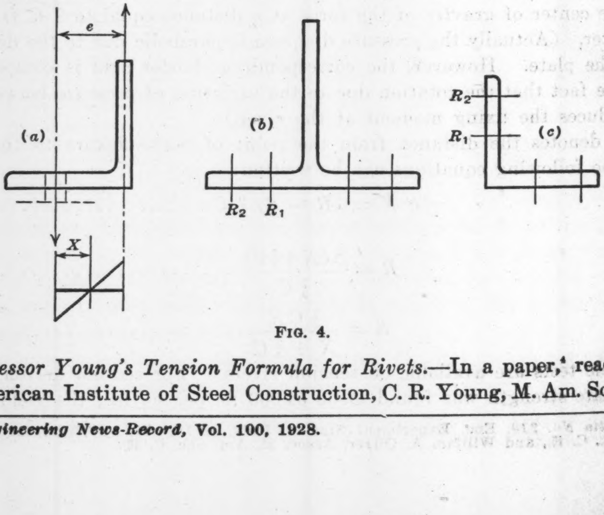

FIG. 4.

Professor Young's Tension Formula for Rivets.—In a paper,[4] read before the American Institute of Steel Construction, C. R. Young, M. Am. Soc. C. E., presented the following equation for tension stress in rivets:

---

[4] *Engineering News-Record,* Vol. 100, 1928.

$$f_r = 21\,000 - 8\,000\,d - 5\,500\sqrt{e}\ldots\ldots\ldots\ldots\ldots(3)$$

in which, f_r is the permissible tension stress on the rivet (factor of safety of 4); d, the diameter of the rivet, in inches, before driving; and, e, the eccentricity of loading on the rivet.

Equation (3) is based on tests using 4 by 4-in. angles. In comparing the values from it with the values derived from Equation (2*b*), it becomes important to use the right judgment relative to the eccentricity, e (Fig. 4(*a*)). If the test angles were free to move sidewise without any restraint on the outstanding leg, the values, e and X, should correspond. However, this condition is unlikely.

Assuming a condition as shown in Fig. 5 (*a*) and Fig. 5 (*b*), and expressed by $A - X = \frac{2\,A^2}{4\,A + B}$, the point of contraflexure of the angle would be located at a distance of about 0.65 e from the rivet center. (The foregoing equation is derived subsequently.) Table 2 has been prepared giving permissible pull on the connection per rivet on the following assumptions:

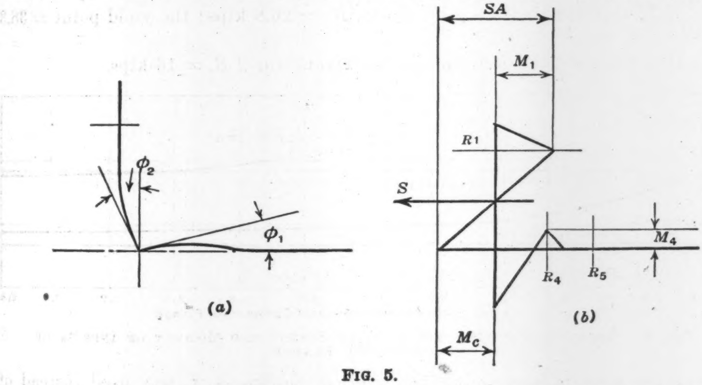

FIG. 5.

For values from Equation (2*b*):

Factor of safety of 2 on initial stress on gross area of rivet, $C = 1.5$ in.

For values from Equation (3):

Factor of safety of 4 on ultimate strength, $e = \frac{X}{0.65}$.

TABLE 2.—COMPARISON OF WORKING STRESSES

Nominal size, in inches	X, in inches	Eccentricity, $e = \frac{X}{0.65}$ in inches	PERMISSIBLE TENSION PER RIVET, IN POUNDS	
			Equation (2*b*)	Equation (3)
3/4	0.75	1.15	3 840	4 000
3/4	1.50	2.31	2 690	2 930
7/8	0.75	1.15	5 100	4 850
7/8	1.50	2.31	3 560	3 400
1	0.75	1.15	6 500	5 500
1	1.50	2.31	4 600	3 630

Equation (1) applies only for stages at the initial tension of the rivet. Lower values are meaningless because the rivet stress is never less than the initial tension value. From this point on, the rivet elongation must be taken into account.

The following equation can be derived from the loading condition, as shown in Fig. 3(*e*):

$$\delta_S - \delta_R = \Delta_R = (R - R_i)\,\frac{g}{EF} \qquad (4)$$

in which, R is the total stress on the rivet; R_i, the total initial stress on the rivet; g, the rivet grip; F, the area of the rivet; E, the modulus of elasticity; Δ_R, rivet elongation; δ_R, rivet elongation due to the force, R; and δ_S, rivet elongation due to the force, S.

Fig. 6 illustrates the relation between the total rivet stress (for two rivets) and the moment of inertia of the connection flange for a condition of loading as shown in Fig. 3(*a*). The values used in plotting the curves were: $I = \frac{1}{12}\,bt^3$; and, for the two $\frac{3}{4}$-in. rivets, $R_i = 26.8$ kips; the yield point $= 38.3$ kips; and, the total tension, $2R$, on two rivets, for $2\,S, = 16$ kips.

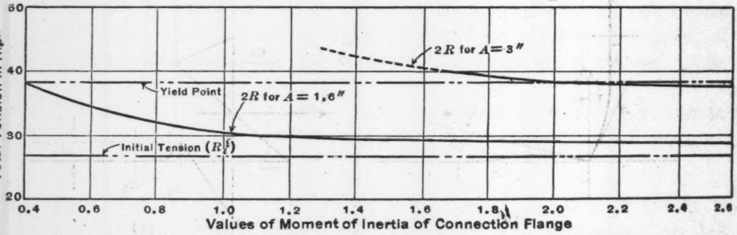

FIG. 6.—RELATION BETWEEN TOTAL RIVET STRESS AND MOMENT OF INERTIA OF CONNECTION FLANGE

For the sake of simplicity, the average thickness, *t*, was used instead of variations from *u* to *m* (Fig. 3(*a*)). From a study of Fig. 6, it is forcibly shown that the total tension developed on connection rivets under a constant force, 2 *S*, varies materially with the gauge distance, *a*, and with the thickness of the connection member up to a certain limit, after which increased thickness does not materially affect the tension developed.

Connections with more than one line of rivets, such as shown in Fig. 4, have merit only because of increased shearing value. Analyzed on the elastic theory, using commercial sizes, it is not possible to rely on any tension on the second line of rivets, R_2, unless the stress in the first line of rivets, R_1, exceeds not only the initial tension of the rivet, but also the yield point.

FLANGE ANGLE CONNECTIONS

A bending moment, *M*, at the joint, shown in Fig. 7 (*b*), is resisted by a couple, of force, *S*, acting on an arm, *Y*. The compression force, *S*, is transmitted directly into the column. The only bending effect at the lower angle is the influence of an eccentric action for the vertical load.

At the top, the tensile force would tend to pull the angle away from the face of the column, introducing bending moments in both legs of the angle.

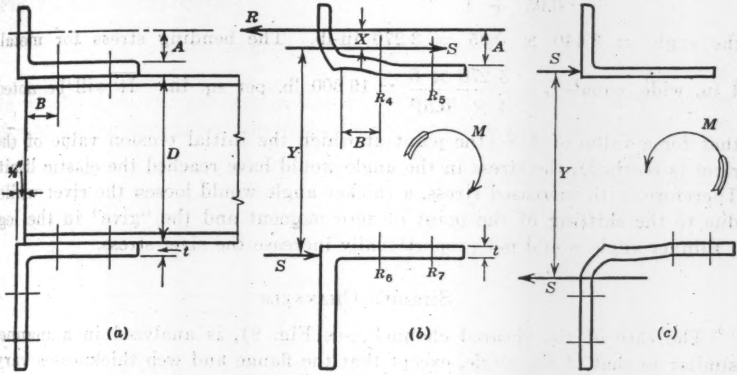

FIG. 7.

The elastic line of the deformed angle remains vertical at Rivet R_1, and horizontal at Rivet R_4. Rivet R_5 has no other effect than horizontal shearing resistance.

Referring to Fig. 5, the angle is assumed to be completely fixed at R_4. Hence, $M_4 = -\frac{1}{2} M_c$; and, $\phi_1 = \frac{1}{4} M_c \frac{B}{EI} = \phi_2 = \frac{SA^2}{2EI} - \frac{M_cA}{EI}$.

The corner moment (M_c in Fig. 5(*b*)), is,

$$\frac{2SA^2}{4A + B} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

and the distance from the upper face of the angle to the point of zero moment equals,

$$(A - X) = \frac{2A^2}{4A + B} \quad \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

The total moment at the joint, M, equals $S\,Y$. Let the thickness of metal equal t, and the depth of the beam, D; then (Fig. 7),

$$Y = D + \frac{t}{2} + t + A - X \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

For a moment in the opposite direction, the effect on the angles is reversed. The combined effect of bending on the lower angle from a force, S, plus eccentricity from the application of the direct load, would make a more serious condition than is the case for the top, except for the fact that, in most cases, the moment from the gravity loads is deductible from the wind moment, reducing tension at the bottom.

Example 2.—For a top angle, 6 by $3\frac{1}{2}$ by $\frac{1}{2}$ in., $A = 2 - \frac{1}{2} = 1\frac{1}{2}$ in.; $B = 2\frac{1}{2} - \frac{3}{8} = 2.13$ in.; and, $C = 1.5$ in. From Equation (6), $A - X = 0.55$, and $X = 0.95$ in. The permissible pull per rivet with a factor of safety of 2 is, $S = \frac{1}{2} \times \dfrac{13\,410}{0.95 + 1} = 3\,440$. The maximum bending moment on the angle $= 3\,440 \times 0.95 = 3\,270$ in-lb. The bending stress for metal, 4 in. wide, equals $f_s = \dfrac{3\,270 \times 6}{4 \times (0.5)^2} = 19\,600$ lb. per sq. in. It will be noted that for a value of 2 S (the point at which the initial tension value of the rivet is reached), the stress in the angle would have reached the elastic limit. Therefore, with increased stress, a thicker angle would loosen the rivet while, due to the shifting of the point of zero moment and the "give" in the leg, a thinner angle would not proportionally increase the rivet stress.

SHEARED CHANNELS

The case of the sheared channel (see Fig. 8), is analyzed in a manner similar to that of the angle, except that the flange and web thicknesses vary. If the average moment of inertia of the flange is I_F and that of the web, I_W, Equation (6) can be re-written for channels:

$$(A - X) = \frac{A^2}{2A + \dfrac{I_F}{I_W} \times \dfrac{B}{2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

SHEARED I-BEAMS

This case has been covered under the section, "Tension Rivets." Note that $Y = D + t$. For a constant thickness, t, of the flange, $X = \frac{1}{2} A$, and for a straight-line variation from u (the thickness at the rivet) to m (the thickness at the web), the distance, X, is equal approximately to,

$$X = \frac{u}{u + m} A \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

BEHAVIOR BEYOND THE ELASTIC LIMIT

The equations developed for the location of points of contraflexure of connections have been based on stresses within the elastic limit. Above the elastic limit, re-adjustments take place. The writer is not in a position definitely to determine these re-adjustments. Probably tests would be required. However, some approximate values can be derived. A redistribution of the moments in relation to the section modulus does not seem unreasonable. In that case, the distance, X, equals, approximately,

$$X = \frac{u^2}{u^2 + m^2} A \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

The same reasoning applied to angles would make $X = \frac{1}{2} A$ for all cases above the elastic limit.

ROTATION FROM DEFORMATION OF CONNECTIONS

The rotation of the beam end, due to deformation of the connection (see Fig. 9), can be expressed:

$$\phi = \tan \phi = \frac{(\Delta_1 + \Delta_2 + \Delta_3 + \Delta_4)\ S}{D + t} \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

in which, Δ_1 is the elongation due to bending in the top connection from $S = 1$; Δ_2, the elongation due to tension in the top connection only, for $S = 1$;

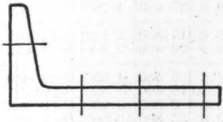

FIG. 8.

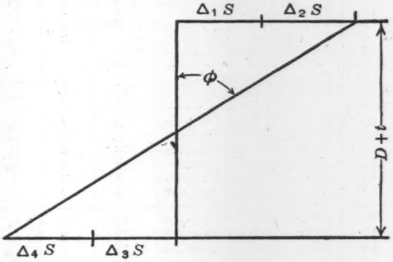

FIG. 9.

Δ_3, the shortening in the bottom connection due to $S = 1$; and, Δ_4, the shortening due to compression when $S = 1$.

For a case as shown in Fig. 7(*b*):

$$\Delta_1 = \frac{1}{3\ E\ I}\left[X^3 + (A - X)^3 + (A - X)^2\ B\ \tfrac{3}{4}\right] \ldots\ldots\ldots (12)$$

and,

$$\Delta_2 = \frac{l}{E\ F'} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

in which, l is the effective length of connection, and F', the total area of web for sheared I-beams or horizontal leg for angles. Δ_3 = shortening in the bottom connection due to bending from $S = 1$. In most cases this value is zero, as the connection butts up against the column or adjacent connection. Δ_4 = shortening due to compression from $S = 1$. For most cases $\Delta_4 = \Delta_2$.

For a total moment, M, at the joint, ϕ is the angle of rotation due to deformation (see Fig. 9), and can be expressed: $\phi = k\ M$, or,

$$k = \frac{\phi}{M} = \frac{\Sigma\ \Delta\ S}{(D + t)\ Y\ S} = \frac{\Sigma\ \Delta}{(D + t)\ Y} \ldots\ldots\ldots\ldots\ldots (14)$$

Table 3 gives values of Δ_1 and Δ_2, when S equals unity, for typical commercial connections. This table also gives the total pull, S, which stresses rivets up to 75% of the initial tension value, and the corresponding stress on flange and web. In Column (1), the various types correspond with those shown in Fig. 10.

FIG. 10.

JOINTS

Gravity Loads Only.—For joint equilibrium the following rotations must balance:

(*a*) The rotation due to a gravity load on a freely supported span is,

$$\phi_{GA} = \frac{W L^3}{24 E I} \qquad \text{.........................(15)}$$

(*b*) The rotation due to negative moments induced by gravity loads is,

$$\phi_{MA} = \frac{L}{E I}\left[\frac{M_{GA}}{3} + \frac{M_{GB}}{6}\right] \qquad \text{..................(16)}$$

and, for a typical symmetrical case, in which, $M_{GA} = M_{GB} = M_G$,

$$\phi_{MA} = \frac{L}{2 E I} M_G \qquad \text{.........................(17)}$$

(*c*) The rotation due to the connection is, $\phi_k = k\, M_{GA}$; thus,

$$\frac{W L^3}{24 E I} = \frac{L}{2 E I} M_G + k\, M_G$$

and,

$$M_G = \frac{1}{L + 2 E I k} \times \frac{W L^3}{12} \qquad \text{..................(18)}$$

Wind Forces Only.—For wind forces, as shown in Fig. 11(*b*), and for the corresponding moments, M_{HA} and M_{HB}, the column rotation can be expressed:

$$\phi'_{HA} = \frac{L}{6\,E\,I}\,(2\,M_{HA} + M_{HB}) \quad \ldots\ldots\ldots\ldots\ldots\ldots (19)$$

from beam deformation, and,

$$\phi''_{HA} = k\,M_{HA} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (20)$$

FIG. 11.

from the "give" in the connection (see Equation (14)). If $M_{HB} = -M_{HA}$, the total rotation due to wind is,

$$\phi_{HA} = M_{HA}\left(\frac{L}{6\,E\,I} + k\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (21)$$

Equation (21) expresses the rotation of the joint due to the wind forces, including the effect of the "give" in the connection. This rotation, it should be noted, also expresses the unit horizontal deflection, as the influence from the gravity loads is small and can be neglected, so that the horizontal deflection from one story to the next can be assumed equal to:

$$q = \phi_{HA}\, h + \left\{ \frac{H\, h^3}{12\, E\, I_c} \right\} \quad \text{.....................(22)}$$

in which, h is the story height; H, the wind force (Fig 11(b)); and I_c, the moment of inertia of the column.

Combined Effect of Wind and Gravity Loads.—Where connections are of such proportions that the elastic limit is not reached, the moments from gravity and wind must be combined, so that the total rotation is expressed by:

$$\phi_A = \frac{W\, L^3}{24\, E\, I} - \left[\frac{L}{3\, E\, I} + k \right] \left[M_{GA} + M_{HA} \right] - \frac{L}{6\, E\, I} \left[M_{GB} - M_{HB} \right] . \text{(23)}$$

Example 3.—In many practical cases it will be found that the elastic limit of the connection is reached before the maximum intensity of the moment. This is due to the prevalent practice of neglecting the gravity loads. That this is erroneous (for stages within the elastic limit) can best be illustrated with an example. Assume a beam (Fig. 11 (e)), in which, $\frac{W L^2}{8} = 900\,000$ in-lb.; $M_{GA} = M_{GB} = M_{HA} = - M_{HB} = 585\,000$ in-lb.; the length of span $= 20$ ft.; the depth of beam $= 12$ in.; $I = 200$; and $\Delta_1 + \Delta_2 + \Delta_3 + \Delta_4 = \frac{2}{E}$

The total work done in deforming all fibers, is, for beams:

$$W_1 = \tfrac{1}{2} \sum \frac{M^2\, \Delta_x}{E\, I} \quad \text{.....................(24)}$$

and for connection,

$$W_2 = \tfrac{1}{2} \left(\sum \Delta \right) \frac{M^2}{Y^2} \quad \text{...................(25)}$$

This gives a total of 3 830 in-lb. for a condition equivalent to the moment curve, $G + H$, and 10 940 in-lb. for the moment curve, H, or nearly three times as much work. Therefore, from the theory of least work, the curve, $G + H$ (combined gravity and wind), is the only true moment curve.

Since the floor acts as a monolithic mass, the side movement (deflection) as expressed by Equation (22), must be the same for all joints. A weaker joint is relieved by the stronger, to some extent compensating for any misjudgment by the designer.

RELATIVE BEHAVIOR WHEN CONNECTION IS STRESSED TO THE ELASTIC LIMIT

The connection may reach the elastic limit in one of the following ways:

(A) The web of the sheared I-beam, or the horizontal leg of the angle, reaches the elastic limit from tension.
(B) The flange of the sheared I-beam, or the vertical leg of the angle, reaches the elastic limit from bending.
(C) The rivet stress reaches the elastic limit.

If it is not possible to design the connection within the elastic limit, the writer believes that care should be taken at least to protect the rivets from being overstressed.

A study of the relative stresses as shown Table 3 will help to balance the design. For example, for flange-angle connection, the rivets are relatively stronger than the vertical leg up to and including angles, $\frac{5}{8}$ in. thick, for $\frac{3}{4}$-in. rivets, and angles, $\frac{3}{4}$ in. thick, for $\frac{7}{8}$-in. rivets. Many of the sheared I-beam connections as used to-day would reach the elastic limit on the rivets long before the flange and web stresses are nearly that high.

Bending Moment Effects

Consider for a moment gravity loads alone. Comparing the bending moment as computed from Equation (18), with the rigid frame (in which, $k = 0$), it will be found that the connection does not lower, to any great extent, the value of the negative moment. The effect of an angle connection may be as great as 10% reduction, while the effect of the sheared I-beam is nearer 4 per cent. Therefore, the moments as obtained from monolithic frame action are from 4 to 10%, and even more, on the safe side.

Designers should not neglect checking the connection for gravity loads only. Especially for the upper stories, under relatively smaller wind forces, the negative moments induced from gravity loads will predominate. These gravity negative moments are serious because they exist on both sides of the joint (Fig. 11(*f*)), with approximately the same intensity, and there is no balancing effect from the weaker to the stronger connection; while in a wind moment, if the elastic limit is reached on one side of the column, the bottom connection on the opposite side of the same column (Fig. 11(*g*)), will immediately take its capacity of the remainder.

Fig. 11(*d*) illustrates the case in which the gravity loads do not carry the stresses to the elastic limit. Not all the wind moment, M_{HA}, but a part of it, can be added before the limit is reached. A redistribution takes place whereby the remainder of the wind moment is taken by the connection on the opposite side of the column. (The wall column is an exception. In this case the monolithic floor will re-adjust the stresses, transferring them to the interior joints.)

If the wind moments are greater than the gravity moments, the main objection to the common method of using wind moments only in designing the connection, is that the elastic limit is likely to be reached on some part of the connection and harmful effects may arise, particularly the danger of loose rivets under repeated stress.

Summary and Conclusions

Formulas have been developed for the determination of tension in rivets, effective lever arm of connection, rotation of joint, joint equilibrium, horizontal deflection (sway), etc., for the commonly used connections, such as flange angles, sheared channels, and sheared I-beams. The insecurity in the present method of rivet design has been illustrated, showing particularly how a stress of 18 000 lb. per sq. in. on the rivet as used by many designers, may develop stresses actually twice that amount.

The importance of analyzing the relative strength of the various parts of the connection has been stressed, and a warning against making the rivets the weakest link has been given. Finally, the designer has been cautioned against neglecting gravity loads, particularly under the condition when the wind forces are comparatively small.

Discrepancies between current practice and rational analysis emphasize the need for further experimentations along these lines.

With the introduction of lighter forms of construction, making buildings more vulnerable to wind, the influence of riveted connections on the life of structures becomes increasingly important, and should be reflected in better balanced details.

APPENDIX I

NOTATION

In the paper, the following notation is adopted:

a = gauge distance.
b = length of a structural element in a connection.
d = diameter of rivet before driving.
e = eccentricity of a load acting on a rivet.
f = unit stress; f_s, due to bending; f_F, stress in the flange, or in the vertical leg of an angle; and f_w, tension stress in the web, or in the horizontal leg of an angle; f_r, stress in rivet.
g = rivet grip.
h = story height.
k = a coefficient in Equation (14) $= \frac{\phi}{M}$.
l = effective length of a connection.
m = thickness of a flange at the face of the web.
q = horizontal deflection.
t = average thickness of a flange between the center of a rivet and the face of the web.
u = thickness of the flange at the center line of the rivet.
w = work (w_1) in beams, or (w_2) in connections.
z = a polar ordinate (see Fig. 2).
A = distance from face of web to center line of rivet.
B = rivet distance.
C = distance from center line of rivet to effective bearing edge of flange.
D = depth of beam.
E = modulus of elasticity.
F = area of a rivet; F' = total area of web for sheared I-beams, or horizontal leg for angles.
H = a wind force.
I = moment of inertia; I_F = average for the flange; I_W = average for the web; and I_C = average for the column.
L = span length.

M = bending moment. (A subscript, c, denotes moment in the corner of an angle; Subscripts g and h denote moments due to gravity and wind loads, respectively; and Subscripts A and B denote moments at the ends, A and B, respectively, of a beam.)

R = a tensile force on a rivet. (A subscript, i, denotes initial force.)

S = an eccentric force opposing R.

W = total weight per foot.

X = distance from the point of contraflexure to the center line of rivet.

Y = a moment arm.

δ = the elongation of a rivet; δ_S, due to the force, S; and δ_R, due to the force, R.

Δ = total elongation, or shortening of a member. Numerical subscripts denote cause of elongation, as follows: (1) Bending in the top connection due to $S = 1$; (2) tension in the top connection due to $S = 1$; (3) bending under $S = 1$, causing shortening in bottom connection; and (4) compression under $S = 1$, causing shortening.

ϕ = rotation of the end of a beam due to the deformation of the section, ϕ_k, due to the connection; and ϕ_M, due to bending moments induced by gravity loads. The significance of the subscripts, G, H, A, and B, is as defined under M.

DISCUSSION

David Cushman Coyle,[5] **M. Am. Soc. C. E. (by letter).**—The author is quite correct in stating that it is sometimes unsafe to disregard the dead load negative moments which are to be added to the wind moments usually figured on the beam connection. His analysis in detail is, however, open to some qualification.

Consider the connection shown in Fig. 3 (*a*), regarding the possibility of loosening the rivets. Assume two ¾-in. rivets for which A equals 1.6 in., t is 1.4 in., and $C = 1\frac{1}{2}$ in. Let the total pull equal the yield-point strength of the two rivets, 38 320 lb. Then, by Equation (2*a*):

$$2R = 38\,320 \times \frac{(0.67 + 1)}{1} = 64\,000$$

As this stress is far above the yield point, the rivets will yield until they are as in Fig. 3 (*b*), when the rivet stress will have become $2R = 2S = 38\,320$ lb. Let $b = 3$ in. so that the flange is just strong enough to hold this load at its own yield point. Then, at the rivet, C being $1\frac{1}{2}$ in.:

$$\frac{dy}{dx} = -\frac{W\,(A - 0.2)^2}{2IE} = -\frac{19\,160 \times 1.4^2}{60\,000\,000 \times 0.69} = 0.00091 \times 1.5 \text{ in.} = 0.0014 \text{ in.}$$

that is, at the point when R becomes equal to S the total elongation of the rivet is 0.0014 in. Meanwhile, from Equation (4), if $g = 2$ in.:

$$\Delta_R = \frac{(19\,160 - 13\,410) \times 2 \text{ in.}}{30\,000\,000 \times 0.518} = 0.00075 \text{ in.}$$

which is the elastic stretch.

On removal of the load, the rivet contracts 0.0014 in., reducing the tension in the rivet; thus:

$$\frac{-0.0014 \times 30\,000\,000 \times 0.518}{2} = -10\,800 \text{ lb.}$$

After this experience the rivet has a permanent or "initial" stress of about $19\,160 - 10\,800 = 8\,360$ lb., instead of the original 13 410 lb. If the flange is less stiff it is obvious that it will not allow $2S$ to reach 38 320 lb., so the total elongation of the rivet will be slightly less in order to bring it down to its yield point, and its final permanent stress slightly more.

If the flange is stiffer, $\frac{dy}{dx}$ will be less, and, again, the final permanent stress will be more. It seems, therefore, that there is no way to reduce the permanent stress to zero, and loosen the rivet, without carrying the total pull beyond the yield point of the rivets. For this reason it would seem that the factor of safety against loosening the rivets is the ratio of the yield strength of the rivets to the actual pull on the connection.

---

[5] Cons. Engr., New York, N. Y.

Another point has to do with Table 3. Consider, for instance, a 15-in., 50-lb. channel, with a 24.2-kip pull (see Fig. 12). Assuming the dimensions shown, the uplift on the first two rivets in the channel web is more than $\frac{24.2 \times 2}{1.7} = 29.5$ kips. The bending in the web of the channel is about 29.5×1.2 in. $= 35.5$ in-kips. With a section modulus of $\frac{12}{6} \times 0.716^2 = 1.02$, the bending stress is 35 kips; also, the direct stress is 2.8 kips per sq. in., making a total tension in the upper surface of the web of about 37.8 kips per sq. in., which is high.

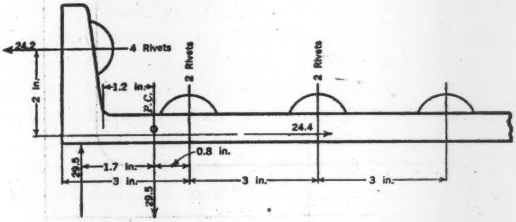

FIG. 12.

These rough figures indicate that 4-rivet angle or channel connections are likely to have such high stresses in tension in the first pair of rivets and in the horizontal leg that they have little theoretical safety factor. Their greatest use is on jobs which, on account of the shape of the building and the number of walls and partitions, need no wind-bracing, except to comply with legal requirements.

Beam stub connections, therefore, would seem to be stronger, and angle connections weaker, than is claimed by the author. This fact does not in any way detract from his main point, the comparative lack of stiffness in top-and-bottom connections, and the immense superiority of the knee-brace.

WILLIAM R. OSGOOD,[6] ASSOC. M. AM. SOC. C. E. (by letter).—The author points out a sore spot in structural practice, which well deserves the attention he gives it. The fact that premature failures of many connections of the kind he discusses do not occur, may be attributed to the "cleverness of the material"[7] in adjusting itself to conditions which overstress it. The reserve of strength in such connections is necessarily very small.

It is interesting to apply Mr. Berg's method of analysis to the tests made by Professor C. R. Young, at Toronto, Ont., Canada, in 1927.[8] After the initial tension in the rivet has been exceeded, the force, $R - S$, begins to move outward; and at failure, if the material is stiff enough, this force will have moved close to the outer edge of the connection, as shown in Fig. 13. Professor Young's test angles were free to move sidewise without any restraint on the outstanding leg, so that the values of e and X do correspond. From Fig. 13:

[8] "Tensile Working Stress for Rivets," by C. R. Young, Address before the Fifth Annual Convention, Am. Inst. of Steel Construction, Inc., Pinehurst, N. C., October, 1927; also, *Engineering and Contracting*, December, 1927.

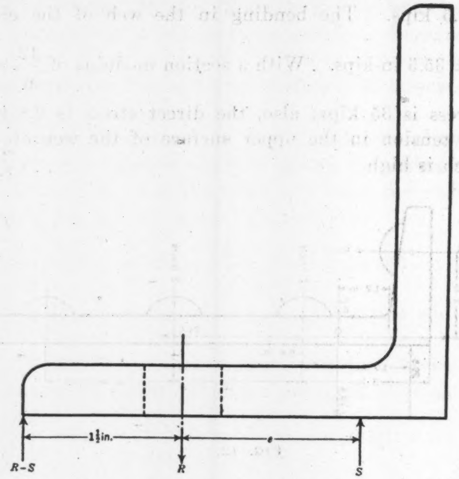

FIG. 13.

$$S = \frac{1.5\,R}{e + 1.5} \quad \text{..........................} (26)$$

and if this equation is used to compute the strengths of the rivets in Professor Young's tests, the results in Table 4 are obtained, with a factor of safety of four. The agreement between the computed values and the test values is better than that obtained by either Professor Young's formula or the formula proposed by the writer.[9]

O. G. JULIAN,[10] M. AM. SOC. C. E. (by letter).—This paper is an able presentation of a much neglected subject. It is believed that too often the stresses resulting from eccentricity of connections are given insufficient attention and that at times the rigidity of joints is neglected altogether.

It is clear without mathematical analysis that if all the joints of a rigid frame rotate through equal and reasonably small angles no error in the computed moments is introduced thereby. However, if the relative rotation of the joints is other than unity, errors of considerable magnitude in the computed moments may be introduced, because the less rigid connections and portions of the main members that intersect at a joint are relieved of, and transfer moments to, the more rigid portions of the frame. Tests by Professors W. M. Wilson and H. F. Moore[11] indicate that the relative rotation of well-designed rigid joints equipped with brackets, may introduce errors of about 8% in moments computed on the basis that the connections prevent, entirely, the relative rotation of the main members intersecting at a joint. Furthermore, the relative rotation of joints built without special consideration as to absolute rigidity may cause large errors in the computed moments. Due to deformation of the connections, the total deflection of a rigid frame equipped with well-designed and bracketed joints may be increased by as much as 20%, while the total deflection of frames equipped with strong but comparatively less rigid joints may be more than doubled. It is apparent that, in the design of rigid frames, the absolute and relative rigidity of the connections should be given careful consideration, as well as the stresses.

The author introduces the important but controversial question of the use of rivets in tension. Many specifications do not mention tension rivets, while some others state that rivets shall not be subjected to applied tensile stress. It appears to the writer that the latter provision places an undue restriction upon the design of structural connections. Tests made at the University of Toronto[12] and at the University of Illinois[13] indicate that tension rivets are reliable. Several recent specifications permit tensile working stress on rivets varying, with the specification, from 30 to 100% of the allowable stress in shear. Tension rivets are practically always also stressed in shear. Some authorities claim that the direct shearing and tensile stresses are independent of each other and need not be combined. Professor C. R. Young, suggests the following tentative formula for rivets in combined tension and shear:[14]

$$p_t = 21\,000 - 8\,000d - 6\,750\left(\frac{V'}{T'}\right)^2 \quad\ldots\ldots\ldots\ldots\ldots(27)$$

[14] *Bulletin No. 8*, Section No. 16, Univ. of Toronto, Formula 6, p. 418.

in which, p_t is the permissible tensile stress on rivets, in pounds per square inch of rivet before driving; T', the total tension on the rivet due to all causes; V', the total shear on the rivet due to all causes; and, d, the diameter of the rivet, in inches, before driving.

Equation (27) is based on a factor of safety of 4 with respect to the ultimate strength, and was devised to take account of variations in the ratio of V' to T' from zero to 0.85, the latter being the highest value covered by the tests.

The tensile stress in a rivet must of necessity be at least equal to the initial stress due to driving and cooling. It has been claimed by some that the applied tension is additive to this initial tension. However, both theoretical considerations and tests show that if fillers are not used between the active parts, this view is fallacious,[15] and that the initial tension is not increased by an applied tension of lesser magnitude. If fillers are used between the active members, an applied load, P, which is less than the initial tension, increases the total tensile stress to,

$$\frac{R}{A_R} = \frac{R_t}{A_R} + \frac{P}{A_R + A_p} \text{ .... } (28)$$

in which, A_R is the area of the rivet; and, A_p, the effective area of the plate compressed by the rivet in question.[16]

It is believed that in most cases, $A_R + A_p$ may be taken as equal to the area of the plate (normal to the axis of the rivets) between adjacent rivets or, in the case of isolated rivets, as at least 9 sq. in. Then, for a ⅞-in. rivet, with $\frac{R_t}{A_R} = 26\,000$ lb. per sq. in., and an applied load, P, of 15 600 lb. (26 000 lb. per sq. in.): $\frac{R}{A_R} - \frac{R_t}{A_R} = \frac{15\,600}{9} = 1\,730$ lb. per sq. in.; that is, an applied load equal to the initial tensile force on the rivet in this case increases the tensile stress only 6.7 per cent.

It has been shown[17] that the limiting (elastic limit or yield point) stress of members subjected to direct shear (by applying torsion) is approximately 60% of the limiting stress in tension or compression. Furthermore, it has been shown that the limiting stress produced by simultaneously applying tension and shear at right angles to each other, may be determined according to the maximum strain theory up to the point where the limiting stress according to the maximum shear theory[18] (with the limiting stress in shear taken as 60% of that in tension), is reached. Beyond that point the maximum shear theory applies. The limiting stresses according to these two theories are represented graphically by Curves (1) and (2) of Fig. 14. The equations of the curves in this diagram are, as follows:

$$f_v = 61.2\left[1 - \left(\frac{f_t}{100}\right)^2\right]^{\frac{1}{2}} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots (31)$$

Curve (4), Hancock's ellipse:

$$f_v = 60\left[1 - \left(\frac{f_t}{100}\right)^2\right]^{\frac{1}{2}} \quad\ldots\ldots\ldots\ldots\ldots\ldots (32)$$

in which, f_t is the limiting tensile stress in percentage of limiting stress in direct tension; and f_v is the limiting shear stress, in percentage of limiting stress in direct tension.

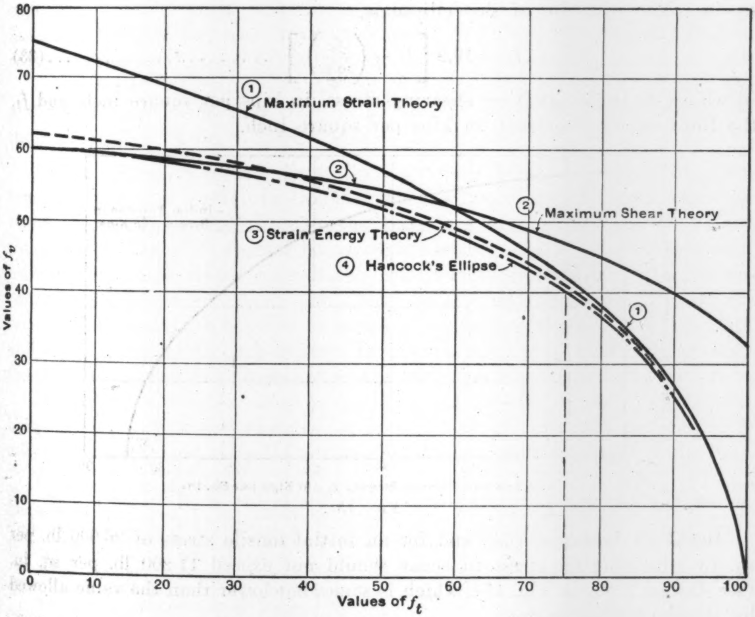

FIG. 14.

Curve (2) has been drawn with the limiting stress for direct shear taken as 60% of the limiting stress for direct tension. Curve (3) indicates the limiting stress computed according to the strain energy theory.[19] In determining Curves (1) and (3), Poisson's ratio has been taken as one-third. The writer believes that, for practical purposes, Curves (1), (2), and (3), of Fig. 14 may be replaced by Hancock's ellipse[20] which is shown by Curve (4). The application of this curve may be illustrated by the following example: If a member is stressed to 75% of the limiting stress in direct tension, an additional shearing stress, amounting to 40% of the limiting value in direct tension, will result in the total limiting stress being reached. (See dashed lines on Fig. 14.)

It is evident that all properly driven rivets are subject to initial tension. The magnitude of this tension for hot-driven rivets has been found to be at least 70% of the yield point strength of the rod from which the rivets are manufactured[18] (average, 37 184 lb. per sq. in.); that is, the initial tension is at least 26 000 lb. per sq. in. From the foregoing considerations, it would appear that the working stress in shear should be limited to such a value as to insure that the elastic limit in combined tension and shear is not exceeded. Fig. 15 is based on Hancock's ellipse and is drawn for a limiting tensile stress of 32 kips per sq. in. (which is assumed to be the elastic limit), and a limiting shearing stress of 60% of this value; that is, 19.2 kips per sq. in. The equation of this ellipse is,

$$f_v = 19.2 \left[1 - \left(\frac{f_t}{32}\right)^2\right]^{\frac{1}{2}} \dots\dots\dots\dots\dots\dots (33)$$

in which, f_v is the limiting shearing stress, in kips per square inch, and f_t, the limiting tensile stress, in kips per square inch.

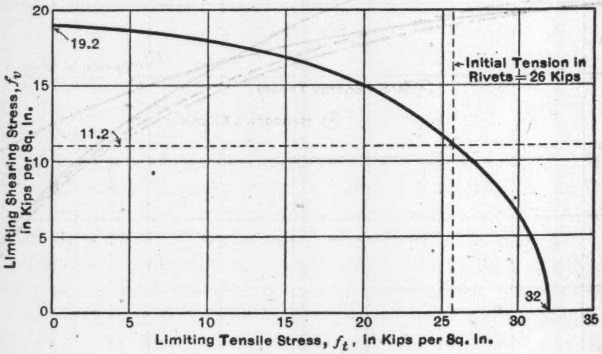

FIG. 15.

Based on Equation (33) and for an initial tensile stress of 26 000 lb. per sq. in., the working stress in shear should not exceed 11 200 lb. per sq. in. (see dashed lines on Fig. 15), which is somewhat lower than the value allowed by standard specifications.

[20] "Results of Tests of Materials Subjected to Combined Stress," by E. L. Hancock, *Proceedings*, Am. Soc. for Testing Materials, 1908, p. 373 *et seq.*; also, "The Strength and Stiffness of Steel under Biaxial Loading," by Albert J. Becker, *Bulletin No. 85*, Eng. Experiment Station, Univ. of Illinois.

Regarding the connection shown by Fig. 2 it is evident that the rivets above the neutral axis of the connection between the hitch angles and the column are in tension as well as in shear. However, it is not clear that this neutral axis coincides with that of the girder itself. Four texts[21] consulted by the writer on this point give three materially different answers. It would appear that this question is not as simple as it is usually represented, the location of this neutral axis and, hence, the tensile stress in the rivets, being dependent upon the rigidity of the bearing surfaces, the initial tension in the rivets, and the axial load on the girder.

The author mentions the "prevalent practice of neglecting the gravity loads." It is difficult to understand how such a practice can be defended or how it became prevalent. Standard textbooks[22] give methods of determining the moments resulting from gravity as well as from wind loads, and the corner moments resulting from gravity and wind loads can be determined by means of the Cross method of distributing fixed-end moments.[23] It appears obvious that frames should be proportioned so that when the structure is subjected to the most unfavorable reasonable combination of dead, live, and wind loads, no part, including details and rivets, will be stressed beyond the endurance limit for the range of stress to which the part is subjected. The endurance limit for 0.2% carbon steel subjected to complete reversal of stress has been shown to be about 25 000 lb. per sq. in.[24] Dr. Timoshenko gives a corresponding limit of 27 000 lb. per sq. in. for mild steel.[25]

A number of interesting and useful formulas have been presented by the author. It is believed that their value would be considerably enhanced by the amplification of their derivations.

Harold S. Richmond,[26] Esq. (by letter).—Much of value has been brought out by the author in emphasizing the important problems involving rivets in tension acting through the thin legs of lug-angles. The point illustrated in Fig. 4(*b*) cannot be over-emphasized, that is, in a tension connection only those rivets immediately adjacent to the pulling stem of the connecting lug are effective. In a case sometimes encountered, two such lugs or diaphragms are opposed to each other on opposite sides of a web-plate and at right angles to each other. In such a case, it is obvious that only those rivets nearest the intersection are effective in tension.

In dealing with this class of problem the writer makes a distinction between static loads and variable or reversible loads and also between self-relieving stresses and those of a definite nature. For example, if the connection illustrated in Fig. 2 is considered to be merely a shear connection and not of use as a bracing connection, then thin lug-angles will make those stresses resulting from static loads self-relieving, but the stresses resulting from variable or reversible loads will result in fatigue unless held within the elastic range. Mr. Berg's comment that "the computed stresses in the angles are high, but harmless," therefore, will be taken as safe counsel only to the extent that the detail is subject to deflection from static loads. The danger in this case is that the design when put into use seems to be a successful one; yet the structure cannot be considered permanent unless all variable stresses lie within the elastic range. The writer sometimes satisfies his conscience by considering that the variable-load stresses are self-relieving to the extent of ranging themselves between a positive and a negative stress of equal magnitude after self-adjustment, rather than between zero and a higher stress, but always of the same sign.

[26] With Gibbs & Hill, Cons. Engrs., New York, N. Y.

In a case encountered by the writer, of a girder connection in a railroad viaduct, similar to that shown in Fig. 2, the lug-angle was split at the root, due presumably to fatigue. Whether or not the structure was built of wrought iron or steel, the criticism will apply with sufficient force, and designs of this kind will call for extremely careful calculation should wrought iron ever come back into vogue as a structural material.

While it is important to calculate and limit the tension in the rivets, it is at least equally important to limit the bending stresses in the legs of the connection lugs in the case of variable stresses. If the author's calculations are used, the tension in the rivet will range between the initial stress and the yield point—a range of only 11 100 lb. per sq. in.—and this only, needs to be considered in relation to fatigue effects, whereas, the variable bending stresses in the lugs will usually run much higher. There is, of course, a bending stress in the rivet due to the "ripping" effect of the lug. The theory would be difficult to develop and designers might possibly assume that this bending stress is partly self-relieving.

In brief: Connection lugs of thin material are indicated for constant loads, while thick material with the design carefully analyzed to keep stresses within the elastic range is indicated for variable loads. There would be danger of overstressing the rivets in the case of high moments due to constant loads and danger of fatiguing connection lugs in the case of variable loads.

Robins Fleming,[27] Esq. (by letter).—By his painstaking paper Mr. Berg has again brought to the attention of structural engineers the importance of the proper design of wind-bracing connections. In addition to Mr. Berg's paper three others lie before the writer, namely: "Design of Wind Bracing," by Edward Smulski;[28] "Connection Angles Subjected to Bending," by Norman B. Green;[29] and "Details for Wind Connections in Tier Buildings," by Walter H. Weiskopf,[30] Assoc. M. Am. Soc. C. E.

[27] With The Am. Bridge Co., New York, N. Y.

[28] *Journal*, Boston Soc. of Civ. Engrs., Vol. XVII, p. 491, November, 1930.

[29] *Western Construction News*, Vol. 5, p. 137, March 10, 1930.

[30] *Engineering News-Record*, Vol. 99, p. 396, September 8, 1927.

The opinions of these writers and those of other engineers show at times a variation of 100% in the strength of connections. In actual practice the variation is even greater. It would thus seem that tests are necessary before definite and convincing conclusions can be reached. In fact, the theories put forth from any set of assumptions should be substantiated by a series of full-sized tests covering a wide range of connections as well as a number of connections of the same type.

Mr. Berg states,

> "The insecurity in the present method of rivet design has been illustrated, showing particularly how a stress of 18 000 lb. per sq. in. on the rivet as used by many designers, may develop stresses actually twice that amount."

Others will doubtless examine, critically, the reasoning that leads to such a sweeping claim. The writer will call attention to a few points.

Mr. Berg locates the point of contraflexure by the theory of flexure. In his analysis of the flange of a 24-in. 120-lb. beam, he assumes a span of 2½ in. and an average depth of about 1¼ in. The theory of flexure is scarcely applicable to a beam of these proportions. Moreover, the deformation from shear would be nearly as large as that from flexure.[31]

Mr. Berg refers to a paper by Professor Young and states, "* * * it becomes important to use the right judgment relative to the eccentricity, e (Fig. 4(*a*))." In the paper to which reference is made[32] Professor Young states,

> "In the eccentric loading tests, the rivet connecting the cross-piece to the longitudinal member was tested by applying the load to the cross-piece at a distance of 1⅛ and 2¼ in. from the gage line of the angles by means of knife-edges attached to the ends of the inverted U-shaped casting."

This clearly defines e as the distance from the center of the rivet to the knife-edge or point of contraflexure, which is the same as that defined by Mr. Berg. The author, however, takes e as $\frac{X}{0.65}$, which is too large. This changes the results of his Table 2.

Sometimes e is taken as $\frac{1}{2A}$, A being the distance from the face of the web to the center line of the rivet. This, however, assumes that the vertical leg is fixed at the root. With thin flange angles or channels there is a tendency to bend about the rivets in the horizontal leg.

The question of rotation from deformation of connections should be determined from tests. The structural engineer is not often concerned about "Behavior Beyond the Elastic Limit." His efforts are directed to keeping stresses within the elastic limit. Nevertheless, it is well the subject should be understood. Mr. Berg has written an able paper but experimental data are needed to confirm his results. In conclusion, a valued correspondent will be quoted. He writes:

[32] "Tensile Working Stresses for Rivets Investigated," by C. R. Young, M. Am. Soc. C. E., *Engineering News-Record,* Vol. 100, p. 128, February 2, 1928.

> "The only wind detail that has been used up to date that is susceptible of an exact mathematical analysis is the detail where there was a common inserted web plate between the column and the wind girder. This detail has not been used for a long time it having for commercial reasons passed out of the picture."

L. E. Grinter,[33] Assoc. M. Am. Soc. C. E. (by letter).—This paper opens for discussion an important division of the general field of structural design. Its publication is timely in that there seems to be an unusually wide interest in the subject of wind-bracing at the moment. The extension of the tall building frame to the 1 000-ft. tower naturally has led engineers to conclude that a review of standard methods of design is desirable.

Mr. Berg undoubtedly has many followers in his belief that the simple approximate methods that have characterized such design, need to be replaced by more exact processes. The writer accepts this viewpoint wherever he is convinced that the resulting complication with its attendant possibility of error can be justified by greater reliability in the finished structure. Unless such increased reliability can be demonstrated beyond reasonable doubt, there is always an important advantage in reducing analysis and design to the simplest possible processes.

The mere fact that hundreds of buildings have survived heavy wind storms, many of hurricane intensity, is a reasonable indication that wind-bracing as evolved in the past cannot be radically wrong, although such observations do not preclude improvement in the future. Where (as Mr. Berg shows) an application of the theory of elasticity indicates stresses twice as great as those calculated by the designer, one may well investigate either the assumptions upon which the analysis is based, or the hypothesis of elasticity.

The author discusses the action of tension rivets through the flange of an I-beam stub connection, and by use of certain assumptions, shows that the tension stress in a rivet may be nearly twice the stress found by dividing the total pull by the number of rivets. His major premise is that the flanges are held flat against the face of the column by the initial tension in the rivets, as shown in Fig. 16(*a*). However, it is important to realize that when stressed above their initial tension the rivets will elongate, and the deflected shape of the connection may approximate the condition shown in Fig. 16(*b*) even before any permanent elongation occurs in the rivets. Certainly, only small permanent distortions of the rivets are necessary to permit the action shown in Fig. 16(*b*) and to change the stress per rivet to the total load divided by the number of rivets.

The question then arises as to whether a situation such as this does not justify the neglect in design of the relatively high rivet stresses which Mr. Berg shows may exist at lower loads. The writer would make an important distinction between this case and another which is also discussed in the paper; that is, the case of two lines of tension rivets through one leg of an angle. In the latter case, one line of rivets must be stressed far past the yield point in order to stress the second line appreciably, and it seems impossible to justify the neglect of this fact.

---

[33] Prof. of Structural Eng., Agrl. and Mech. Coll. of Texas, College Station, Tex.

The author's discussion of the stresses that exist in the rivets of wind-bracing angles is of particular interest. As in the case of the stub I-beam, there is a possible reduction in the tension which he would calculate in the rivets, from the effect of elongation of the rivets after the initial tension has been exceeded (see Fig. 17). When considered from this viewpoint, the advantage of using thick angles (to reduce stress and deflection) becomes apparent. Again, there is a clear argument to support the contention that such high rivet stresses at low loads are of less importance than their values may indicate, since an increase in the load does not increase the stresses in direct proportion.

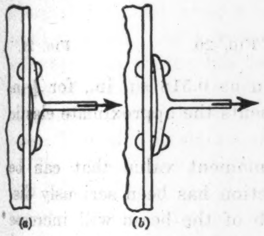

FIG. 16.

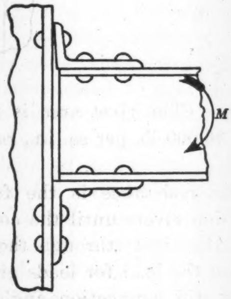

FIG. 17.

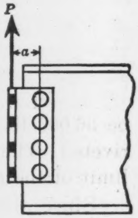

FIG. 18.

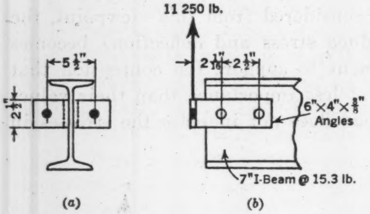
Mr. Berg discusses standard end connections for beams, and mentions an objection to the use of heavy connection angles, namely, that their stiffness may be sufficient to overstress the tension rivets. His point is well taken, but the discussion is not complete until one has investigated the actual stresses in the rivets through the web of the beam. Standard handbooks give the value of this connection as the direct shear or bearing value of the rivets through the web of the beam. Actually, there is a bending moment to be resisted, and, if the angles can be made sufficiently flexible to reduce the stress in the tension rivets to a low value, the bending moment is approximately equal to the load, *P*, times the lever arm, *a*, as shown in Fig. 18. On the other hand, one then finds that the stresses in the rivets through the web of the beam are increased greatly by the moment of the eccentric force.

As an example, consider the simple end connection shown in Fig. 19. The value of the connection is 11 250 lb., which is the resistance of the rivets in bearing on the web.[34] Considering the moment of the eccentric force, one finds that the maximum stress per rivet is increased from 5 625 lb. to approximately 20 500 lb. Since the working stress in the rivet is only 5 625 lb., the connection is seriously overstressed. Clearly, the tension resistance of the rivets through the outstanding legs of the angles is required to produce a resisting moment that will oppose the moment of the eccentric force. If the effective lever arm for this tension is taken as one-half the length of the angle less $\frac{1}{4}$ in., or 1.0 in., the rivet stress to produce a resisting moment equal to the moment of 37 300 in-lb. produced by the eccentric force, would be 36 000 lb. per sq. in. (The rivet area is taken as 0.518 sq. in., for $\frac{3}{4}$-in. rivets.) The stress of 36 000 lb. per sq. in., represents the approximate elastic limit of the rivet.

---

[34] Handbook of Steel Construction, Am. Inst. of Steel Construction, First Edition (1932), p. 277.



(a) (b)

FIG. 19.

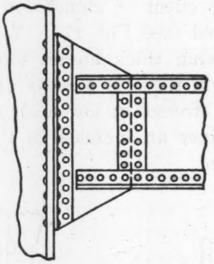


FIG. 20.

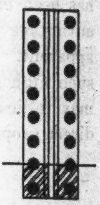

FIG. 21.

Since the foregoing resistance is the full moment value that can be obtained from the tension rivets until the connection has been seriously distorted, the stresses in the rivets through the web of the beam will increase much more rapidly than the load for loads greater than those used in design. The use of reasonably stiff connection angles to insure moment resistance, therefore, seems necessary, even if their effect may be to stress the tension rivets highly. To obtain a thickness of angle that would produce a nicety of balance so that the two groups of rivets would approach their elastic limits at the same time, would be desirable, but with standard connections one probably must depend upon some plastic deformation to accomplish essentially the same purpose.

It appears expedient to mention here a misconception that seems common in regard to the proper calculation of the tension stress produced in a line of rivets by flexure. Such rivets occur through the outstanding leg of a clip angle, such as may be used on a wind-bracing gusset (see Fig. 20). Since the stiffness of the gusset in its own plane is extremely high, it is assumed that its connection to a relatively stiff column remains essentially a plane section. The beam formula, $S = \frac{Mc}{I}$, may be used, therefore, to calculate the stresses in the tension rivets, but it is necessary first to locate the neutral axis. When the connection is unstressed by moment, there is a uniform pressure between the clip angles and the face of the column, caused by initial tension in the rivets. Ordinary negative moment in the beam will reduce the bearing pressure at the top of the connection and increase it near the bottom. Until the maximum reduction in pressure equals the initial pressure, the true neutral axis lies outside the section, but the reduction in pressure can be determined correctly by assuming a neutral axis at the mid-height of the vertical angles.

After the initial tension in the upper rivet is overcome by the applied moment, an entirely different condition prevails, and the true neutral axis gradually moves downward from the top toward the bottom of the angles. At failure, the connection undoubtedly 'rides" on the bottom of the angles, the neutral axis having reached its lowest possible position.

During the initial period when the angles are in bearing on the face of the column, the neutral axis for flexure lies at the mid-height, but since the neutral axis actually approaches the bottom of the angles at the point of failure, it seems highly conservative to compute the stress from the first position of the neutral axis. On the other hand, to assume that the neutral axis is at the lower edge of the connection angles actually assumes that failure is imminent, since the upper rivets, being placed perhaps 2 or 3 ft. above the neutral axis, would be severely distorted by even an extremely small rotation. As a reasonably conservative procedure between these two extremes, the writer has been accustomed to take the neutral axis at the center of gravity of the effective section, considering the cross-sectional area of tension rivets above, and the entire area in bearing below, the neutral axis. This area is shown cross-hatched in Fig. 21.

The author discusses the need for considering gravity forces (dead load plus live load) in the design of wind connections. He indicates, without definite recommendation, that wind-bracing connections should be designed for dead load, live load, and wind, although he states that gravity moments at the joints may be reduced as much as 10%, or even more, by elastic distortion of the connection angles. It seems desirable to reconsider the possible effects that may reduce the bending moment as caused in a wind connection by gravity loads. These may be listed as follows:

(1) Elastic distortion of the connection angles;
(2) Slip in the riveted connection;
(3) Elastic elongation of tension rivets when stressed above their initial stress; and
(4) Plastic deformation of the rivets, connection angles, end of beam, or face of column, when the stresses exceed the elastic limit.

Only the first item of this list is considered by Mr. Berg. The second item, slip in riveted connections, has been treated[35] by Professors Wilson and Moore. They have demonstrated that a wind connection of the type considered by the author may be expected to show an angle change due to slip of nearly 0.003 radian when the rivets through the beam flanges are stressed to one and one-half times their normal working stress in shear. It is of interest in a study of this effect to note that the end rotation of a simple beam uniformly loaded, where the span is ten times the depth, is approximately 0.004 radian when stressed to a normal working stress. However, a wind connection of the angle type would not be designed capable of developing the moment resistance of the beam, and, hence, the slip alone might readily be sufficient to release practically all end restraint in so far as dead load is concerned.

---

[35] *Bulletin No. 104*, Eng. Experiment Station, Univ. of Illinois.

It is to be noted that the foregoing discussion does not consider end adjustments that may occur as the connection approaches its ultimate resistance. The ultimate strength of the connection tested by Professors Wilson and Moore corresponded to a load of more than two times the load that produced a slip of 0.0028 radian, and the maximum rotation was approximately 0.015 radian.

At several places Mr. Berg mentions the fact that "marked re-adjustments" of moments may be expected to occur when stresses pass the elastic limit. Undoubtedly, re-adjustments do occur, and perhaps the usual tendency is for the re-adjustment to relieve distress in the structure by preventing rapid increase of stress at points of weakness. Nevertheless, one should not depend too seriously upon this phenomenon. Consider a panel of a building in which wind connections are identical at the two ends of the girder. If the point of contraflexure in the girder moves sufficiently toward the right to overstress the left-hand connection so that a partial failure develops, there will probably be an immediate shift of the point of contraflexure to the left-hand side of the center with a resultant over-stressing of the right-hand connection. If this damage is started by a faulty joint, the resistance will then be transferred entirely outside this panel, possibly without serious damage to the structure, but if the over-stress is general throughout several panels of the structure, failure is impending.

Mr. Berg's paper was quite properly restricted to riveted joints. On the other hand, the structural engineer now faces an entirely new problem in this field, the design of welded wind-bracing connections. A service can be performed by any one who will study the design of welded connections from the viewpoint adopted by Mr. Berg. Where welded joints are designed properly, essentially perfect continuity is obtainable, and the design of the joint for both gravity loads and wind loads becomes necessary. An analysis of welded joints by the theory of elasticity would not be open to the criticisms that have been mentioned in this discussion.

C. R. Young,[36] M. Am. Soc. C. E. (by letter).—The distinctive weaknesses of "knuckle" connections are treated in a definite and quantitative manner in this commendable paper by Mr. Berg. That knuckle connections have proved satisfactory for low buildings is probably due to the fact that the force of the wind never reaches the intensity prescribed in the specifications. If, in addition to the negative moments due to gravity loads, there were anything like the expected wind moments, a less satisfactory story of these connections would have to be told.

Recognition of the existence of high stresses in connections due to end moments is not new in structural literature. In discussing web connections of beams to girders or columns, Jacob Friedland[37] pointed out twenty years ago the existence of high tensile stresses in the rivets connecting the beam to the girder or column. For characteristic I-beams, tensile stresses in the rivets, based on the area of the rivet as driven, were found to be as high as 29 100 lb. per sq. in., and on the basis of the area of the rivet before driving, as high as 34 200 lb. per sq. in. There is no doubt that in countless cases the tension rivets, under gravity loads only, have been stressed close to the elastic limit of the material in them, and probably beyond the initial stress in the rivets.

---

[36] Prof. of Civ. Eng., Univ. of Toronto, Toronto, Ont., Canada.

[37] *Engineering News*, April 25, 1912, p. 786.

In asserting in the first paragraph that "the mass inertia creates additional resistance against gusts of wind," the author is correct if he means that an addition to mass lessens the frequency; but he is in error if he means that it lessens the deflection or amplitude of vibration that would follow the application of wind force. As has been pointed out by H. V. Spurr,[38] M. Am. Soc. C. E., and D. C. Coyle,[39] M. Am. Soc. C. E., the deflection and amplitude of vibration of a building are independent of mass. This is evident if, for simplicity, the building be considered as a simple cantilever. In the common deflection formula no quantity appears representing the mass of the structure. However, the weight of a building affects the frequency of vibration since, other things being constant, the frequency varies inversely as the square root of the mass.

There is merit in basing the allowable load on a rivet on its initial tension value. While against failure there is the entire margin between actual load and ultimate strength, the increased emphasis now being placed on rigidity makes it particularly desirable, under all circumstances, to keep below the point at which the deformation of the joint will begin to be affected by tension rivet yield. Based on work done at the University of Toronto in 1928, the writer has held that within the initial tensile value of the rivet there is no appreciable elongation.[40] He consequently concurs in the author's assumption to that effect.

The soundness of the choice of representative test values for tension rivets made by Mr. Berg from the results of Professor Wilson and Mr. Oliver may not be entirely obvious. The average ultimate strength of rivets in tension was not 54 000 lb. per sq. in., as might appear from the statement following Equations (2), but considerably greater. This value was the minimum mean observed and was for $\frac{3}{4}$-in. rivets (effective diameter, $\frac{13}{16}$ in.), driven with air-hammer at a cherry-red heat and having a grip of 5 in. For a 2-in. grip the mean was 63 900 lb. per sq. in. In low buildings, and for the upper stories of tall buildings, where the column metal is thin, the grip is likely to be nearer 2 in. than 5 in.

The yield point assumed—that is, 37 000 lb. per sq. in.—is for the material from which the rivets were made. It is not the yield point of the rivet as driven, since that quantity was not observed by Professor Wilson and Mr. Oliver, or in the University of Toronto tests.

---

[38] "Wind Bracing", pp. 114–115.

[39] *Civil Engineering*, May, 1931, p. 700.

[40] "Permissible Stresses on Rivets in Tension", by C. R. Young and W. B. Dunbar, *Bulletin* 8, Section 16, School of Eng. Research, Univ. of Toronto.

As the the initial tensile stress would probably be a smaller fraction of the yield point of the rivet as driven than it is of the bar stock, or the manufactured rivet, an assumed initial tensile stress of 70% of the yield point of the bar is fair.

The author has applied Equation (3) in a manner not intended by its proposers. In the presentation of the results upon which this formula was based,[41] it was recommended that the eccentricity, *e*, should be taken as about two-thirds the value of the gauge for the outstanding leg. This distance was supposed to give, in typical cases, the position of the point of inflection with respect to the rivet center. As far as the rivet under consideration is concerned, the application of a force parallel to the rivet at the point of inflection would produce the same result as a load applied by a knife-edge at a corresponding distance from, and parallel to, the gauge line. It was in this manner that the specimens tested in combined tension and flexure were loaded, and the formula should be used assuming that the applied force has an eccentricity equal to the distance from the rivet center to the point of inflection.

On this basis the values of f_r from Equation (3) would be as given in Table 5. Examination of this table shows that the two equations compared, give results that are very close for 1-in. rivets, and that Equation (3) gives somewhat higher values than Equation 2(*b*) for the smaller rivets.

TABLE 5.—COMPARISON OF WORKING LOADS ON RIVETS SUBJECTED TO A COMBINATION OF TENSION AND FLEXURE

Nominal size of rivet, in inches	Assumed X, in inches	Eccentricity, $e = \frac{X}{0.65}$ as used by author, in inches	Eccentricity, $e = X$, as used by writer, in inches	PERMISSIBLE TENSION PER RIVET, IN POUNDS	
				Equation 2 (*b*), gross area	Equation (3), nominal area
¾	0.75	1.15	0.75	3 840	4 520
¾	1.50	2.31	1.50	2 690	3 660
⅞	0.75	1.15	0.75	5 100	5 550
⅞	1.50	2.31	1.50	3 560	4 370
1	0.75	1.15	0.75	6 550	6 480
1	1.50	2.31	1.50	4 680	4 940

Fig. 6 is apparently based on the application of an equation similar to Equation (8), although the author does not so state. Insufficient data are given in the text to permit the checking of the curves. In order to do this it would be necessary to know the values of B and b used by the author. In establishing Equation (11) for the angular rotation imposed upon the beam by the connection, apart from the effect of tension rivet yield, the author has neglected two factors.

To make this clear, let it be assumed that for purposes of measuring rotation, or tilt, a plane is passed transversely through the beam at the outer edge of the connection and parallel to the face of the column. The movement of this plane away from the column at the tension face of the beam would be influenced (neglecting tension rivet yield) by bending in the tension connection, by elongation of the material of this connection, by shear deformation or slip of the rivets through the beam flange, and by the extension of that part of the beam between its end and the section plane. Similar influences would be operative at the compression face of the beam. The result of including the two factors not considered by Mr. Berg would be to permit a greater rotation than he calculates and a correspondingly smaller moment of restraint.

---

[41] *Bulletin No. 8*, Section 16, School of Eng. Research, Univ. of Toronto, p. 408.

Another factor not discussed in detail by the author is the effect of repeated and reversed loading. For the rivets attaching the connection to the beam flanges, for example, there would be under stress a deformation which, in part, would be non-elastic and, in part, elastic. The ratio of these will change with the repetition of stress, and what might be called a steady elastic state is not reached until several repetitions or reversals have occurred.

If one were to make a general criticism of Mr. Berg's paper, it would be on the ground that it is rather too greatly condensed. It would have made for clarity if he had indicated his processes a little more in detail. For example, in Table 1 the values of the rivets given in the last three columns are based on areas of rivets as driven and not on the nominal area. In the second paragraph under "Flange Angle Connections," it should be made clear that it is the elastic line of the deformed angle that remains vertical at the rivet, R_1 and horizontal at the rivet, R_2 and not the rivets themselves that preserve these directions.

C. H. SANDBERG,[42] ASSOC. M. AM. SOC. C. E. (by letter).—This paper brings to the attention of the Engineering Profession a greatly neglected phase of wind-bracing design in tall steel buildings. As pointed out by Mr. Berg, since connections of the type shown in Fig. 2 are designed for shear only, on the assumption that the details are so flexible that only a negligible end moment is developed, there is danger that excessive tensile stress will be developed in the rivets unless this phase is specifically investigated. The author's analysis showing the possibility of high tensile stress in this and other types of connections, therefore, is considered timely.

Since 1927 or 1928 there has been an abundance of printed matter on wind-bracing analysis, but very little has been written on the equally important subject of the moment resistance of riveted joints. The few papers that have been published on the subject have been based on assumptions unsupported by experimental data. In the writer's opinion Mr. Berg's paper is the best one that has appeared on this subject; yet his results also are based on unverified assumptions. These seem reasonable enough, but designers have no means of knowing how closely they approach actual conditions. In view of this lack of knowledge on the subject, it is surprising that this important design feature has not been studied experimentally long ago.

In 1928, Professor C. A. Hughes and the writer began a series of tests at the University of Minnesota to determine the resistance of different types of riveted joints. The types of connections selected for this investigation are typical of those commonly used in present-day construction.

---

[42] Asst. Engr., Bridge Dept., A. T. & S. F. R. R., Chicago, Ill.

The deformation of connection details is not quite as simple as indicated by the author in Figs. 3 and 7, in which they are parallel to the plane of the web of the beam only. In addition to these, there are deformations of the connection details and the column flanges due to bending in a direction normal to the web of the beam. This results in a marked difference in the distribution of stress on the rivets adjacent and remote to the web of the beam or the web of the column. This point has been considered by Sub-Committee 31, Committee on Steel, of the Structural Division, of the Society, as is evidenced by the statement, "* * * rivets in the column should be kept in single gauges near the column web."[43] If the rivets considered effective for moment are limited to gauge lines adjacent to the web of the sheared I-beam and the web of the column, the safe moment of resistance of this type is limited and is much less than has been attributed to it in many designs.

The author cautions against neglecting the combined effect of wind and gravity loads in determining the moment at the end connections, especially where the rivets are in tension. This point is well taken as there are cases, in which brackets are used for end connections, where the negative moment can be larger than $\frac{WL^2}{12}$, due to the fact that the common assumption of constant section throughout the beam does not hold. This may also be true when the spans are unequal.

Connections have been and are being designed, however, for wind moment only, and there are some justifications for this practice. Bracket connections with tension rivets are usually designed too conservatively. One of the common methods is to assume the rotation of the joint at the center of gravity of the tension rivets (rivets into column), while actually the point of rotation is considerably lower. Beams and columns encased in concrete will also add greatly to the rigidity of the connection. A large part of the wind resistance is usually designed to be taken through the spandrels and, in some cases, one or two additional lines. This arrangement makes it necessary to select the wind-resisting lines of beams for wind loads in all except the upper stories, and the actual moment due to the gravity loads in the end connections is a small part of the total. Another factor in support of ignoring the moment due to gravity load is that if a connection on one side of the column is over-stressed the connection on the other side of that column will be under-stressed, and an adjustment will take place. There will also be a distribution through the floor which will cause a stronger joint to relieve a weaker one.

It is common knowledge that since about 1927 the use of the sheared I-beam type of connection has been overdone. This is due largely to the fact that it gives minimum interference with architectural features, and also that some designers undoubtedly do not realize that the bracket connection is the next in effectiveness and economy to diagonal cross-frame bracing.

---

[43] *Proceedings*, Am. Soc. C. E., February, 1932, p. 222.

In the design of end connections there are as many ramifications as in the problem of analyzing and distributing the wind moments in the frame of the building, and this cannot be done satisfactorily or in a hurry by an inexperienced designer.

The writer wonders whether it is not being unduly conservative to base the factor of safety for tension in rivets on the initial tension rather than on the yield point. Until the yield point is reached, the deformation of the extreme tension rivets in a connection and the consequent "give" or "slip" of the joint will be so slight as to be practically negligible. Another factor that should be considered in this connection is that the measured values of initial tension are probably too high. Information now available was obtained from tests of shop-driven rivets on comparatively small specimens, on which driving and bucking conditions were ideal, and it is reasonable to expect that the average initial tension of field-driven rivets in large joints will be somewhat less.

Considerable work has been done and much progress made in determining the horizontal loads on structures and in developing rational and relatively simple methods of analysis for frames. It is hoped that further tests of riveted connections will be undertaken so that the design of joints of adequate resistance may be placed on an equally satisfactory basis.

N. A. RICHARDS,[44] M. AM. SOC. C. E. (by letter).—The action of usual types of angle, channel, and beam-section connections is treated in an interesting and stimulating manner in this paper.

Building laws and conservative practice require that beams and girders be generally proportioned on a simple span basis for dead and live loads, but it is quite obvious that, as heavy wind-bracing connections are added, the members cannot so act, and in wind analyses, they are assumed to be restrained at the ends. The added stresses resulting in the rivets and connections, due to live load and dead load action of the members, should receive more thought and attention.

One feature that might add interesting further study is the prying action resulting from the pivoting of a beam or girder near the outer edge of the supporting seat, and the corresponding lift at the heel of the upper angle as the member deflects under load.

In reviewing the paper the writer found difficulty in following some of the rather abruptly stated mathematical steps; as, for instance, under "Flange Angle Connections," referring to Fig. 5, $M_4 = \frac{1}{2} M_c$, and below Equations (5) and (6). This is probably due to the rustiness in pure mathematics and mechanics acquired in many years of general practice; but, inasmuch as many interested readers will no doubt find similar difficulty, the author would do well to explain the mathematics of the study with a little less abruptness.

The paper as a whole is a distinct contribution, and is well worth study by those engaged in the design of structures involving connections of the types considered.

---

[44] Vice-Pres., Purdy & Henderson Co., New York, N. Y.

Jacob Feld,[45] Assoc. M. Am. Soc. C. E. (by letter).—The author gives a timely warning of a frequent error. The design of wind-bracing has become involved in so much mathematical detail that engineers have lost sight of rational and logical carrying out of stress analysis. Too often, a careful analysis of stress is completed and then scrapped because clearance or head-room requirements insisted on by the architect do not allow space for the necessary details.

If the engineer insists on the required space he very often finds himself displaced by another engineer who, according to the architect, is a more efficient designer because he can design wind-bracing without using up more space than can be permitted.

As a result, and possibly also because they do not know any better, some designers believe in an extreme theory of "educated stress methods." In practice, the method consists of summating the resisting moments of all beam-to-column connections on a floor and if such sum is greater than the wind moment of that floor, calling it a sufficient design. If not, a few additional rivets put in here and there make up the necessary total. The method is really based on the principle of least work, or its special statement known as the Moseley principle of least resistance, which is that, if a series of resistances consistent with the conditions of stability can be determined, that series is sufficient to take care of all external forces, although it may not be the most efficient system that can be devised. The application to the foregoing method of wind-bracing design is in error because the major premise is forgotten; namely, that the assumed resistances must obey the conditions of the problem. One condition is that the summation of forces and moments acting on each unit member and connection must vanish.

The universal assumption that a steel beam is simply supported as far as vertical loads are concerned and that the same beam is rigidly connected as far as lateral loads are concerned, is not consistent with the truth or even with logic.

That similar assumptions are sometimes made in reinforced concrete design is true, but the results appear almost immediately. The large reserve of unused strength which exists in steel structures does not exist in reinforced concrete improperly reinforced because of the low tensile strength of plain concrete. When improper assumptions of steel distribution are made, cracks appear, and the cracks are not always caused by poor workmanship, temperature, or shrinkage during setting. Disregard of moments in columns due to unbalanced loads gives cracks in the exterior faces of exterior columns, especially in flat slab buildings; disregard of the two-way action of panels gives cracks in the slabs along girders, unless special reinforcement is provided across the top of the girders; disregard of the rigidity of connection between beams and columns when unequal spans are supported by the same columns, gives cracks in the tops of the beams when full loads occur on the longer spans; and disregard of the torsion in exterior beams always loaded on one side only gives the diagonal cracks visible in so many concrete lintels. These are only a few of the more common errors of details visible in concrete structures. In flexible steel frames similar errors are not visible; yet the effects exist, and the true factors of safety of the steel frames are much lower than is usually assumed. If the basic assumption of wind-bracing design is that connections in a steel frame are rigid, they must certainly be rigid before the wind starts to act, and the author's recommendations are timely and important.

---

[45] Cons. Engr., New York, N. Y.

DANA YOUNG,[46] JUN. AM. SOC. C. E. (by letter).—The analysis of wind-bracing connections given in this paper is important in calling attention to various factors often neglected in design. Theoretical formulas are developed, which indicate that present design practice is seriously in error. The question arises naturally as to which is more nearly correct, theory or practice. This can be settled satisfactorily only by tests. The formulas given are based on various assumptions, the effect of which, while perhaps slight, cannot be definitely determined analytically. As the author states tests are necessary to establish their accuracy.

A number of tests of tension rivets have been made. However, before fully accepting the formulas given in this paper for tension rivets, it is important to consider the assumptions upon which the analysis is based and how these compare with the test conditions.

As shown in Fig. 3, a section of the angle or sheared beam is taken through the rivet, and bending only in the plane of this section is considered; but, since the rivets are not continuous along the length of the member, sections between rivets are not restrained in the same manner as the section considered. The stress conditions will be different for all sections. This has some indeterminate effect on the rivet value.

The assumption that the connection angle or beam is rigidly fixed (that is, that it has a horizontal tangent) at the center line of the rivet is not strictly true. Since both the rivet and the member to which the connection is fastened are elastic there must be rotation at this point.

As the author states, both the distance, C, and the pressure distribution under that part of the connection are uncertain. For accurate results, it is necessary to make reasonably correct assumptions for these factors. The importance of these assumptions is shown by Equation (2*b*), from which it is seen that any variation in C or its coefficient will affect the value of S in almost direct proportion.

With a flange-angle connection the rivets are also subject to shearing stress due to the end moment. In addition, the rivet may receive shearing stress from the end shear of the beam. These stresses, in combination with the direct tension, produce a principal tensile stress somewhat greater than the direct tensile stress. In some cases this may affect the strength of the rivet appreciably.

It is practically impossible to determine analytically the effect of these various assumptions, either singly or in combination. Designers must rely on tests to establish the accuracy of the formulas.

---

[46] Washington, D. C.

The tension rivet tests[47] of Professor Wilson and Mr. Oliver, furnish authoritative data in regard to rivets in pure tension, but this condition does not exist for the rivets used in wind-bracing connections. The tests reported[48] by Professor C. R. Young, are better for this case because they not only include rivets in pure tension, but also rivets with an eccentrically applied load. For this latter condition, 4 by 4-in. clip angles were riveted to a supporting piece and the load was applied through knife-edges bearing on the riveted leg of the angle (the riveted leg was horizontal) at a distance, e, from the center line of the rivet. Part of the tests were with $e = 1\frac{1}{8}$ in. and part with $e = 2\frac{1}{4}$ in. This method of loading is equivalent to establishing the distance, X, used in the author's formulas at $1\frac{1}{8}$ in. and $2\frac{1}{4}$ in., respectively, from the center line of the rivet. In computing Table 3 the author assumes that this eccentricity is equal to $\frac{X}{0.65}$, but from the method of loading with knife-edges there could be little restraint and, therefore, e must equal X.

TABLE 6.—COMPARISON OF TEST AND COMPUTED VALUES FOR RIVETS IN TENSION

Rivet size, in inches (1)	ULTIMATE STRENGTH OF RIVET, IN POUNDS PER SQUARE INCH				
	Pure tension, test value (2)	Tension with Eccentricity = $1\frac{1}{8}$ Inches		Tension with Eccentricity = $2\frac{1}{4}$ Inches	
		Test (3)	Computed (4)	Test (5)	Computed (6)
$\frac{5}{8}$..........	74 400	41 500	35 000	27 400	22 900
$\frac{3}{4}$..........	74 600	36 500	35 100	26 000	23 000
$\frac{7}{8}$..........	63 100	30 300	29 700	21 000	19 500

While the formulas in this paper do not apply to cases beyond the yield point, it is interesting to compare Professor Young's results with values computed from Equation (2b), in the same manner that the flexure formula is used for computing the modulus of rupture. In this case $C = 1.5$ in. From Equation (2b), for $e = X = 1\frac{1}{8}$ in., the value of S is 0.47 R, and $S = 0.308\ R$ for $e = X = 2\frac{1}{4}$ in. Table 6 shows the ultimate strength of the rivets as found in the tests and the values as computed. Each test value given is the average of six results. For the computed values, R was taken equal to the pure tension strength as given in Column (2) of the table. Everything considered, the computed and experimental values check very closely. The maximum difference is 20%, and the minimum, 2 per cent. However, it must be noted that these tests do not give any data as to the accuracy of Equation (6) for determining X; nor is it necessarily true that tests with angles of other sizes, or with sheared beams, will show equally close agreement.

A flange-angle connection is subject to forces perpendicular to the direction of the pull, S. This is shown in Fig. 22. As a result there is shear on the column rivet and tension on the beam rivet, in addition to the forces generally considered. In most cases these will be small and probably may be neglected. There are also the shearing stresses set up by the end shear of the beam to consider. An idea of the relative magnitudes of the forces involved, may be gained by noting that, in Fig. 22, when $a = b$ and $e = d = \frac{1}{2} a$: $R = 2.2\ S$; $V = 0.6\ S$; $T = 1.0\ S$; and $X = 0.6\ A$.

[47] *Bulletin No. 210*, Eng. Experiment Station, Univ. of Illinois.

[48] Address before the Fifth Annual Convention, Am. Inst. of Steel Construction, October, 1927, (Abstract), *Engineering News-Record*, February 2, 1928, p. 188.

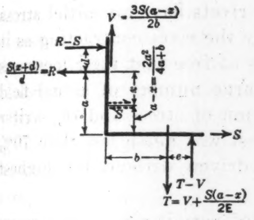

FIG. 22

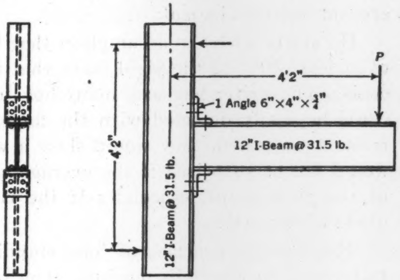

FIG. 23.

Equation (12) may be simplified. Since X is a function of A and B, as given by Equation (6), B may be eliminated and Δ_1 expressed as,

$$\Delta_1 = \frac{A^2}{6\,EI}(3\,X - A) \quad \ldots\ldots\ldots\ldots\ldots\ldots (34)$$

For $X = 0.5\ A$, this reduces to $\Delta_1 = \frac{A^3}{12\,EI}$, which is the deflection formula for a beam fixed at both ends, but displaced perpendicularly to its length.

Equation (11) is subject to the various assumptions used in the preceding theory and besides it does not take into consideration the slip in the beam rivets and bending in the column flanges. Rivet slip, especially, will greatly increase the angle of rotation. This may be demonstrated by referring to a test made by Professor W. M. Wilson and H. F. Moore[49] to determine the rigidity of riveted joints. The test piece and method of loading are shown in Fig. 23. For a load, $P = 4\,500$ lb., the rotation at the joint as computed by Equation (11) is $\phi = 0.000156$ radian. The test showed a rotation of $\phi = 0.0028$ radian. This is a large difference and shows the need of further experimentation.

However, regardless of the possible error in the formula for joint rotation, the effects of this rotation, as pointed out by the author, are important. The fact that many buildings have been designed neglecting joint rotation and the effect of gravity moments on wind-bracing connections, does not mean that these factors can always be neglected. The factor of safety, the bracing effect of walls, and the fact that the full design loads are seldom realized, have all helped to cover up poorly designed details.

---

[49] "Tests to Determine the Rigidity of Riveted Joints of Steel Structures," by Wilbur M. Wilson M. Am. Soc. C. E., and H. F. Moore, *Bulletin No. 104*, Eng. Experiment Station, Univ. of Illinois.

A. J. Wilcox,[50] M. Am. Soc. C. E. (by letter).—The design of wind-bracing connections is a subject on which there is a wide difference of opinion although until one has made a considerable study of them, it appears to be a very elementary problem. The author has pointed out some of the conditions that make these connections difficult to design along undisputable theoretical lines. His solution is based on certain assumptions which the writer believes are not entirely logical.

He starts with the assumption that hot driven rivets have an initial stress of at least 70% of the yield point that is set up by the rivet contracting as it cools. The writer has seen many hot driven rivets so free that their looseness could be easily detected with the fingers. If a large number of actual field rivets were tested, they would show a wide variation of stress and the writer would not be surprised if the average of such a test was much less than 70% of the yield point, especially if the rivets were driven without the highest grade of inspection.

Engineering practice of long standing does not permit any such stresses to be used in rivets in tension. The practice, until recent years, was to use the shearing value of 12 000 lb. per sq. in., increased 50% for wind stresses. When this unit stress was increased to 13 500 it was not considered safe to increase the stress for wind 50%; this was changed to 33⅓%, the result being no increase over the 18 000 lb. per sq. in. formerly used. This limit is not definitely set by any building code or standard specifications, but as the result of many years of experience by the leading men in the profession. Many of them were keenly interested in producing the most economical structural steel to meet competition from other forms of construction. This experience must have convinced them that it was not safe to take advantage of an apparent defect in the codes.

The point is often argued that since it is impossible to drive hot rivets consistently without occasionally setting up cooling stresses much in excess of the standard limits, and since it is impractical to relieve them, it is entirely proper to make use of such stresses. However, after considerable designing experience and study of the subject of distribution of wind stresses, the writer feels that the day is far distant when these stresses can be distributed accurately. The more general methods used by many engineers, because of their simplicity, appear to give results that are not approximately correct. Furthermore, the common practice of to-day is to neglect the effect of the continuity of the dead and live load moment. These factors would most certainly alter the designed stress in wind-bracing connections.

The author used the diameter of the hole and not the nominal diameter of the rivets in determining his rivet areas; again, this is against standard practice. This assumes that when separately punched pieces are fitted together, the holes match exactly. Such workmanship requires machine-shop practice. Because of the cost involved in the use of holes punched so accurately that the rivets or bolts would have a tight fit throughout, larger holes are a more practical solution. This assumption requires the rivet to fill the hole completely.

---

[50] Cons. Engr. (H. G. Balcom), New York, N. Y.

With a combination of good detailing, workmanship, and inspection, the writer believes this result can be approached. However, when the grip is long, it is more uncertain. Practically all codes and standard specifications further reduce the standard stress on the nominal area for long-grip rivets. The designer should also be governed on important work by the quality of workmanship he may expect.

Inspection of material and workmanship requires as much skill as design, although along a somewhat different line. The chief inspector and his assistants could be selected with as much care as the designing force. No workman in any trade cares to be made to do his work over again, and many workmen are more skilled in covering up defective work than inexperienced inspectors are in detecting it.

The author also assumes the connecting member fixed at the rivet as shown in his Fig. 3(*c*). He arrives at this by assuming for the distance, C, that there is no deformation over the distance, X. In his Example 1, $C = 1.5$ in. and $X = 0.415\ A = 0.87$ in. If there is a deformation in the length, X, there most certainly is a deformation in the length, C, which is almost twice the value of X. The writer believes an eccentric force must be applied to the rivet, and its amount depends on the stiffness of the connection.

In Example 2, Mr. Berg uses an angle 4 in. long and does not deduct the rivet hole, although he assumes the maximum stress at that point. Besides using the gross length, he assumes a uniform stress over the full length. With moment arms of about 1 in., there is considerable question concerning the proper length to use.

Going further into the design, the members to which the connection is made, should be considered. Four rivets in a horizontal line can be used in a 14-in. column in either web or flange. If moment arms of less than 1 in. are used to design a connection, certainly the outside rivets in such connections are not stressed the same as the inside pair. In investigating the strength of the column at the point of the connection, through what vertical length does the stress act in the flange or web and with what variation of stress?

The principal point, the writer wishes to bring out is that the application of theory to wind-bracing connections is a complicated problem. This also applies to ordinary shear connections. No liberty should be taken with rivet values and reasonable efforts should be made to favor rivets in tension until some time as sufficient tests have been made, and made public, to indicate to the designer just what distribution of stresses takes place.

Until such time, the single shearing unit stresses should be used for tension in rivets; the connections should be designed using a thickness of metal equal to the nominal diameter of the rivet; and the gauge should be the minimum driving clearance, riding the fillet $\frac{1}{8}$ in. There is also doubt in the efficiency of channel stubs because of their thin webs. This recommendation is based on considerable study, and the results of such meager tests as the writer has seen.

R. D. DALTON,[51] ESQ. (by letter).—The assumption that the force, $R-S$, in Fig. 3(*c*), is distributed as a triangular load on the length, C, is untenable. The surface upon which this force is presumed to be distributed is steel against steel and not steel against any other softer material. The overhanging length, C, is a cantilever and will take the form of a cantilever depending upon its load. It is inconceivable that the surface of the column steel would assume a shape such as to cause this distribution of load. It seems to the writer that the force, $R-S$, should be considered a concentrated load and that there must be some elongation of the rivet due to the lever action of the T-flange.

In Example 1, the assumption that the flange of the **T** acting as a beam is fixed at the rivet presumes an infinite force in the rivet or a deflection of the overhanging length, C, in the direction of the force, $R-S$. This deflection of the overhanging end seems impossible of attainment under the conditions.

In Fig. 7(*b*), if the heel of the upper angle is pulled away from the column face as indicated, the structural beam must have rotated about the point where the lower force, S, is applied, and the horizontal leg of the upper angle would have turned downward through the same angle with the top surface of the structural beam. Then, ϕ_1 does not equal ϕ_2 and Equations (5) and (6) do not hold true.

Also, if the structural beam is rotated, the horizontal leg of the lower angle is bent downward and the vertical leg of this angle is a cantilever. Therefore, the lower force, S, will be moved downward a certain distance, depending on the stiffness of the angle leg, and the value of Y will be somewhat greater than is given by Equation (7).

In Equation (11), Δ_1 is the only Δ that needs to be considered since the structural beam is assumed to extend at least to the face of the column in

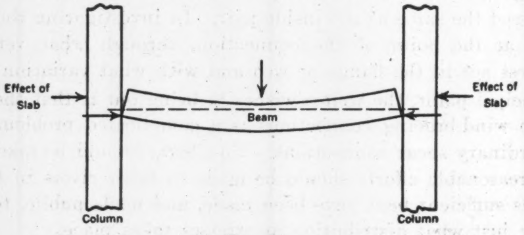

FIG. 24.

moment equations, and the horizontal leg or stem of the connections is substituted for, and is approximately equal to, the immediately adjacent parts of the top and bottom flanges of the structural beam. If the horizontal parts of the connection are approximately equal in area to the adjacent parts of the top and bottom flanges, Δ_3 and Δ_4 are already taken care of in the I and L of the structural beam.

---

[51] Structural Engr., City Bldg. Dept., Oakland, Calif.

There is one action, where a continuous-slab floor is used, that may tend to relieve the bending in the connections due to gravity loads, and especially that due to live loads. When a beam is bent the tension side becomes longer and the compression side shorter. Therefore, if the slab will hold the columns a constant distance apart, a force is set up at the column face in line with the lower flange of the beam. (See Fig. 24.) Whether this action actually exists and, if it does, to what extent it may be depended upon, is very problematical and the idea is only presented here with the thought that it may or may not be found useful after investigation.

Lest this discussion appear too critical, the writer agrees with Mr. Berg in his conclusions that designers should not neglect the effect of gravity loads on the connections, and should strive for better balanced connections and a better analysis of joints. Although he believes more logical basic assumptions might be made, the paper is a forward step in breaking away from the rule-of-thumb methods of the wrought-iron age.

Further tests on typical joints should be made with special reference to the action of connecting angles and **T**'s under stresses below the elastic limit. Tests beyond the yield point or to failure do not give much information on the distribution of moments in a structure if the members of the structure are working at a stress below the elastic limit.

John J. Gould,[52] **Assoc. M. Am. Soc. C. E.** (by letter).—In the Synopsis of his paper the author states that where wind connections are provided, the effect of vertical loads on these connections as well as their adjoining members should not be neglected. It is common practice, however, to pay no attention to the effect of the vertical loads on the relatively rigid wind connections. Generally speaking, the structural engineer proceeds along the following routine.

Step 1.—Design of a Structure for Vertical Loads.—Beams and columns are designed as a statically determinate system; that is, the connections between beams and columns are assumed to be hinged and frictionless. The columns take vertical loads only; no moments are transmitted from the beams. The elastic behavior of the material according to Hooke's law is accepted.

Step 2.—Design of a Structure for Horizontal Loads.—Beams and columns are designed as a statically indeterminate system; that is, the connections between beams and columns are assumed to be rigid. The columns and beams take moments as well as shears. Hooke's law is accepted as under Step 1. It is usually assumed that the masonry takes no loads.

In comparing the fundamental principles underlying the design analysis as stated under Steps 1 and 2, the logic of the routine appears to be highly questionable.

Both analyses are based on Hooke's law that the strain is proportional to the stress. In one design for one kind of loading, a joint is assumed to be able to rotate freely, while in the next step for another kind of loading this same joint is converted into a rigid connection.

---

[52] Structural Engr., with L. H. Nishkian, M. Am. Soc. C. E., San Francisco, Calif.

Some engineers are raising the question as to what is happening to this joint when gravity alone is at work, and are led to assume that the conflict between the different assumptions can be reconciled because steel has an additional quality, namely, ductility. It is also claimed that the steel frame adjusts itself.

In looking honestly into these problems the explanation is given that the "adjustment" referred to, takes place in the connections and that "ductility" implies that steel becomes malleable when subjected to high stress.[53]

The writer believes that at present the problems of adjustment of connections have been placed within reach of a sound analysis. Tests made by Professor W. M. Wilson and Professor H. F. Moore,[54] have demonstrated that rigidly built connections fulfill their duty for any kind of loads if designed within the elastic limit. It is shown that errors on the frame due to adjustments are either negligible or can be properly analyzed and guarded against.

Ductility, however, still remains one of the magic forces. So far as the writer understands the present building practice, it is quite sufficient to overstress some particular part of a structure, generally the wind connections, make the steel malleable, thereby raising the elastic limit, and the structure will stand up.

The proponents of the ductility theory have not availed themselves, during the past half century, of the opportunity to clarify their case.[55] In order to take definite advantage of ductility in a design, systematic research, together with a rational theory, should form the basis of an analysis rather than speculative assumptions. Tests of connections, built according to the ductility theory, and subjected to reversible dynamic forces, are also suggested.

It appears to the writer that the major adjustment of a structure does not take place in the connections or in the property of the material, but in the actual factor of safety of a structure. In other words, if a typical structural steel frame were built without any load-resisting walls of fireproofing; if it were then loaded vertically and horizontally to the extent of the assumptions and designed along the routine as outlined under Steps 1 and 2, it would have an actual factor of safety considerably smaller than that calculated.[56] Theoretically, such a frame would be inefficient and uneconomical because of its non-uniform distribution of stress and strength.

In regions where a structure is never called upon to deliver its ultimate strength capacity, this condition is apparently of little consequence to the investing public. It also does not seem to bother, seriously, the conscience of the professional structural engineer.

The problem, however, becomes magnified in countries where either earthquakes or hurricanes are expected. In such countries the building public is vitally interested in maximum protection for a minimum cost. It should be apparent that the owner of a building is entitled to a structural frame in which the elastic limit of the material is not exceeded before the disaster occurs, and that a safety margin of a building should not be assumed in the steel frame while actually a great part of it is in the fire-proofing and masonry walls.

[55] *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 1213.

[56] *Loc. cit.*, p. 1485.

In the action of earthquakes on buildings one of the few definitely known facts is that a shock will produce bending moments and shears at the beam and column joints. In designing a steel structure as a continuous elastic frame for vertical loads, the savings made in the beams are placed in the connections and columns. This will make a structure far more immune from earthquake damage with about the same amount of investment, or very little more, than could be done according to the present design practice.

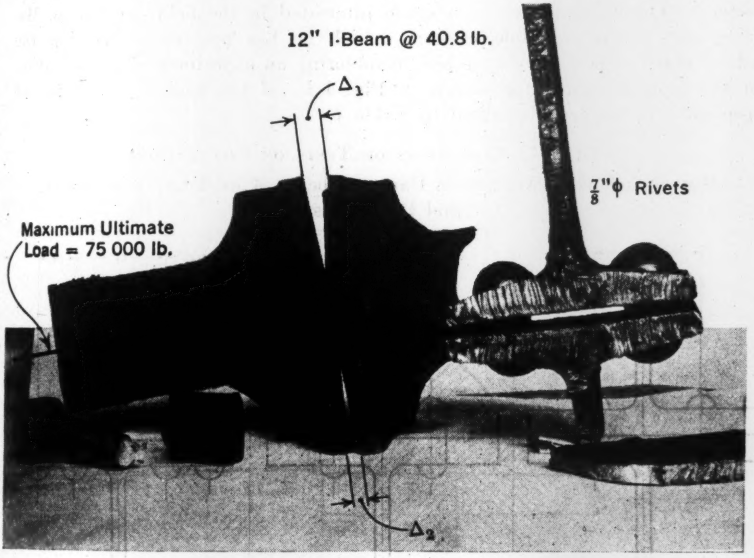

FIG. 25.

It is not intended to suggest that an engineer should apply to all structures a tedious analysis, but rather that he should be aware of the relative merits to the building owner of his fundamental assumptions.

As an addition to Mr. Berg's commendable paper, Fig. 25 illustrates a case in which the relative value of rivets and bolts in tension, of the same diameter, were tested. These tests were made by L. H. Nishkian, M. Am. Soc. C. E. Of all the tests made, the rivet had an ultimate strength of about 40% (without breaking) greater than the bolt. It is interesting, furthermore, to note that the half I-beam suffered great deformations in the direction parallel to the web (Δ_1 Δ_2, Fig. 25). Reference is also made to the author's Fig. 3(*b*), concerning which the statement is made that the flange cannot act as a cantilever.

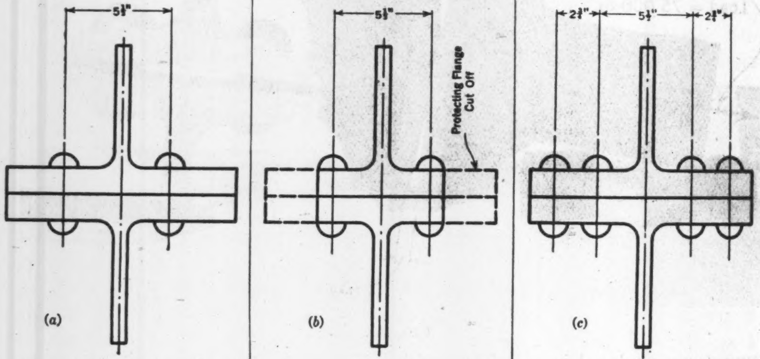
Undoubtedly, this condition is true for most of the cases. It is possible, however, that where long rivets are used, the elongation of the rivet under normal stress condition, will prevent the outer edges of the flange from bearing on the column flanges. In these cases, the flange will act as a cantilever.

The writer would recommend that in conjunction with the theoretical discussion of the author, full-sized tests of half I-beam connections be made, in order to verify their safe loading capacity so as to keep their efficiency factor within that of the structure as a whole.

W. C. Huntington,[57] M. Am. Soc. C. E., and Paul Nielsen,[58] Esq. (by letter).—The writers have been much interested in the field covered by Mr. Berg and in the valuable material which he has presented. During the school year, 1931-32, they have been conducting an experimental investigation of the type of connection shown in Fig. 4(*b*) of the paper. The types of specimens tested are illustrated in Table 7.

TABLE 7.—Conditions of Tests on Connections

(Material: One 30-in., 240-lb. Carnegie beam, 4 in. long; $\frac{7}{8}$-in. rivets; and $1\frac{5}{8}$-in. bolts.)



(a)	(b)	(c)
Specimen *A*: Rivets; initial tension	Specimen *B*: Rivets; initial tension	Specimen *C*: Rivets; initial tension
Specimen *F*: Bolts; initial tension	Specimen *H*: Bolts; initial tension	Specimen *E*: Bolts; initial tension
Specimen *G*: Bolts; no initial tension*	Specimen *I*: Bolts; no initial tension*	Specimen *D*: Bolts; no initial tension*

* In order to hold these specimens firmly together it was necessary to have some initial tension in the bolts.

The riveted specimens were made by first cutting longitudinally along the center of the web a 240-lb. Carnegie beam of sufficient length to provide the desired number of specimens. The flanges of the two parts of the beam were then riveted together, as illustrated in Table 7, the arrangement of the rivets being such as to yield the desired specimens when the member was cut into 4-in. lengths. The rivets were driven by hand with a gun riveter and are equivalent to those obtained in field riveting. It is hoped that the investigation can be extended to include shop rivets.

---

[57] Prof. of Civ. Eng., and Head of Dept., Univ. of Illinois, Urbana, Ill.

[58] Instructor in Gen. Eng. Drawing, Univ. of Illinois, Urbana, Ill.

Plugs are inserted in the ends of each rivet and bolt in such a manner that the deformation of the shank can be measured accurately. This arrangement is illustrated in Fig. 26. All deformation readings are taken with an extensometer, making use of an Ames dial. Each division on the dial corresponds to a deformation of 0.0002 in., and the fractional part of each division is estimated.

A comparison of the results secured from Specimens *A* and *C* (Table 7) indicates the effect of the outside row of rivets. The effect of the bearing between the flanges on the area outside the rivets is indicated by a comparison of Specimens *A* and *B*. The effect of initial tension on the stress distribution among the rivets is indicated by comparing the results of a riveted specimen with those of a similar, bolted specimen in which the bolts are tightened only enough to hold the specimen firmly together. In Specimens *E, F,* and *H* the bolts are tightened to give the desired amount of initial tension as indicated by their deformation. These specimens give a quantitative measure of the effect of initial tension which can be varied as desired.

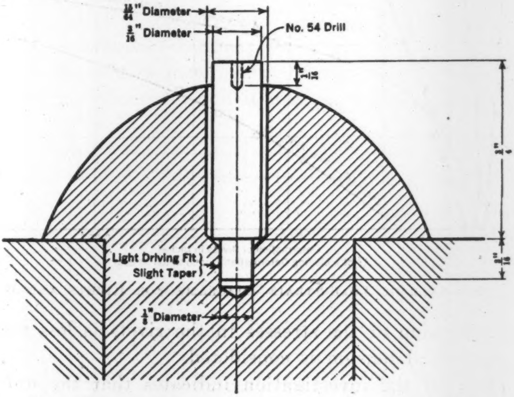


FIG. 26.—SECTION THROUGH RIVET HEAD SHOWING GAUGE-PIN.

A part of the data secured in this investigation is shown on the load-strain diagrams in Fig. 27. The deformations given are in addition to the initial deformations due to the initial stress in the rivets or bolts. These diagrams will not be discussed in detail, but it may be readily noted that the outer rivets add materially to the strength of a connection of these dimensions. For instance, for the rivet stress corresponding to a deformation of 0.001 in. in excess of the initial deformation, the load carried by the *A* specimen that has no outer rivet is 30 000 lb., while the load carried by the *C* specimen with outer rivets is 49 000 lb. That the effectiveness of the

C specimen is due to initial tension in the rivets is apparent when the load-strain diagrams for this specimen are compared with those for the *D* specimen in which the initial tension is only sufficient to hold the specimen firmly together. The effect of even this small initial tension is important, however, when calculations involving these diagrams are made. For instance, in some cases, the sum of the stresses in the rivets is less than the applied load, unless the initial tension is considered.

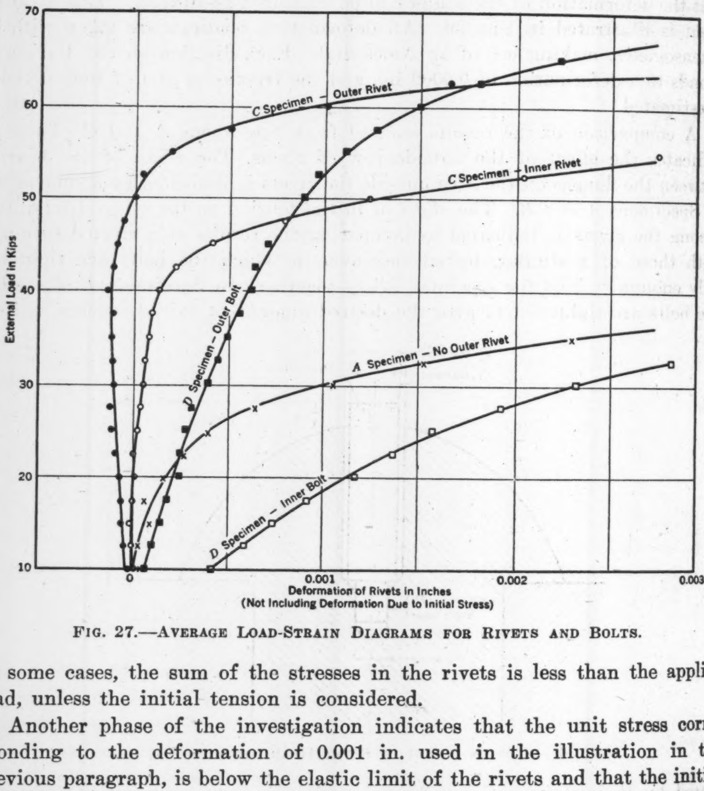

FIG. 27.—AVERAGE LOAD-STRAIN DIAGRAMS FOR RIVETS AND BOLTS.

Another phase of the investigation indicates that the unit stress corresponding to the deformation of 0.001 in. used in the illustration in the previous paragraph, is below the elastic limit of the rivets and that the initial stresses in the rivets are about the same in the *A* and *C* specimens. The data given in Fig. 27 are the averages obtained from three *A* and *C* specimens and two *D* specimens. These tests confirm other investigations which have indicated that rivets can be relied upon to carry tensile stresses.

A. TORIGGINO,[59] ESQ., and ERLE L. COPE,[60] M. AM. SOC. C. E. (by letter).—Some tests of full-sized wind connections, of cut I-beams, were made in connection with the design of the Mills Tower in San Francisco, Calif., in 1930. Fourteen specimens were tested, with rivets from $\frac{3}{4}$ in. to $1\frac{1}{4}$ in. in diameter, each having four rivets in tension. Detail dimensions of the heavier specimens, measured before testing, are given in Table 8, and the key Fig. 28, from which it is seen that the accuracy of the shop work was no greater than that in ordinary building construction. All the tension rivets were driven with an ordinary pneumatic hammer.

* Dimensions of Carnegie *A*, 1⅛-in. are with respect to center of beam web which was 0.50 in. off center of column web.

The jaws of the testing machine would not grip a width as great as the desired width of the specimen, and it was necessary to reinforce the webs of the 24-in. I-beam sections to insure them against failure. The webs of the girder-beam sections were forged to dimensions to suit the testing machine. The largest beam sections in use at the time the tests were outlined, were the 36-in. 300-lb. Carnegie beams and the 36-in. 260-lb. Bethlehem beams. Before the design of the Mills Tower was completed a 36-in., 300-lb. Bethlehem beam was produced, that has greater thickness of flange at the web than either of those tested, and this heavier section was used in the building. A

FIG. 29.—MAKING OF TESTS SPECIMENS IN TABLE 9.

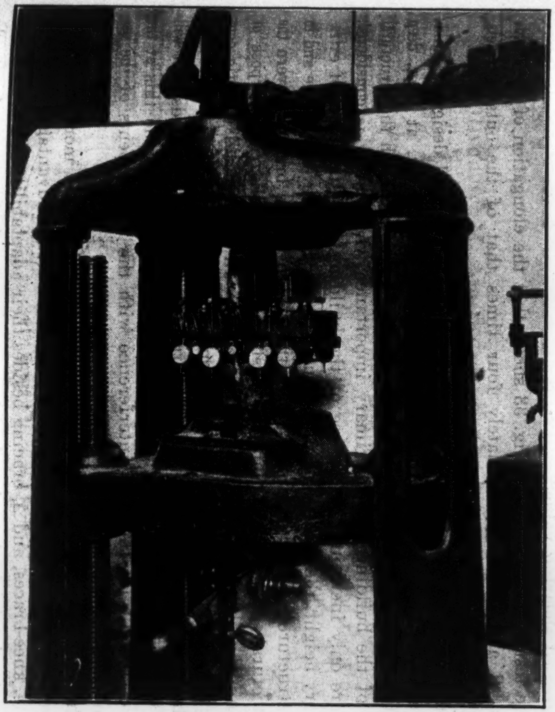

FIG. 30.—SPECIMEN, BETHLEHEM *A*, 1⅛-INCH, BEFORE LOADING, SHOWING DIAL DEFORMETERS ON RIVETS AND FLANGES.

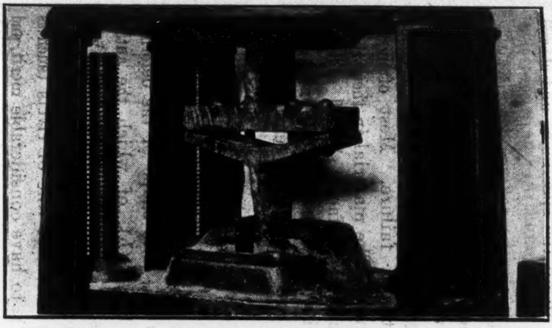

FIG. 31.—SPECIMEN BETHLEHEM *A*, 1⅛-INCH, AFTER FAILURE AT 209.8 KIPS.

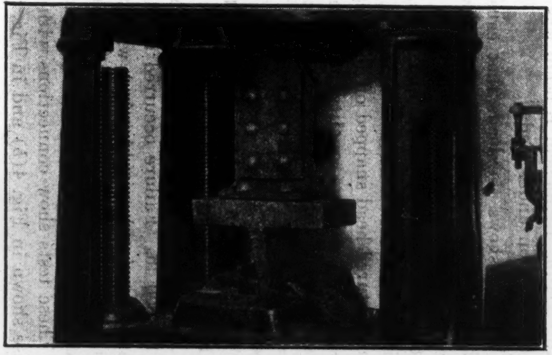

FIG. 32.—SPECIMEN 1 *B*, 1-INCH, AT LOAD OF 175 KIPS. FAILURE OCCURRED AT 212 KIPS.

16-in., 384-lb., Bethlehem **H**-beam was used in all the specimens and showed no deformation under load.

Table 9 shows the loads that caused deformation of 0.005 in., 0.05 in., and 0.5 in. at the center. It also shows the ultimate strength in each case. Fig. 29 shows the typical make-up of the various sections. While the ultimate strength of the $1\frac{1}{8}$-in. and $1\frac{1}{4}$-in. rivets (Items 7 to 14, Table 9) was satisfactory, their elongation varied greatly at failure. Most often the manufactured head snapped off to cause failure. The material in these rivets was not of uniform quality and the fractured surfaces showed a coarse crystalline structure. The tests show that rivets can be depended on to resist tension, and the writers believe that they are stronger in tension than in shear.

Test Specimen Bethlehem *A*, with $1\frac{1}{8}$-in. rivets (Item 7, Table 9), is shown in Figs. 30 and 31.

Fig. 32 shows the deformation of a cut **I**-beam connection under a load of 175 000 lb. Failure occurred at 212 000 lb. The shape of the deformed connection is almost identical with that Fig. 3(*b*), of which the author states: "It is readily seen that the **I**-beam stub connection (Fig. 3(*a*)), with a tension force of the value, 2 *S*, cannot deform as illustrated in Fig. 3(*b*)."

These tests show connections with more than one line of rivets (such as those shown in Fig. 4(*b*) and in Fig. 29(*c*)), to have considerable merit, and the writers cannot agree with the author's statement that, "connections with more than one line of rivets, such as shown in Fig. 4, have merit only because of increased shearing value."

The test record plotted in Fig. 33 shows that the elongation of the inside rivets, *B* and *C*, is approximately four times that of the outside rivets, *A* and *D*.

Many engineers are of the opinion that the architectural design of buildings should always permit the use of diagonal bracing or, at least, deep gussets or knee-braces. It should be remembered that although the structural parts of the building are of primary importance when safety is considered, they are only incidental to the use of the building. In structures of extraordinary height, the bracing assumes much greater relative importance and in such structures it may be proper to let the design of the bracing govern the architectural arrangement, but in most cases the utilitarian purpose of the building should be the controlling factor. In other cases esthetic considerations do not permit deep connections or *X*-bracing.

The structure must have sufficient strength to resist the loads that will come upon it and it is the function of the engineer to provide this at the least cost and with the least interference with the requirements of the use of the building.

The shallow types of connections are not so rigid, are more costly, and are generally less efficient; however, they have some advantages over deep gussets, knee-braces, and *X*-bracing besides their adaptability. One important advantage is the high ratio of ultimate strength of the connection to the working stress. In structures subject to forces of unknown magnitude, such as tornadoes and earthquakes, this is a very desirable characteristic. Frames with connections that will deform when highly overstressed, without failing (thereby relieving the bending stresses in the beams and columns) are much more likely to stand up than those with stiffer and more unyielding connections.

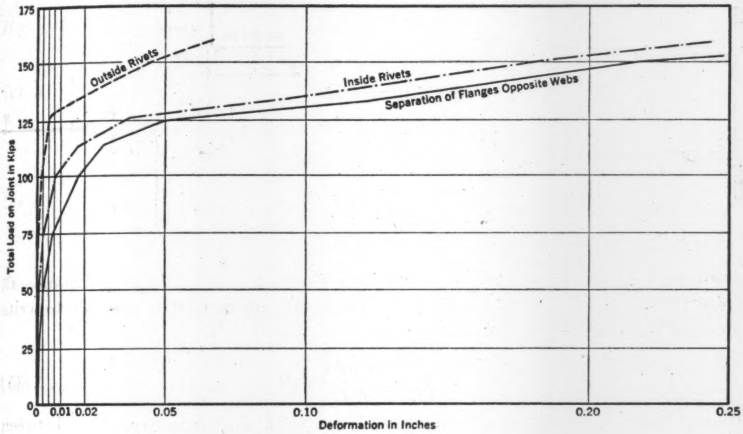

FIG. 33.—DEFORMATION OF SPECIMEN BETHLEHEM *A*, 1⅛-INCH RIVETS UNDER LOAD.

R. A. CAUGHEY,[61] M. AM. SOC. C. E. (by letter).—A problem that has been generally recognized as difficult, but which has not received much attention as far as definite solutions are concerned, is attacked in a commendable manner in this paper. It will be recognized by any one who has given the problem any thought that the author's solution is not by any means the final word on the subject, but that he has made many steps in the right direction. It is not with the idea of criticism that the writer has prepared this discussion, but rather with the hope that some of his suggestions may help in a small way in arriving at a generally accepted solution.

Angle Connections.—Referring to the derivation of Equations (5) and (6) the writer would call attention to the fact that they have been derived in such a manner as not to call attention to the shear on the rivets in the outstanding legs of the angles, caused by the tendency of the angles to straighten. Fig. 34 shows two common types of connection. The author's notation is used, except that the center line of the angle is taken as the working line of a rigid frame. The shear referred to is denoted by the symbol, *H*, in Fig. 34(*c*). This diagram shows only one angle, which is one of a pair of angles such as is used in Fig. 34(*a*), or Fig. 34(*b*).

---

[61] Prof. of Structural Eng., Iowa State Coll., Ames, Iowa.

As the unit pressure on the column caused by the bending of the outstanding leg of the angle is rather small considering the material, it will be assumed that the bending is resisted by a force, $R - S = D$, at a distance, C, from the rivet. Since the distance, A', does not change, it is possible to write an elastic theory equation as follows:

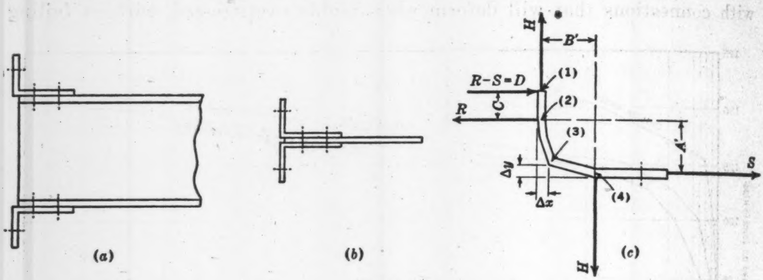

FIG. 34.

$$\int_{(2)}^{(4)} \frac{M\,x\,ds}{E\,I} = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (35)$$

Using Point (2) as an origin, it is seen that the quantity, $M\,x$, between Points (2) and (3) is zero, since $x = 0$. Between Points (3) and (4), $M = -D\,(A' + C) + R\,A' - H\,x$ and $ds = dx$. Then,

$$\int_{(3)}^{(4)} \frac{M\,x\,ds}{E\,I} = \frac{1}{E\,I}\int_{0}^{B}\Big[-D\,(A' + C)\,x + R\,A'\,x - H\,x^2\Big]\,dx$$

$$= \int_{0}^{B}\Big[-D\,(A' + C)\,\frac{x^2}{2} + \frac{R\,A'\,X^2}{2} - \frac{H\,X^3}{3}\Big]\frac{1}{E\,I} = 0$$

from which,

$$H = \frac{3\,R\,A' - 3\,(A' + C)\,D}{2\,B'} \quad \ldots\ldots\ldots\ldots\ldots\ldots (36)$$

Assuming the change in angle between tangents to the curve of the angle at Points (2) and (4) equals zero, the following elastic theory equation may be written:

$$\int_{(2)}^{(4)} \frac{M\;ds}{E\,I} = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (37)$$

Again, using Point (2) as an origin, M between Points (2) and (3) $= -\;D\,(y\;+\;C)\;+\;R\;y$ and $ds\;=\;dy$. Between Points (3) and (4) $M = -\,D\;(A' + C) + R\,A' - H\,x$ and $ds = dx$.

Using the values of moment specified, the elastic equation is developed as follows:

$$\int_{(2)}^{(4)} \frac{M\,ds}{E\,I} = \frac{1}{E\,I}\int_{0}^{A'}\Big[-\,D\;(y + C) + R\,y\Big]\,dy$$

$$+\,\frac{1}{E\,I}\int_{0}^{B'}\Big[-\,D\,(A' + C) + R\,A' - \,H\,x\Big]\,dx = 0 \ldots\ldots\ldots (38)$$

from which,

$$\frac{-D\,(A')^2}{2} - D\,C\,A' + \frac{R\,(A')^2}{2} - D\,A'\,B' - D\,C\,B' + R\,A'\,B' - \frac{H\,(B')^2}{2} = 0$$

or,

$$H = \frac{-D\,(A')^2 - 2\,D\,C\,A' + R\,(A')^2 - 2\,D\,A'\,B' - 2\,D\,C\,B' + 2\,R\,A'\,B'}{B^2} \quad\text{..(39)}$$

Equating the values of H given in Equations (36) and (39) and solving for R,

$$R = D\left[\frac{C\,B' + A'\,B' + 2\,(A')^2 + 4\,A'\,C}{2\,(A')^2 + A'\,B'}\right] \quad\text{............ (40)}$$

Substituting for D the quantity, $R - S$, in Equation (40) and solving for R,

$$R = S\left[\frac{C\,B' + A'\,B' + 2\,(A')^2 + 4\,A'\,C}{+\,C\,B' + 4\,A'\,C}\right] \quad\text{............(41)}$$

or,

$$S = \frac{R\,(4\,A'\,C + C\,B')}{[2\,(A')^2 + 4\,A'\,C + A'\,B' + C\,B']} \quad\text{............(42)}$$

Having adopted a value of R, and having computed S by Equation (42), the value of H may be obtained from Equation (36), remembering that $D = R - S$.

In order to illustrate the method of procedure that the writer has in mind, Example 2 of the paper will be solved by use of the formulas proposed. The angle in question with applied forces and moment diagrams is shown in Fig. 35.

FIG. 35.

Taking into account the difference between A' and B' as defined by the writer and A and B used by the author, $A' = 2 - \frac{1}{4} = 1\frac{3}{4}$ in.; $B' = 2\frac{1}{2} - \frac{1}{4}$

$= 2\frac{1}{4}$ in.; and $C = 1\frac{1}{2}$ in. Using $\frac{3}{4}$-in. rivets and allowing tension to the amount of one-half the initial tension as does the author, $R = \frac{13\,410}{2}$ $= 6\,705$ lb. per rivet. By Equation (42),

$$S = \frac{6\,705\,(10.50 + 3.37)}{(6.12 + 10.50 + 3.94 + 3.37)} = 3\,890$$

Substituting proper values in Equation (36),

$$H = \frac{3 \times 6\,705 \times 1.75 - 3 \times 3.25\,(6\,705 - 3\,890)}{2 \times 2.25} = 1\,730$$

Fig. 35 shows the moment diagrams for the legs of the angle from Point (1) to Point (4). The value of S is 3 890 against a value of 3 440 computed by the author, and the maximum moment is 4 220 against a value of 3 270 computed by the author. The fiber stress due to bending, using 4 in. as the width of metal as did the author, is $\frac{4\,220 \times 6}{4 \times (0.5)^2} = 25\,300$ lb. per sq. in., against 19 600 lb. per sq. in. obtained by Mr. Berg. The value of X is 1.08 in. as compared to 0.95 in. obtained by the author.

The deflection, Δx, of Point (3), Fig. 34(c), may then be found from the moment diagram by the moment-area method, remembering that the deflection of Point (3) with respect to Point (2) equals the moment of the moment-area diagram about Point (3) multiplied by $\frac{1}{E\,I}$,

$$\Delta x = \left[\frac{2\,585 \times 0.67}{2} \times \frac{0.67}{2} - \frac{4\,220 \times 1.08}{2} \times 1.39\right]$$

$$\times \frac{1}{30\,000\,000 \times \frac{1}{12} \times 4 \times \left(\frac{1}{2}\right)^3} = 0.0023 \text{ in.}$$

This deflection, it seems to the writer, is very essential in the computation of the rotation of the ends of beams; it influences, very directly, the amount of moment carried by the beam at different sections.

Sheared **I**-*Beam Connections*.—If sheared **I**-beam connections are considered, the formula given for S in Equation (42) may still be used by making the distance, B', equal to zero. Referring to the author's Example 1 and changing the value of A' to 2.5 in. to correspond to the distance from web center line to rivet center line instead of clear distance from web to rivet center line,

$$S = \frac{6\,705\,(4 \times 2.5 \times 1.5)}{(2 \times 2.5 \times 2.5 + 4 \times 2.5 \times 1.5)} = 3\,650 \text{ lb.}$$

The author's value is 3 585 lb. For the flanges of the sheared **I**-beam, moments and deflection may be computed from a moment diagram as noted in the case of the outstanding legs of angles in a previous paragraph.

This method gives the results desired in a direct way and everything is taken into account that can be accounted for conveniently in a theoretical way. There may be cases in which the horizontal reaction, H (Fig. 35), on the rivets of the outstanding leg of an angle connection, with a resulting tension in the rivets of the other leg, would be very heavy. It is with the idea of taking this reaction into account and assisting in the development of a general method for the design of this type of construction (either angle or sheared I-beam connections) that the writer submits these formulas.

It becomes evident, however, as one studies this problem that more experimental data are greatly needed. Granted that there is no appreciable deformation in rivets under initial stress and that the deflection of the connection pieces is possible of close computation, there still remains the effect of the behavior of column flanges or webs to which the beam is connected, the deflection in connection pieces due to shear, etc.

U. T. BERG,[62] ASSOC. M. AM. SOC. C. E. (by letter).—High ultimate strength for connections, as given by Messrs. Toriggino and Cope, are not surprising; nor is the shape of the deformed connection anything but natural at the later stages of loading. However, in the modern steel tower, stiffness rather than ultimate strength is the important factor. H. V. Spurr, M. Am. Soc. C. E., has shown[63] that steel tonnage may have to be sacrificed to keep deformations within desirable limits; therefore, a careful study of each connection becomes imperative.

The Wilson-Oliver tests mentioned in the paper, showing uniformly high values for the initial tension of rivets, seemed to the writer to give promise of a definite basis for the design for stiffness. With rivet stresses less than the initial tension, and, consequently, practically no rivet elongation, the joint deformation would be confined mostly to the connection to the beam. Unfortunately, the tests reported by Professor Huntington and Mr. Nielsen, do not appear to substantiate initial tension values as high as 70% of the yield-point strength. This obviously jeopardizes any practical application of the initial tension values, unless the "factor of safety" is lowered proportionally.

The test results shown on Fig. 27 undoubtedly prove that connections with more than one line of rivets have merit, but the curve for the C specimen shows clearly that the inner rivets reach the yield point at a load approximately only 18% greater than 43 000 lb., which is the standard working stress for $4\frac{7}{8}$-in. rivets.

That there may be inferior workmanship, as mentioned by Mr. Wilcox, does not appear to be a sound reason why rational design methods should not be attempted. Surely, the cost of the riveting work is a small part of the total cost of a building, so that time spent for inspection could be increased many times without appreciable extra expense.

The writer has used the actual area of the rivet hole rather than the nominal area, in order to conform to the test values used as a basis for the paper and given in Table 1. Of course, a hot driven rivet can not fill the hole completely after cooling. This leads directly to the question of rivet slip and its effect on the rigidity of the joint.

[63] In his book on "Wind Bracing."

Several discussers have pointed out that the value, Δ_3, is incomplete and that an additional item should be included for the rivet slip. The reason for omitting it is based on the report of the Committee of the American Railway Engineering and Maintenance-of-Way Association[64], which concluded that:

(1) The resistance of a rivet joint against deformation by shearing forces, up to the yield point, is due to the friction between the surfaces held in contact by the rivets.

(2) The yield point of a riveted joint is reached when the shearing forces are equal to the friction of the surfaces held in contact by the rivets.

(3) The deformation of a riveted joint at the yield point is caused by the slipping on each other of the surfaces held in contact by the rivets. This slipping, is due to the "diametral" contraction of the rivets in cooling after they are driven, which leaves a space between the body of the rivets and the edge of the rivet hole.

(4) After the slip at the yield point has occurred and the rivet is brought to bear against the edge of the rivet hole, a deformation of the body of the rivet takes place with an accelerating increase in the resistance until the entire side of the rivet has been brought to bear against the edge of the rivet hole. This deformation continues beyond this point with a diminishing increase in the resistance until the ultimate strength of the rivet in shear has been reached.

An examination of the effect of a tensile force, S, acting at each end of a connection, as shown in Fig. 36, suggests that the shearing stress can not be distributed evenly among the rivets. The upper plate between Rivets R_4 and R_5 would be stressed five times as much as the lower plate with corresponding elongations. A gradual movement must take place to adjust these differences in deformations. The tests mentioned previously indicate that the friction at the plates is overcome by a force equivalent to a shearing stress on the rivet equal to, say, 10 000 lb. per sq. in., after which a gradual slipping takes place.

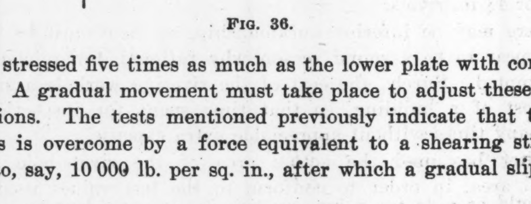

FIG. 36.

---

[64] *Proceedings*, Am. Ry. Eng. and Maintenance-of-Way Assoc., Vol. 5, 1905.

The force, S (Fig. 36), would first have to overcome the friction at the rivets, R_4 and R_9. A slip would then take place, but this is limited to the amount of elongation between the rivets, R_4 and R_5 and, also, R_8 and R_9. The friction at Rivets R_5 and R_8 has not yet been overcome, and the elongations are fully elastic in spite of the gradual slipping at the first line of rivets. Subsequently, the friction at Rivets R_5 and R_8 is overcome, permitting Rivets R_6 and R_7 to come into action. It is not until the friction at all rivets has been overcome that any slipping not included in the elastic elongations will enter into the value of the total elongation.

The approximate value of the combined elongation of both plates can be expressed as follows:

Effect from Rivets R_4 and R_9 only:

$$\frac{S}{3}\,\frac{1}{E}\left(\frac{2\,B}{F} + \frac{5\,B}{2\,F}\right) = \frac{S}{3}\,\frac{B}{E\,F}\ (4.5) \quad\ldots\ldots\ldots\ldots (43)$$

Effect from Rivets R_5 and R_8 only:

$$\frac{S}{3}\,\frac{1}{E}\left(\frac{4\,B}{F} + \frac{3\,B}{2\,F}\right) = \frac{S}{3}\,\frac{B}{E\,F}\ (5.5) \quad\ldots\ldots\ldots\ldots (44)$$

Effect from Rivets R_6 and R_7 only:

$$\frac{S}{3}\,\frac{1}{E}\left(\frac{6\,B}{F} + \frac{B}{2\,F}\right) = \frac{S}{3}\,\frac{B}{E\,F}\ (6.5) \quad\ldots\ldots\ldots\ldots (45)$$

The sum of these elongations is:

$$5.5\,\frac{S\,B}{E\,F} \quad\ldots\ldots\ldots\ldots (46)$$

Equation (46) applies to both plates. However, in a practical case, the lower plate would be the flange of the I-beam and this elongation is included in Equation (17), except that the approximation is made that the moment, M_G, is constant. Actually, the value of M_G increases from zero at the face of the support, to the full value at the last line of rivets (R_9 in Fig. 36). The angular rotation corresponding to this new form for the negative moment can be expressed as:

$$\phi = \frac{L\,M_G}{E\,I}\left(\frac{1}{2} - \frac{l}{2\,L}\right) \quad\ldots\ldots\ldots\ldots (47)$$

This actually increases the value of M_G compared with the straight-line assumption.

Assuming that the elongation of the upper plate is the same as that of the lower one (actually this condition may vary; on some structures the plate may be the stiffest and, on others, the I-beam flange), and keeping in mind that the lower plate, corresponding to the flange of the I-beam, is included in the deformation as expressed in Equation (17), the net additional elongation to be included in Equation (11) would be one-half the total expressed by Equation (46), namely, $2.75\,\frac{S\,B}{E\,F}$.

This would provide for values up to a force equivalent to a shear on all rivets of about 10 000 lb. per sq. in. An examination of the aforementioned elongations[64], suggests to the writer that if the full length of the connection is included in the elongation ($6\,B$ for a condition, as shown in Fig. 36), full provision is made for a slip up to an average shearing stress on all rivets equal to, say, 18 000 lb. per sq. in. Applying the full length does not materially alter the fact that as far as determining the amount of rigidity of the connection, the reduction in the fixing moment due to the connection is small and had better be neglected.

The writer believes that if the value for Δ_2 is based on an effective length of the connection equal to the full length (to the center of the last rivet), full provision would be made for any deformation that may come into play within the practical limit of the connection (up to the point when the yield point of the tension rivet is reached), and that no additional value should be included for slip of rivet or elongation of any part of the **I**-beam, as these conditions are all included.

(The values, $E\,\Delta_2$, in Table 3, are based on an effective length assumed to be equal to one-half the distance from the first to the last rivet plus 3 in.)

Mr. Fleming points out the importance of shear deformations. Unquestionably, they would increase the values, $\Delta_1 E$, as given in Table 3—in some cases considerably—but the influence in reducing the fixation value of the joint is not appreciable. The effect on the rivet elongation is also unimportant. The writer has computed many variations of the general Equation (4), but in all these cases the effect on the rivet elongation was small. However, the influence is important on cases similar to that given by Mr. Coyle.

In his example (in which, $2\,R = 2\,S = 2 \times 19\,160$ lb., $A = 1.6$ in., $t = 1.4$ in., $C = 1.5$ in., $I = 0.69$ in^4., and $b = 3$ in.), the bending effect is: $\frac{dy}{dx} = -\frac{W A^2}{2\,EI} = 0.00118 \times 1.5 = 0.00178$ in. The shear effect is expressed by, $\frac{dy}{dx} = -\frac{3\,W}{bt\,E} = 0.00045 \times 1.5 = 0.00068$ in., and the combined effect is, $-0.00178 + (-0.00068) = -0.00246$ in. When the load is removed the tension is reduced an amount equal to $\frac{0.00246 \times 30\,000\,000 \times 0.518}{2} = 19\,200$ lb. Therefore, the permanent initial stress is equal to $19\,160 - 19\,200 = -40$ lb., which indicates a loose rivet.

For a connection such as that of Fig. 3(a), with a flange thickness varying from $u = 1$ in. to $m = 1.4$ in., the corresponding values are, as follows: The bending effect is approximately 33% more than for $t = 1.4$ in., that is, $0.00178 \times 1.33 = 0.00237$ in. The shear effect is approximately 40% more than for $t = 1.4$ in., or, $0.00068 \times 1.4 = 0.00095$ in. The combined effect is $0.00237 + 0.00095 = 0.00332$ in. In this case, when the load is removed the tension is reduced an amount equal to $\frac{0.00332}{0.00246} \times 19\,200 = 25\,800$ lb. Therefore, the permanent initial stress is $19\,160 - 25\,800 = -6\,640$ lb., which indicates the presence of a loose rivet even on a stiffer connection.

Mr. Dalton questions the assumption relative to the location of the force, $R - S$. The effective value of C is influenced, of course, by the plate thickness, hence the value, $C = \frac{1}{2}$ rivet head $+ 1\frac{1}{2}\,u$, was adopted as the maximum when computing Table 3.

Within this limit, and at the point at which the initial tension is reached on the rivet, the distance, $\frac{2}{3}\,C$, does not seem unreasonable if one is willing to assume that the initial tension presses the plates together approximately uniformly at the stage when no outside force is acting. However, for exceptional cases, such as Test Specimen B, Table 7, in which the value of C is approximately 0.75 in., and that of A approximately 2.3 in., the pressing down of the edges would increase the force under which initial rivet tension is reached.

The shortening due to plate pressure is approximately $\frac{R_i\,t}{2\,C\,b\,E}$. This leads to the following equation for the rotation at rivets:

$$\frac{R_i\,t}{2\,C\,b\,E} \times \frac{1}{2\,C} = \frac{S\,A^2}{2\,E\,I} \qquad \text{.....................(48)}$$
